Indications for Operation.—The advisability of an operation in any individual case of hernia must depend very greatly upon such circumstances as age, occupation, place, residence, and the like. In the vast majority of cases, unless there be some definite contra-indication, operation is by far the best method of treatment. Operation is indicated: (1) In all cases in young adults; (2) When a truss fails to keep up a hernia; (3) In patients whose occupation renders a truss unsuitable; (4) In cases of irreducible omental hernia; (5) In femoral hernia when operation is possible; (6) In patients who travel much or are going to reside in out-of-the-way places; (7) In patients desiring to enter the public services; (8) In children.

Contra-indications.—The operation is contra-indicated in the case of patients over sixty, except in special circumstances, and in stout persons with irreducible herniae.

Hernia in Infants.—Operation is not advisable in infants under six months of age unless the hernia is causing symptoms and a truss will not keep it up. In children over six months operation is the best treatment, though if the child is breast-fed it is advisable to wait till it has been weaned. A wool truss, if properly applied, is generally sufficient to keep up the hernia in infants; should it not do so, a pneumatic rubber truss should be used. The operative treatment of hernia in young children is more successful than in adults, as practically all that is necessary is the removal of the sac; the muscles grow together and soon close the ring. The operation is almost free from risk, and a permanent cure of the condition results with a minimum of scar. On the other hand, truss treatment is very tedious, and more often than not fails to cure the hernia; while even should it cure, there is considerable probability of its recurring when the child reaches adult life, and the operation will then be necessary, perhaps when the time for it can ill be spared. To effect a cure in a hernia in a child by means of a truss, it is absolutely necessary that the hernia should never at any time be permitted to come down, and the truss should be worn constantly for two years at least.

Strangulated Hernia.—Prompt treatment is here indicated if the patient's life is to be saved. Gentle taxis after the patient has sat in a hot bath may be tried, but if it fails, immediate operation is the proper treatment. Repeated and forcible attempts to reduce the hernia by taxis are not advisable, as considerable damage to the bowel not infrequently results. It is better to use taxis, except of the gentlest description, only in those cases where for some reason operation is impossible. When taxis is to be employed, the patient should be placed on his back, with the buttocks well raised and the legs drawn up so as to relax the parts as much as possible. The tumour should be gently compressed by squeezing it with the whole hand to drive out the contents, and if this is successful the hernia should last of all be pressed upwards towards the internal ring.

OPERATION FOR STRANGULATED HERNIA.—The skin having been thoroughly cleaned, an incision is made over the swelling, and the sac exposed. The sac itself must then be opened carefully to avoid injury to the contained bowel:

this opening is generally followed by the escape of a little blood-stained fluid. The sac being opened, it is next necessary to examine the site of strangulation and to relieve the constriction. A flat hernia director is passed up through the neck of the sac (this is often facilitated by drawing the bowel gently downwards); a hernia knife is then passed along the groove in the director, and the neck of the sac nicked (in the case of an inguinal hernia the nick should be made upwards.) When the strangulated neck has been sufficiently cut, the bowel should be drawn out and inspected. If its vitality is not seriously impaired, it should be carefully returned into the abdominal cavity. The wound can then be sewn up. When there is serious doubt as to the vitality of the bowel, the best procedure in most cases will be to stitch the damaged loop of bowel to the skin so as to form an enterostomy, or to excise the damaged portion and tie a Paul's tube into each end. A few days later, when the patient has recovered from his obstructive symptoms and proper preparations can be made, anastomosis of the bowel ends can be performed. The reader is, however, referred to a surgical text-book for the description of these procedures.

The chief difficulties in the operation for strangulated hernia are the recognition of the sac and finding adhesions between the sac and the bowel. The sac can generally be detected by the fact that there is fluid underneath it and between it and the bowel. In the case of adhesions, it is best to expose the whole sac, when it will generally be found that there is some portion which is not adherent. Great care must be taken in separating the adhesions, or the bowel may be torn.

Strangulation of a hernia rarely occurs in children, and reduction is usually easy. The child should be placed in bed with the buttocks raised well above the shoulders on several pillows, or he should be slung by the legs so that the weight of the intestines tends to pull the hernia out of the sac. If in about an hour the hernia has not gone back, and will not go back with gentle manipulation, an anæsthetic should be administered and gentle taxis tried. That failing, operation should be proceeded with at once.

Radical Cure of Inguinal Hernia.—An incision is made over the neck of the sac, the external oblique muscle is divided, and the sac having been exposed up to its neck, is opened: it is now separated and ligatured as high up as possible, and the part below the ligature is cut off. The gap in the muscles is then closed by buried sutures. The exact procedure differs according to the method adopted. The important points are to secure a good hold for the deep sutures, and to obliterate the sac as completely as possible.

In infants it is most important to obliterate the sac. Unless the ring is large, it is seldom necessary to close it by sutures, as after the sac has been removed the muscles soon grow together and close the weak spot in the abdominal wall.

The results of the radical cure of hernia are very satisfactory, and in most cases the patient has no further trouble. Recurrence of the hernia is not common, and in children is very rare indeed. In elderly people the operation is generally done because a truss will not keep up the hernia, and in such patients it is often necessary to wear a truss after the operation, though one with a lighter spring can generally be substituted for that previously worn.

Umbilical Hernia.—This occurs principally in two classes of patients: children, and elderly women who have borne children. It is very common in children, and generally curable without operation. All that is necessary is to keep the hernia from coming down until the ring has had time to close together. In quite young children a piece of American strapping about two inches wide applied across the umbilicus sufficiently tightly to cause a crease and to prevent the hernia from protruding will quickly cure it. Another favourite

method is to sew a large flat cork into the child's binder so that it keeps back the hernia.

In the other type of case a cure cannot be secured apart from operation. A truss can be fitted, and may be quite satisfactory in keeping up the rupture, but in many cases, owing to the patient having a loose, pendulous abdominal wall, or the hernia being irreducible, it is very difficult, if not impossible, to treat the case properly by means of a truss. These patients are often not good subjects for operation, which, if the hernia be large and irreducible, is often a most difficult and serious matter, so that much careful consideration is necessary before deciding on the best method of treating a large umbilical hernia in an elderly woman.

For cases where the hernia is large, very successful results can be obtained by the introduction of a silver-wire filigree between the muscle layers. A bed is made in the thickness of the abdominal wall for the filigree, which must be of a size and shape suitable for the particular case, and large enough to extend well beyond the limits of the opening. The wire filigree is allowed to remain permanently in the abdominal wall, and acts as a most efficient protection against a recurrence of the hernia. Absolute asepticity is essential, as if any infection of the wound occurs the filigree will have to be removed.

Ventral Hernia differs in no important particulars from umbilical hernia except that it follows an operation scar in the abdominal wall. Operation to close the opening by stitching up the gap in the abdominal wall is the proper treatment (*Fig. 36*), if there is no contra-indication in the matter of age, etc. Some very successful results have followed the use of silver wire filigree placed between the abdominal muscles in cases where the gap in the abdominal wall is large, and some most desperate cases of large ventral hernia have been successfully operated upon by this method.

Fig. 36.—Showing the method of stitching up the gap in the abdominal wall in cases of Umbilical and Ventral Hernia. The muscles are split and stitched as shown, and a large mattress suture, tied over pieces of ebonite or rubber, is inserted to take tension of the deep sutures.

Femoral Hernia—A properly fitted truss will in most cases keep up a femoral hernia satisfactorily. A good fit is essential, however, as owing to the movements of the thigh the pad of the truss is more likely to become displaced than is the case with an inguinal hernia. There are several operations for the radical cure of femoral hernia. Bassini's aims at closing the crural canal by stitches; others close it by suturing a flap of the pectineus muscle or some other structure into the crural canal.

J. P. Lockhart Mummery.

HERPES.

Herpes Zoster.—From the nature of the affection, it cannot be expected that any treatment will diminish the actual eruption. The pain by which this is often preceded is usually combated by the administration of morphine, phenazone, etc. Spraying the painful spot with chloride of ethyl has been recently recommended.

When the eruption has commenced to appear, the parts should be protected from irritation in some way. Cotton-wool and a bandage may be applied: in the writer's opinion the best application is Unna's zinc gelatin, which seems to cut some of the lesions short in the papular stage.

If the vesicles become infected, and suppuration occurs, a weak antiseptic

paste (e.g., hydrarg. ammoniat. 5 gr., zinc oxide and vaseline, of each $\frac{1}{2}$ oz.) should be continuously applied. In most situations the sooner the vesicles dry up into scabs the better : but in supra-orbital herpes, a not uncommon variety of the disease, the formation of scabs tends to make the scars, which almost invariably develop in this situation, only still more evident. It is therefore advisable to keep the part soft with some simple antiseptic ointment, so as to encourage the granulations to reach the level of the surrounding skin.

The neuralgia which so often follows zoster, especially in elderly people, is often far more troublesome than the disease itself. The number of remedies suggested for its relief is eloquent testimony to the difficulty of treatment. General tonics, especially arsenic, are usually of some benefit, and galvanism and high-frequency currents are sometimes followed by marked improvement, while a complete change is often the most efficacious remedy of all.

Herpes Genitalis is best treated by cleanliness, and the application of a simple dusting powder. It is liable to recur on very slight provocation, and the parts should therefore be protected from irritation of all kinds, particularly sexual. It may not be out of place to note how frequently herpes genitalis is followed by a true Hunterian sore, and the prognosis should always be guarded.

Herpes Labialis.—The cases which develop in connection with pneumonia and other acute conditions require no special treatment, and indeed, in any case not much beyond protection from injury is of any value ; but in those constantly recurring eruptions to which, on any slight disturbance of health, many persons are unfortunately liable, something may be done to diminish the severity of the attack by bathing with very hot water when the familiar symptoms first appear. The same result is sometimes achieved by the application of collodion or nitrate of silver.

Norman Walker.

HERPES OPHTHALMICUS.—(See CORNEA, DISEASES OF).

HICCUGH.—In mild cases the spasm may be arrested by producing a forcible action of the diaphragm, e.g., by holding the breath for a minute, taking a long draught of water, etc. Warm applications to the region of the diaphragm are of service. An alkaline and carminative draught should be given, e.g., 1 dr. of aromatic spirits of ammonia in 2 oz. of peppermint water, or an aperient draught of rhubarb and magnesia made up with tincture of cardamoms, spirits of chloroform, and peppermint water. If the spasm persists, the following may be tried :—

1. Nitroglycerin ($\frac{1}{100}$ gr. in tablet form) two or three times a day, or when recurrence threatens.
2. Turpentine (1 dr. in mucilage).
3. Bromides, valerianate of zinc, or chloroform in full doses.
4. The hypodermic injection of morphia.
5. In hysterical cases success has followed full ether narcosis, the spasm not recurring after recovery of consciousness.
6. Forcible traction on the tongue, maintained for one or two minutes at a time.
7. The application of a blister on each side of the cervical spine over the roots of the third, fourth, and fifth nerves.
8. Faradization of the epigastrium or of the phrenic nerves.

HYDROCELE.

Acute Hydrocele occurs as a complication of acute inflammatory conditions of the testis or epididymis. The treatment of the hydrocele is a secondary consideration in these cases. If the sac becomes tensely distended with fluid and is the cause of pain, it may be tapped with trocar and cannula.

Chronic Hydrocele.—The following conditions are included under this name :

Fig. 37.

Hydrocele complicating chronic diseases of the testicle or epididymis, chronic vaginal hydrocele, spermatocele, encysted hydrocele of the cord, congenital hydrocele, and infantile hydrocele.

1. *Chronic Hydrocele complicating Diseases of the Testicle or Epididymis* may rarely require treatment. The hydrocele may then be tapped with trocar and cannula. No injection of irritating fluids is permissible, nor should operative procedures be adopted apart from the treatment of the causative disease.

2. *Chronic Vaginal Hydrocele* is the common form of hydrocele that requires treatment. This may consist in (a) Tapping; (b) Tapping followed by injection; (c) Excision or other cutting operation.

a. The simplest method is tapping by means of a trocar and cannula. The sac refills in from four to six months; rarely it fills rapidly and is tense in three weeks. The cannula should have a

fine calibre: a large instrument causes unnecessary pain, and may give rise to bleeding. The following precautions should be taken before tapping a hydrocele. A hernia in close relation to the sac should be reduced, or, at least, its position clearly defined. The position of the testicle must be ascertained by shining a strong light through the hydrocele. The testicle normally lies behind the lower part of the hydrocele, and appears as a narrow crescentic opacity in its wall. The position of large scrotal veins should be noted. The skin of the scrotum must be washed with an antiseptic, and the trocar and cannula sterilized.

Fig. 38.

Method of Tapping. The patient is recumbent, and the operator stands on his right side. The hydrocele is grasped with the left hand at its upper part, and pressure applied so that the whole cyst is projected downwards to the bottom of the scrotum, and the scrotal wall is stretched tensely over it. By this means the hydrocele is made very tense and the tension sustained, and the wall of the sac is kept in close contact with the stretched scrotal skin. This grasp is maintained from start to finish of the operation. The trocar and cannula is held in the right hand, with the forefinger acting as a guard an inch from the end (*Fig. 37*) to prevent its penetrating too deeply. The instrument is plunged through the wall of the scrotum and sac with a stabbing movement, at a point at the lower part of the anterior surface. This is near the normally-placed testicle, and here the last few drops of fluid will lie. After insertion, the cannula is pushed off the trocar with the forefinger of the right hand, and is pushed in up to its hilt, and held in with this finger during the whole operation (*Fig. 38*). When the last few drops of fluid are expressed the cannula is withdrawn, and the tiny puncture washed with antiseptic lotion. No collodion or other dressing is required.

Accidents may occur during the tapping, and are due to neglect of these precautions. The cannula may slip out of the sac and lie between the skin and the hydrocele. This follows neglect to maintain sufficient tension with the left hand and to support the cannula with the right. The fluid escapes into the areolar tissue of the scrotum. If in quantity, it passes upwards, causing a tense acute œdema of the skin of the penis and mounting up over the abdominal wall. In old people this may lead to dangerous sloughing of the skin. Attempts to repuncture the sac are usually unavailing.

Hæmorrhage into the loose areolar tissue of the scrotum may follow the puncture of a scrotal vein. It is treated by application of an ice-bag and support to the scrotum. Hæmorrhage into the hydrocele sac is usually the result of puncture of the testicle. Similar treatment is adopted here. Later, if the effusion has been considerable, incision and turning out the tarry fluid and clot, followed by a radical cure of the hydrocele, is the best treatment.

Cases in which gangrene of the scrotum has followed the operation of tapping a hydrocele have been recorded. Lack of antiseptic precautions, and a feeble circulation, probably accounted for these cases. A very few patients have been permanently cured by this operation, but it is essentially a palliative measure, and no promise of cure by its employment can be given.

b. The method of tapping and injection aims at a radical cure, but it is uncertain and is now abandoned by all but a very few surgeons. It is carried out as follows :—The needle of a large hypodermic syringe is plunged into the sac and left while the syringe is filled with the injection fluid. The hydrocele is now tapped with a trocar and cannula, and when it is quite empty and the cannula removed, the syringe is attached to its needle and the fluid injected. The needle is now withdrawn, and the fluid manipulated through the whole extent of the sac. The scrotum is surrounded with wool, and slung. The patient should remain in bed for one or two days. After injection the fluid rapidly reaccumulates by the pouring out of inflammatory effusion. This is reabsorbed in two or three weeks. If it remains longer the collection may be tapped. Tincture of iodine (*Edin. Phar.*) has been used for the injection (2 dr.), but has been abandoned for carbolic acid on account of the pain it produces. Sixty minims of a 95 per cent mixture of carbolic crystals with glycerin are used. The carbolic acid numbs the sensation.

c. A cutting operation, consisting of excision of the sac, or turning the sac inside out, or merely displacing the testicle into the areolar tissue of the scrotum, is the method by which cure may be assured. The patient is in bed for a week.

3. *Spermatocele*, if large, may be treated by tapping and injection ; or, better, by excision.

4. *Encysted Hydrocele* of the cord should be treated by excision.

5. *Congenital Hydrocele* occurs in infants. The funicular process remains patent, and the hydrocele thus communicates with the abdominal cavity.

If a hernia descends into the sac, a truss should be applied until the infant is old enough (about a year) for a radical operation. Sometimes the truss suffices to obliterate the communication. If the opening is very small, so that no hernia is present, the sac may be tapped, and a cure result.

6. *Infantile Hydrocele*.—The funicular process is closed at the abdominal end, but the rest of the tube remains patent and, together with the tunica vaginalis, forms a large hydrocele. This should be punctured in several places with a surgical needle ; failing a cure by this means, it should be tapped with a fine trocar and cannula.

J. W. Thomson Walker.

HYDROCEPHALUS.—This condition must be regarded as a symptom or sequela of a variety of pathological processes, some of which are by no means clearly understood. As an acquired condition it occurs in connection with tumours, more particularly infra-tentorial, which produce a mechanical block preventing the egress of cerebrospinal fluid from the ventricles into the sub-arachnoid space. In a similar manner, adhesions resulting from meningitis may block the foramina of exit of the fluid in the neighbourhood of the fourth ventricle. The ventricles are variously distended according to the position of the obstruction ; thus, with a mid-brain tumour, the fourth ventricle escapes ; and in other circumstances, a single foramen of Munro may be obstructed so as to produce distension of one lateral ventricle only. In the "congenital" form, the fluid may be entirely intraventricular ; but this is not always the case, and there is not infrequently a free communication between the distended ventricles and the distended subarachnoid space. In these cases, abnormalities of secretion by the choroid glands, and anomalies of absorption by the Pacchionian bodies, have been invoked in explanation.

TREATMENT.—In the cases resulting from tumour pressure, temporary relief may be afforded : (1) By a simple sub-tentorial decompressive operation ; and (2) By ventricular drainage (see below).

The cases due to sealing up of the meningeal foramina, whether by meningitis or some ante-natal cause, may be treated : (1) By repeated ventricular puncture ; (2) By establishing a new communication between the lateral ventricle and the subarachnoid space, for which a number of different operative procedures have been devised ; (3) By raising the cerebellum from the fourth ventricle, after removing the bone and incising the dura of the cerebellar fossa.

Some degree of success has followed all these operations. The last-named is a severe procedure attended by considerably greater operative risk than the others. Lumbar puncture is to be avoided, as carrying with it a considerable risk of sudden death from herniation of cerebellum and medulla into the foramen magnum. It may be done, however, as a means of ascertaining whether any ventriculo-subarachnoid communication exists ; clearly, when such is the case, the operative procedures mentioned above would be useless. When such communication does exist, repeated lumbar puncture may be tried. Operations have been devised and carried out for draining the subarachnoid space into the subcutaneous tissues, and even into the peritoneal cavity. Drugs have little if any influence in hydrocephalus ; nor has bandaging of the head, unless as an adjuvant measure after tapping or drainage.

For tapping the lateral ventricle, the most convenient situation is Keen's point, situated an inch behind and an inch above the external auditory meatus.

The trocar is entered at this point, and passed in the direction of the summit of the opposite auricle; the instrument should thus pass through the first temporal gyrus into the widest part of the ventricle. The ventricle has also been tapped through the outer angle of the anterior fontanelle, through the corpus callosum, and through the orbital roof. Whichever route is chosen, the trocar should be a blunt one so as to avoid cutting cerebral vessels; the strictest asepsis must be observed; and urotropin should be administered by the mouth. Too rapid withdrawal of fluid may be followed by hyperpyrexia, convulsions, and death.

Percy Sargent.

HYDRONEPHROSIS.—This condition is found of varying degrees. It is due to blocking of the ureter, and the block may occur at any part. The two most common causes are calculi arrested in their descent from the kidney to the bladder, and kinking of the ureter in marked cases of movable kidney. It must not be forgotten, however, that the blocking may be produced by intravesical conditions. Thus the author has seen more than one case in which the drag of a large villous tumour, the pedicle of which sprang from a point in close proximity to the ureteric meatus, caused so much distortion of the orifice that an immense hydronephrosis resulted. In a somewhat similar way the extension of carcinoma of the bladder to the orifice of the ureter may cause so much occlusion that a hydronephrosis results.

Enlargement of the prostate and stricture of the urethra of long standing are frequently the causes of hydronephrosis, the backward pressure causing dilatation of the bladder, ureters, and pelvis of the kidney consecutively. (See **PROSTATE, ENLARGEMENT OF.**)

TREATMENT.—This consists in removing the cause.

In cases of movable kidney, the condition is usually intermittent, and is signalized by great lumbar pain on the affected side, together with a rapidly-forming swelling, which is very tender on palpation. Very frequently the kidney falls back into its right situation, and this is marked by a sudden considerable flow of urine into the bladder, with subsidence of the swelling and relief of the pain.

Frequently recurring attacks of this nature cause serious damage to the kidney, and must be prevented either by the application of a properly fitted belt or renal truss, or by fixation of the kidney by operation. Hydronephrosis due to stone in the ureter, abnormalities of the ureter, growths of the bladder and prostate, and stricture of the urethra, must be treated by the removal of these conditions. (See various articles on affections of the **URINARY SYSTEM.**)

John George Pardoe.

HYDROPHOBIA.—(See **RABIES.**)

HYDROTHERAPY.—This term may be used to cover all methods of using water externally for the treatment of disease, and will thus comprise the various forms of packs and douches as well as actual immersion.

While the resources of a fully-equipped bathing establishment are required for the proper administration of some of the most useful methods, there are many which are within the scope of the practitioner in whatever circumstances he may be placed. It is to the description of these that this article will mainly be devoted, the more elaborate methods receiving only such notice as will familiarize the practitioner with the principles involved and enable him to decide which cases may with advantage be sent to spas or bathing establishments; further, the differences between the action of ordinary water and of the principal varieties of mineral water used for bathing will be briefly indicated.

The application of water to the cutaneous structures involves chiefly thermal and mechanical effects, whose action is that of irritants to the peripheral sensory nerves. The advantage of water over other agents in producing these effects depends upon its capacity for absorbing and transmitting heat; it absorbs heat without its temperature being much elevated, and gives it off without material reduction. As an example, one pound of iron at 32° F. may be elevated to 130° F. by the same weight of water at 140° F., the latter losing only 43°, while one pound of iron at 140° F. elevates one pound of water at 32° only to 43°, with a loss of 130°. A further advantage is the perfect control which can be exercised in its application, whether in the form of ice, steam, baths, packs, or douches.

To understand clearly its mode of action it is necessary to consider the nervous and vascular apparatus of the skin. The capillary network terminates in capillary loops which are abundantly distributed between the corium and the subcutaneous tissue, and between the two layers of the cutis vera. This network is capable of enormous increase and diminution in capacity, and this variation is regulated by the muscular and elastic coats of the arterioles and the elastic layers and muscles of the skin, the latter being of the involuntary kind and, while distributed generally, most obvious in the dartos tunic of the scrotum, where their action under the influence of heat or cold may easily be observed. The importance of this arrangement has recently been emphasized by Woods Hutchinson, who uses the term "skin heart" to describe it, and advances the view, supporting it with much evidence from the study of similar structures in the lower animals, that these involuntary muscle fibres possess to a great degree the power of rhythmic propulsive contraction, and says: "If we have the right to regard this enormous mesh, capable of containing nearly 30 per cent of the blood of the body, as endowed with the power of independent contraction, we have at once a factor in the circulation which could be depended upon for the production of some most striking results." Unless this view is accepted, it is most difficult to account for the tonic effect of the Brand bath in typhoid fever and of the Nauheim baths in disorders of the heart; and it furnishes a most satisfactory explanation of the mode of action of many other hydropathic procedures. Stimulating applications, whether cool or cold packs or baths, or douches which depend more on mechanical effects, cause the whole mesh to contract forcibly and to drive on the blood contained in it; it then rhythmically dilates, and fills with fresh blood; and the process is repeated. Under normal conditions this function is probably very slight; but it is important to recognize its existence and to take advantage of it by suitable methods when necessity arises.

Upon the nervous supply of the skin depends not only its power of local reaction, but also the reflex effects of skin stimulation which play a large part in heat regulation. The effect of nerve stimulation is primarily to maintain the tone of the cutaneous vessels and thus ultimately of the whole systemic circulation, while the reflex constriction or dilatation of the cutaneous vessels results in increased retention or dissipation of heat, and thus is indispensable to the process of heat regulation. Under the stimulus of cold the peripheral vessels are contracted, so that less heat is lost, the respiration deepens, and the action of the heart is increased. A collateral hyperemia which offers a barrier to the further penetration of cold occurs in the underlying parts, the splanchnic area dilates, and the blood chilled at the periphery passes in the course of circulation through this area and is warmed. The action of the heart being increased, more heat is produced, and if exercise is taken the same end is attained; in the absence of voluntary exercise, shivering may occur, and thus an increased production of heat results. When, on the other hand, the body is exposed to high temperatures, the sensory nerve endings transmit the irritation to the medulla, and the vascular area of the skin is reflexly increased, while at the same time the splanchnic area is narrowed so that the effect of the heated blood on the viscera is kept in check. The sweat glands are stimulated to act, and the evaporation of the sweat tends to abstract heat and to cool the surface. A great number of observations and experiments have been made to demonstrate the effect of wet packs, douches, and baths on the bodily functions which cannot be recapitulated here, but a few of the principal conclusions may be cited. Schuller showed that the application of cold wet compresses to the belly of a rabbit caused dilatation of the vessels of the pia mater, the pulsation became slower and deeper, and the respiration was affected in the same way; warm compresses caused contraction of the vessels, and the pulsation and respiration became less pronounced and more frequent. Hot baths produced the same effects as hot compresses, but of greater intensity and duration. Experiments by Vinaj and Maggiori have shown that brief immersion in a cool bath (50° F.) increases the capacity for muscular work fifty per cent. A warm bath of several minutes' duration gradually cooled (97° to 68° F.) more than doubled the capacity, while the application of a cold wet sheet with rubbing resulted in a return of full capacity in muscles which had been previously fatigued. Other experimenters have shown that the effect of a course of baths, whether cold or hot, is to increase nitrogen metabolism and excretion, while a single bath has little or no effect in this direction. From this brief account it will be seen that the action of baths, etc., upon the system is potent and far-reaching, and by no means limited, as is often supposed, to the reduction of temperature.

Before describing the technique and clinical application of the various procedures comprising hydrotherapy, it cannot be too strongly insisted upon that to obtain successful results the most careful attention to details of technique is essential if success is to be attained ; it is to neglect of such details that the disappointing results obtained by many physicians from such methods as the Brand bath in enteric have been due.

PACKS.

These are the simplest and easiest of application of all hydriatic methods, and moreover can be used with advantage in the most difficult circumstances. They may be general or local, according to the conditions to be treated. For convenience, the drip sheet will be included under this heading and may be described first. The temperature of the room in all wet-pack applications necessitating exposure of the body at any stage should be, if possible, about 70° F. to prevent chill and promote reaction, and it is best, wherever possible,

to use linen cloths or sheets in preference to cotton ; if only cotton is available, the oldest possible should be used.

Fig. 39.—Application of Drip Sheet, 1st position : sheet across chest and under the arms.

The Drip Sheet.—The patient stands in a shallow tub containing about a foot of water at 100° F., and a sheet dipped in water at 75° F. (reduced daily by a degree or two until it reaches 60°) is wrapped round him in the following manner : The end is placed under the left arm and held in position by pressing the arm to the side ; it is carried across the chest and under the right arm well up in the axilla (Fig. 39), round the back, over the left shoulder and arm, covering both (Fig. 40), and thence over the right shoulder and arm and as much further as it will go ; it is then tucked carefully in around the neck and legs (Fig. 41). A basin of water about ten degrees cooler than that used to wet the sheet is poured over

the head and shoulders at short intervals, and rapid light friction, and slapping all over the body and limbs, are kept up by the attendant for five or ten minutes, according to the capacity of the patient. He is then uncovered and rapidly dried with warm towels, when he may dress and take light exercise. The duration of the bath must be judged by the patient's emerging with the skin decidedly hyperæmic, and feeling refreshed ; fatigue, if at all marked, is an indication that the pack has been too prolonged. The effects are : deepening of respiration, diminution of pulse-rate and temperature, and increased muscular capacity. It is of value in chlorosis, and anæmia, neurasthenia, melancholia, hypochondriasis, and some neuralgias ; in fact, in all cases where stimulating and invigorating procedures are required in patients whose health is not too feeble to ensure a sufficient reaction. Its duration may be anything from two to ten or fifteen minutes ; the shorter duration for tonic and the longer for antipyretic effects, while modification in the temperature

of the water and in the vigour of the friction may be made with advantage where indicated.

In more weakly patients the sheet bath may be used, especially as an anti-pyretic method. A rubber sheet or oilcloth is spread over a suitable bed or cot, and covered with a blanket. Upon this a sheet wrung out of water from 80° to 50° F., as may be indicated, is laid, and the patient placed upon it with his arms above his head; the left border of the sheet is brought over the body and should just reach to cover the right axilla, the lower portion being placed between the legs to separate them; the arms are then brought down close to the sides, and the right border of the sheet is carried across the chest and tucked in on the left side; the ends are carefully tucked in around the neck and feet. Friction is then carried out as in the drip sheet, with modifications suited to the strength of the patient, and as different parts of the body become warmed by

Fig. 40.—Drip Sheet, 2nd stage: sheet carried across the back and over the left arm.

Fig. 41.—Drip Sheet: patient completely enveloped and ready for rubbing, etc.

the friction, water at a temperature of 50° to 60° is poured over them from a cup. The duration may be from two to ten minutes; shivering, unaccompanied by chattering of the teeth, is not an indication for stopping unless it is prolonged. The patient may be covered with the blanket and the rubber sheet and left for half an hour if it is desired to enhance the antipyretic effect, or he may be rapidly uncovered, dried, and put back to bed.

The action of this procedure is antipyretic and soothing, and it may be used as a substitute for the cold bath in the reduction of temperature where the latter cannot conveniently be used or where the friends of the patients object to such measures. It is far more effective than sponging in reducing the temperature, and has a tonic instead of a depressing effect.

The Wet Pack is somewhat similar in its mode of application to the foregoing. The bed should be narrow, and placed in such a position that the

attendant has easy access to all sides ; the rubber sheet and blanket are arranged as before. A linen sheet is well wrung out of water at 70° or less, and spread upon the blanket ; the patient is placed thereon so that the upper end of the sheet is level with the ears and the lower end extends for at least 18 inches beyond the feet (*Fig. 42*) ; it is then wrapped round him as closely as possible in the way described in the case of the sheet bath (*Fig. 43*) ; the blanket is drawn firmly round him from the left and tucked in on the right side of the body, and then from the right similarly ; the upper border must be carefully

Fig. 42.—Wet Sheet Pack : sheet carried over from left to right under the arms and between the legs.

secured round the neck and the lower end round the feet. Everything depends on the care taken to pack the blanket closely so that access of air is excluded. A wet cloth may with advantage be wrapped round the head. He may be covered with several woollen blankets if he feels at all chilly, and be left for from half an hour to an hour, the room being kept suitably warmed but well ventilated.

Since no friction is used, the success of the pack will depend on the patient's own powers of reaction, and if successful, the reaction will soon occur, and he

Fig. 43.—Wet Sheet Pack : sheet carried over from right to left ; arms brought down to sides and covered, and sheet tucked in at neck and feet. The blanket will be wrapped over similarly.

will feel calmed and soothed and not infrequently will fall asleep, awaking refreshed. It is then desirable to stimulate the relaxed cutaneous circulation by means of a cool needle bath or douche, or, where these are unobtainable, by a brief immersion bath or sheet bath such as has been described. At the outset of the bath there is a slight shock which may be accompanied by shivering, and this may go on for five or ten minutes, or longer, until the temperature of the sheet is raised to that of the skin ; if shivering is prolonged, the

temperature of the sheet should be higher on the next occasion, or hot-water bottles may be sparingly used; when the patient becomes accustomed to the treatment, the temperature of subsequent packs may be lowered.

This application is valuable, especially in irritable conditions such as delirium and mania, on account of its sedative effect. I have had most excellent results in neurasthenia and kindred conditions. It may be tried with advantage in some forms of sleeplessness, and has been recommended in rheumatism, gout, anæmia, and neuroses of digestion. If used as an antipyretic measure, the pack should be changed as soon as the blanket feels warm to the hand placed under the body. This is best done by having a second bed prepared in a similar manner, so that the change may be effected with as little delay as possible; as many as four or five packs may be given if required to bring down the temperature to the desired level.

"Local Packs."—These are applied on the same principles to whatever part it is desired to treat; for example, the head, throat, thorax, abdomen, or joints. They are commonly termed wet compresses, and may be warm or cold, but the most generally useful temperature is 60° or 70° F. From two to four layers of old linen are used, and cut to such size and shape as may best fit the part to be treated; they are wrung out of water, applied, and covered with a piece of flannel large enough to extend beyond the compress in every direction in order to exclude air. This is much better than using oil silk or other impermeable material.

The *throat compress* is very useful in pharyngitis, laryngitis, tonsillitis, etc., but it is necessary to apply it with care that the throat is sufficiently covered. It should be three or four inches wide for an adult, and the flannel bandage to cover and secure it may advantageously be applied as follows: Take a strip of flannel of sufficient length and width and slit the ends down towards the middle to within about six inches—the exact distance should be determined by measuring from ear to ear beneath the chin; this is then applied with its middle over the compress, the lower tails are carried to the back of the neck, the upper ones pass over the ears to the top of the head; they may be secured there or be carried round and brought under the chin again (*Fig. 44*).

Fig. 44.—Throat compress properly applied.

The *chest compress* is of value in pneumonia, especially bronchopneumonia, and in phthisis; it has a mild antipyretic action if it is frequently changed and the application is prolonged. The most useful temperature is 60° to 70° F., but it may be used warmer if there is a tendency to insomnia or delirium, or cooler in stuporose conditions. The same principles hold in its application, and it is a good plan, having prepared the compress and cut it to fit the patient by hollowing out for the arms, to roll the ends to the middle and apply it by placing it beneath the back and unrolling thence to either side; similarly with the flannel.

The *abdominal compress*, applied in the same way, has been used with good effects in enteric fever, peritonitis, gastritis, appendicitis, and the enterocolitis of children. A modification, however, known as the Neptune girdle, requires description. It is usually worn for eight to ten hours without change, and may be continued for weeks or months. It consists of a bandage of coarse linen or swansdown wide enough to reach from the ensiform cartilage to the pubis, and long enough to go round the body and to cover the abdomen twice at least; it is moistened and applied in the same way as those already described, and

covered with another linen or flannel bandage. The skin should be carefully washed each time the compress is changed. This application was used by the older hydropathists and worn for five or six weeks at a time ; after a week or two a pustular dermatitis usually occurred, termed a crisis, and it has been supposed that toxins were excreted in this way. It is very useful in chronic inflammatory conditions within the abdomen, especially chronic congestion of the liver of tropical origin. Applied at night it will frequently relieve insomnia.

Two sets of bandages should be used whenever they are to be continuously employed, and each should be boiled for fifteen minutes once a day ; the skin also must be washed carefully and frequently ; under these conditions the "crisis" does not usually appear, but otherwise troublesome outbreaks of furunculosis are liable to occur.

Hot compresses are useful in the treatment of lumbago and sciatica. Cold precordial compresses have a tonic effect on the heart, and often relieve palpitation very effectively, but for the latter purpose an ice-bag is more convenient.

BATHS.

The Full Cold Bath.—This is the method associated with the name of Brand, and used by him with great success in the treatment of enteric fever. It is applied as follows : A bath of sufficient length to hold the patient is filled with water from 90° to 65° F. to three-fourths of its depth ; in acute cases it must be of a portable pattern and placed by the patient's bedside ; in cases of great severity, or where conveniences are not available, a bath can be improvised with a rubber sheet and a light wooden frame and placed on a bedstead. A stimulant may advantageously be given before the bath. After the patient's clothes have been removed, his face is bathed with cold water and he is lowered into the bath with the greatest gentleness, some support being arranged for his head. Friction of the whole body is immediately commenced and kept up throughout the time of immersion ; this is of the utmost importance, and should in no circumstances be omitted. It prevents chilling and collapse, and causes redness of the skin, in contrast to the pallor at the moment of immersion, while by bringing a greater quantity of blood to the surface the antipyretic influence of the bath is enhanced. Shivering is not a contra-indication to the use of the bath unless accompanied by chattering of the teeth, nor is blueness of the skin unless affecting the face. The duration of the bath may be from five to twenty minutes, remembering that a short immersion in cooler water is more stimulating though less heat-reducing than a longer bath at a higher temperature. In enteric, as soon as a diagnosis is made, the baths should be started, beginning with about ten minutes' immersion, increasing, say, one or two minutes daily, and then decreasing again, but always being guided by the condition of the patient rather than by fixed rules as to temperature and duration. Where the diagnosis is in doubt, they may be begun if the temperature persistently marks 103° F., the temperature of the bath starting at 90° and being reduced five degrees each time till 65° has been reached ; so long as the temperature is 103° in the rectum the baths should be given three-hourly ; as it falls the frequency may be diminished. During the bath, water from a basin at 50° to 60° may be poured at intervals over the patient's head ; a towel round the forehead will prevent it from flowing over the face.

It is not possible to go fully into the arguments which have been put forward for and against the use of this bath in enteric and similar diseases. Those who wish for an exhaustive examination of the whole subject should refer to Baruch's work on Hydrotherapy, where they will find most detailed instructions as to the principles involved, and a full discussion of the arguments for and against the method. For the present, therefore, it will suffice to quote Osler's words :

"In any large series of cases, the severe manifestations appear to be less common, . . . the beneficial action is not so much special and antipyretic, as general, tonic, and roborant. The typhoid picture is not so frequently seen, and we may have twenty or more cases under treatment without an instance of dry tongue or delirium among them." Osler gives the following statistics for the six years ending May, 1895 : Cases admitted before the introduction of hydrotherapy 33, mortality 24.2 per cent ; cases admitted since the introduction of hydrotherapy 356, mortality, 6.6 per cent.

It must be clearly kept in mind that the object of the bath, while undoubtedly antifebrile, is primarily to stimulate and strengthen the vital organs, and thus to enable them to combat the toxins with success ; and that *the use of friction throughout the bath is absolutely essential to its success*. In cases coming under treatment late, with their powers of reaction seriously impaired, it may be necessary to adopt milder measures as a preliminary, such as the Ziemssen bath or the half warm bath with cold affusions ; which latter I have found of particular value in scarlet fever with high temperatures, especially cases of the septic type, in which it has given excellent results.

The Graduated Bath devised by von Ziemssen is given as follows : The patient is prepared as in the previous case, and the bath is filled one-third full with water at about 90° F. ; the patient having been placed in it, one attendant bathes him constantly with the water, using friction, while another adds water at 40° from a jug, avoiding contact with the patient's body, until the temperature of the bath is about 75° : water must be removed from the bath from time to time lest it become too full. The bath may be prolonged to half an hour, when the patient is removed without drying and placed in a warm woollen blanket.

The Half Warm Bath is similar, but may start at a slightly higher temperature (90° to 95° F.), and cold water is poured in small quantities over the shoulders and back. This should be done from a height or with some force, in order to increase the reaction. The temperature of the bath should be thus brought down to 75° or 70°. According to Rohrer this bath is of especial value in cerebral conditions, whether due to high temperatures, as in pneumonia, insolation, etc., or in meningitis from any cause, on account of its antipyretic influence and its power in controlling convulsive conditions. I have already referred to its value in scarlet fever ; in measles with cerebral symptoms, delirium, etc., it is also valuable ; but as measles patients do not bear abstraction of heat well, it should not be longer than from three to five minutes.

The Full Warm Bath is an agent of great value in calming excitement, relieving pain, and reducing temperature. With the former object in view the temperature should be 100° to 105° F., and should be kept at that level, by the addition of hot water, for ten to thirty minutes ; but if reduction of temperature is aimed at, it should commence at 98° and be reduced gradually to 90°. In neither case must friction be used. In cardiac affections it is contra-indicated.

Douches are important weapons in the armamentarium of the hydrotherapist, but can be obtained only at spas and properly equipped bathing establishments, and therefore need not receive much attention here. The needle bath is well known ; its action is refreshing and stimulating where muscular or nervous tone is impaired ; it acts mainly through the massaging effect of the numerous jets of water, which should be at about 30 lb. pressure. The Scotch douche is a single jet more or less rapidly alternating between hot and cold, and with a pressure of 20 to 30 lb. It is most commonly applied to the spine, and is powerfully stimulating in its effect. The Aix douche is a combination of massage and douching ; it is given by one or two attendants, who massage the whole body while a stream of water is playing upon it from the douche, which is given by a hose-pipe hanging over the operator's shoulder. Its modifications,

the Vichy douche and the Buxton douche, are much the same in principle, but are perhaps more generally preferred by patients. The effect of a douche is much deeper than massage given in any other way, and sets up a powerful vibration in the structures treated, which makes it of great value in chronic rheumatic affections.

The Hip or Sitz Bath is well known. The patient sits in the bath with the feet outside, and, if he has completely undressed, should have the shoulders and legs protected from cold by means of a blanket. The water should just cover the groins, and the temperature must depend on the object to be attained. In atonic conditions of the pelvic organs, 50° to 60° F. is the most useful temperature; in chronic inflammations 80° to 90° F.; constant friction by an attendant should be kept up unless contra-indicated. Cold sitz baths are stimulating, and should not last more than three to eight minutes; hot sitz baths are anodyne and sedative, and may be kept up for twenty minutes to an hour, care being taken to maintain the temperature at the proper level; they are useful in spasmodic conditions, tenesmus, retention of urine from congested stricture or urethral spasm, amenorrhœa, dysmenorrhœa, and ovarian neuralgia. The addition of mustard to the bath increases its derivative effect.

The Hot Foot Bath is a household remedy so widely used as to require no description; its action is derivative, and it is useful in incipient coryza, delayed menstruation, congestive headache, and some forms of insomnia. The cold foot bath with about two inches of water and accompanied by friction is useful for cold feet and insomnia therefrom.

Mineral Water Baths.—The action of mineral water baths, while dependent in some measure on the water, owes much to the saline or gaseous constituents, and as few can be imitated with any advantage at home, a full description would be out of place here. Briefly, so far as their use in bathing is concerned, they may be divided into three classes: thermal, saline, and sulphur.

The thermal indifferent waters, such as Buxton, Bath, Gastein, etc., have for long been noted for their action in rheumatism and gout, for which no satisfactory explanation could be given, since they contain little dissolved mineral matter, though they are as a rule charged with gas which is, in the typical members of the group, nitrogen. Recent researches have, however, shown them to be radio-active in a marked degree, and experiments have proved that this explains their action in great measure. Probably it is not only the effect of the radium emanation on the body, but also that the other constituents are more potent in the presence of the emanations than would otherwise be the case. They produce a more marked reaction than ordinary water, and when prolonged, a remarkable sense of lassitude and fatigue: a course has a decided effect in reducing blood-pressure where it is higher than normal. The use of the douche at the time of the bath is customary in the spas belonging to this group.

The sulphur waters, where sulphur is the chief constituent, are limited in their action as baths, beyond the action of plain water similarly administered, to influencing morbid conditions of the skin; the higher the proportion of other ingredients, the more nearly they approach the action of the next group. Sulphur baths may be prepared at home for use in skin diseases by means of the proprietary preparation 'Sulphaqua.'

The saline waters have a distinct irritative action on the skin and the cutaneous circulation. This is seen in a mild form in the effect of sea-water bathing, but as most of the waters in this group which are used for bathing are highly gaseous, their action in this respect is thus considerably increased. The Nauheim baths, which have obtained so great a reputation for the treatment of disorders of the heart are perhaps the most potent, and since their action can in great measure

be reproduced by artificial solutions, they have been widely used in this country, with results little inferior to those obtained at Nauheim. Any failure in cases suited for such treatment has been due to insufficient attention to the details of the treatment. The baths may be given at home, but rarely with success, since the essential rest and freedom from worries are seldom obtained, and to regulate the strength, duration, and number of the baths requires special experience. They are, however, given with success in most of the English spas. These baths are fully described in the article on SCHOTT-NAUHEIM treatment.

Brine baths also are easily prepared, and are useful in lumbago, sciatica, and chronic rheumatic conditions, as well as in chronic inflammatory disorders of the pelvic viscera. They are best prepared from the salts obtained from saline waters by evaporation; Droitwich salt, among others, is placed on the market for this purpose. The bath should be at a temperature of 95° to 98° F., and fifteen minutes to half an hour is the usual duration, after which the patient should be rapidly dried and removed to bed. Soda baths are prepared in the same way, common washing soda being used, and are useful more especially in chronic rheumatic conditions such as fibrositis. To a full bath 10 to 20 lb. of salt, or $\frac{1}{2}$ to 2 lb. of common washing soda, may be used.

Other medicated baths are occasionally used, such as pine, tar, bran, etc.; these do not require description.

Peat or "moor" baths are in use at many spas in this country and on the Continent. They are prepared by the admixture of finely disintegrated peat with mineral water. At Marienbad, Buxton, etc., a ferruginous water is used, and this is the most frequent type, but sulphurous peat baths are also prepared, and at Buxton the radio-active water is often used. The action of these baths, owing to the heat and friction of the fine particles held in suspension, is to stimulate the nerves and blood-supply of the skin. They can be borne much hotter than water baths, since they retain their heat better, but the most useful range is from 95° to 105° F. At the lower temperature they are sedative to a marked degree.

Fango, a volcanic mud found in various places in Italy, is used in the same way as "moor," and both are used for local packs and for poultices. It is, however, expensive and hardly adapted for home use, as much of the effect depends on subsequent douching or other measures. I have been unable, after careful observation, to detect any advantage of fango over peat.

Charles W. Buckley.

HYDROTHORAX.—This name is given to the passive collection of serous fluid in the pleuræ, owing to cardiac failure, chronic renal disease, or the pressure of tumours on veins and lymphatics within the thorax. If the primary cause be cardiac or renal, attempts may be made to lead to the absorption of the fluid by:—(1) Cardiac stimulants, (2) Purgatives, (3) Diuretics, and (4) Diaphoretics.

The value of the first of these methods is obvious, and in many cases, as the heart condition improves, the hydrothorax disappears and the fluid is absorbed. The drugs available and their method of use are described under CONGESTION.

The use of purgatives, diuretics, and diaphoretics, to disperse a pleural effusion, is based on the clinical fact that it is not very uncommon, in the natural resolution of disease, for a hydrothorax to disappear simultaneously with the onset of diarrhœa, or profuse sweating, or the passage of a large quantity of urine. But it by no means follows that if we artificially induce these conditions we can bring about absorption of pleural fluid. It is well recognized now that all three methods very often fail to produce the desired result, and only exhaust the patient further.

When hydrothorax is present on one or both sides, from cardiac or renal causes, the best course open to us is to aspirate, and draw the fluid off gently. This may be done by syphonage with Southey's tube, the india-rubber tubing being filled with water before the trocar is thrust into the pleura; or with an ordinary aspirator syringe or bottle.

In all cases where the fluid is due to the pressure of an intrathoracic growth, aspiration is the only method available. It is well not to forget, in cases of growth, that sudden death frequently follows the withdrawal of fluid; this happens even though the fluid has been removed slowly and with great care. The relatives should be warned of this before the performance of the operation.

Cecil Wall.

HYPERCHLORHYDRIA.—(See **DYSPEPSIA.**)

HYPERIDROSIS.—General sweating is a part of some general disease. The term hyperidrosis may be taken to apply specially to cases of localized sweating, particularly those of the hands and feet. One recognizes certain constitutional conditions predisposing to this, and these should always be kept in mind, and treated if present. Thus anæmia is a very common predisposing cause in girls; alcoholism in men.

Drugs are not of much avail in directly stopping localized sweating, but a trial may be given to atropine, agaricin, and the like, while Crocker taught that sulphur is often useful, large doses of the drug being administered. Locally, frequent washing with antiseptic and astringent lotions should be systematically carried out, and Condyl's fluid is a favourite application; it is customary to advise the patient to change the socks daily, and dust with some absorbent powder.

R. Acidi Salicylici

3j

Such treatment may suffice in the mild cases, but in severe ones more active measures are required. Chromic acid is used in the French army, formalin in the Japanese, and the excessively heroic method of Neebe comes from Germany: this latter consists in the patient standing for a few seconds in crude nitric acid, sufficiently deep to cover only the soles of the feet. Such treatment is, in this country, reserved for a very small minority of the cases. Recently several cases of complete recovery have been reported (Howard Pirie and others) as the result of exposure to α rays. It is desirable that this treatment should be carried out by an expert, as considerable doses are sometimes required. (See also **PERSPIRATION, OFFENSIVE.**)

Norman Walker.

HYPERPIESIS.—(See **ARTERIOSCLEROSIS.**)

HYPNOTISM, TREATMENT BY.

Methods of inducing Hypnosis.—These have been classed as follows: (1) Physical; (2) Psychical; (3) Those of the magnetizers.

The modern hypnotist, however, whatever his theories may be, borrows his actual technique from Mesmer and Liébeault with equal impartiality, and in this way renders classification well-nigh impossible. Thus, the members of the Nancy school, while asserting that everything is due to suggestion, do not hesitate to use physical means. The passes with contact employed by Mesmer are almost exactly reproduced by Wetterstrand. Fixed gazing generally precedes or accompanies suggestion, and when these fail, Bernheim does not scruple to have recourse to narcotics.

As to physical methods, it is more than doubtful whether these have ever succeeded when mental influences have been carefully excluded and the subjects have been absolutely ignorant of the nature of the experiment. No one was

ever hypnotized by looking at a revolving lark-mirror till Luys borrowed this lure from the birdcatchers and invested it with hypnotic power. On the other hand, any physical method will succeed with a susceptible subject who knows what is expected of him.

My own methods have varied widely. At first I attempted to induce hypnosis mainly by physical means, such as fixed gazing. Later, these were all abandoned, and I relied solely on suggestion. The following is now my usual method: I rarely attempt to induce hypnosis the first time I see a patient, but confine myself to making his acquaintance, hearing his own account of his case, and ascertaining his mental attitude with regard to hypnotism. I usually find, from the failure of other treatment, that the patient is more or less sceptical as to the chance of his being benefited. In most cases, also, he has either read misleading sensational articles on hypnotism, or his friends have painted its dangers in glowing colours. I endeavour to remove erroneous ideas, and refuse to attempt to induce hypnotism until the patient is satisfied of the safety and desirability of the experiment. I never tell a patient I am certain of being able to influence him, but always explain how much depends upon his own mental condition and power of carrying out my directions.

I further explain to the patient that presently I shall ask him to close his eyes, and then shall begin to make suggestions. I tell him that the important point is that he should concentrate his attention upon some drowsy mental picture, and try to turn it away from me and from my suggestions; the theory being that these are addressed to a secondary consciousness. I then ask him to sit down in a comfortable arm-chair, and to close his eyes; as soon as he has done so, I commence to make suggestions of two kinds. The first are in reference to the condition I wish to induce while he is actually in the arm-chair. Thus, I suggest: "Each time you come to see me, you will find it easier to concentrate your attention upon something restful; you will become more and more drowsy and lethargic," etc., etc. The other suggestions are the curative ones, and these vary according to the nature of each individual case. I explain to the patient that I do not expect these suggestions to be responded to at once, though this does occur in rare instances, but that it is the repetition of the suggestion, made in this particular way, which brings about the result. Thus, from the very first treatment the patient is subjected to two distinct processes, the object of the one being to induce hypnosis, that of the other to cure or relieve disease; and frequently the latter is successful before the patient can be described as genuinely hypnotized.

The monotonous suggestions described above are not always necessary in order to induce hypnosis. In a recent case, where the patient was so deaf that I could make her hear only by shouting, I suggested to her in this way, i.e. by shouting to her beforehand, the condition of hypnosis which I wished to induce, and the curative results which were to follow from it. Shortly after closing her eyes, although I had ceased all suggestion, the patient passed into an undoubted hypnotic state, and this was speedily followed by marked improvement in the nervous symptoms from which she suffered.

In young children, I have frequently had good results by making suggestions during natural sleep. I place my hand on the child's forehead and quietly tell him that he is to hear my voice but still continue sleeping, at the same time making curative suggestions.

In cases where none of the usual symptoms of hypnosis are present, curative suggestions apparently differ little from those sometimes made in ordinary life by medical men and others. The results, however, are often very different. For example, a patient suffering from dipsomania had received many and varied suggestions. The loss of health, fortune, and friends were powerful suggestions

to stop drinking. Twelve months passed voluntarily in a retreat ought also to have had a strong suggestive influence. They all failed, however; while treatment by suggestion, associated with hypnotic methods, was speedily followed by success, and the patient has now been an abstainer for many years. It is difficult to explain why suggestion, given in this particular way, should so frequently produce such striking results. Apparently the hypnotic methods, although often producing no true hypnosis, have increased the suggestibility of the patient. It is a mistake to describe such a condition as hypnosis, i.e., sleep. I frequently find, however, that curative suggestions are responded to as readily in this state as in profound hypnosis.

Self-Hypnosis and Self-Suggestion.—Putting aside the question of self-hypnosis amongst fakirs and other religious fanatics, I am not acquainted with many instances in which the primary hypnosis has been induced by the subject himself. Braid, however, stated that he hypnotized himself on more than one occasion, and successfully suggested the disappearance of rheumatic pain. Professor Forel, of Zurich, and Dr. Coste de Lagrave, have also succeeded in hypnotizing themselves, and the latter can influence himself in many ways by suggestion; he states he is able to get rid of pain, fatigue, mental depression, etc.

Shortly after commencing hypnotic work, I found that patients who had been deeply hypnotized could be instructed to reinduce the condition at will. Here suggestions during hypnosis were not necessary for the production of its phenomena; they were equally efficacious when made beforehand in the waking state. The subject was able to suggest to himself when hypnosis should appear and terminate, and also the phenomena which he wished to obtain during and after it. This training was at first a limited one; the patients, for example, were instructed how to get sleep at night or relief from pain. They did not, however, confine themselves to my suggestions, but originated other and widely varying ones regarding their health, comfort, and work. In several instances they made use of self-hypnosis for operative purposes, and astonished their dentists by remaining insensible to the pain of having their teeth extracted. In some cases, this power has been retained for over twelve years.

I have observed the phenomena of self-hypnosis in healthy persons also who have been hypnotized for experimental purposes. Here the subjects, when awake, could suggest to themselves that muscular rigidity, local and general analgesia, etc., should appear during hypnosis, and then hypnotize themselves at will, when the phenomena duly appeared. During self-hypnosis the subjects were either *en rapport* with everyone or only with certain individuals, according to the suggestions they had made to themselves beforehand.

Even in slight hypnosis, and in conditions where it would be impossible to prove that the patient had been hypnotized at all, self-suggestion frequently gives striking results, if the operator suggests to the patient during treatment that he shall acquire this power. For example, I published the following case, the notes of which were written by the patient, a professor of natural history at one of our universities, who had long suffered from insomnia. He had only three treatments, and during the second alone was he at all sleepy, and that very slightly. Not only did his insomnia disappear, but he acquired the power of putting himself to sleep at any time, and used it to escape the sea-sickness from which he always suffered when he crossed the Irish Channel. He lay down in his bunk as soon as he got into the boat, put himself to sleep by suggestion, and remained asleep until he arrived in port.

Method of Terminating Hypnosis.—The hypnotic state tends to terminate spontaneously. In slight hypnosis this usually happens as soon as the operator leaves the patient; in more profound stages it may not occur until after the lapse of several hours. The members of the Nancy school suggest during hypnosis

that the subject shall awake at a given signal ; as, for example, when the operator utters the word "Awake," or counts "One, two, three." The nature of the signal is of little or no importance, the essential point being that the subject shall understand its import. The method just described is the one I usually adopt, and I have never experienced any difficulty in awaking my patients.

Susceptibility.—In April, 1892, Schrenck-Notzing published the results of his "First International Statistics of Susceptibility to Hypnosis." Fifteen observers in different countries furnished returns, which showed that they had tried to hypnotize 8705 persons, with 519 failures, i.e., barely 6 per cent were uninfluenced.

Sex and Nationality appear to have little influence on susceptibility, but as a general rule the hysterical and ill-balanced are much more difficult to hypnotize than persons of intelligence and strong will. The insane are the most difficult of all to influence.

In reference to the methods of inducing hypnosis, susceptibility, etc., the principal points which ought to be kept in mind are : (1) That there is as yet no satisfactory explanation why hypnosis should be evoked by the methods employed ; (2) That the varying susceptibility to hypnosis is equally difficult to understand. We do not yet know why identical methods should induce hypnosis in one instance, and have apparently no effect in another ; (3) That it is equally difficult to explain why susceptibility to curative suggestions should obviously be developed in patients who have undergone hypnotic methods of treatment, but in whom hypnosis has not manifestly been evoked. If the patients have become drowsy during treatment, one might perhaps say, though one could not prove it, that the condition was one of slight hypnosis ; but how is one to explain cases like the following ? Miss —, aged 19, June, 1900, a well-educated and highly intelligent girl, had suffered since July, 1895, from clonic muscular spasms, which first affected the left side only, then all the voluntary muscles. Later there were frequent attacks of violent generalized convulsions. She had continual medical treatment, and was finally admitted as a contributing patient to the National Hospital, Queen Square. After two months she was dismissed unrelieved, and sent to me. For the first fortnight she had violent convulsive attacks every time I treated her, but despite this I made suggestions in the usual way. In three weeks she was well, and is so at the present date.

THE THERAPEUTIC VALUE OF SUGGESTION.

Treatment by suggestion has yielded good results in every form of functional nervous disorder. In addition, the pain of organic disease can frequently be relieved in this way, and sleep procured without narcotics. The following list is simply an illustrative one, and in no way pretends to be complete :—

1. *Hysteria.*—(a) *Grande hystérie*, or hysterio-epilepsy, and the conditions which sometimes persist after the convulsive attacks have disappeared, e.g., paralysees, contractures, spasms, anæsthesia, amauroses, etc.; (b) *Monosymptomatic hysteria*: monoplegia, mutism, aphonia, hiccough, blepharospasm, dyschromatopsia, etc.; (c) The various manifestations of ordinary hysteria: dyspepsia, visceral and menstrual troubles, etc.; (d) Mental troubles of a hysterical nature: perversions of sentiment, obsessions, irresistible impulses, hallucinations, melancholia, maniacal excitement, etc.

2. *Neurasthenia.*—In 1893–94 Schrenck-Notzing published an account of 228 neurasthenics treated by himself and others. The following were the therapeutic results : 72 cases, equalling 31·6 per cent, recovered ; 84 cases, equalling 36·8 per cent, were much improved ; 72 cases, equalling 31·6 per cent, showed no improvement.

In Schrenck-Notzing's opinion impotence of 'psychical origin is sometimes the only symptom of neurasthenia ; out of 18 cases which he reported, 10 were cured by suggestion. I have seen several cases which tend to confirm this view. In the following one, if the patient suffered from neurasthenia, impotence was the only symptom of that disorder.

Mr. —, age 35, healthy and athletic. Continent before marriage. No masturbation. The patient had been married over three years ; he was completely impotent, and this condition had not been improved by medical treatment. Hypnotic treatment was begun on November 28, 1898, and continued for a month. Despite the fact that obvious hypnosis was not induced, curative suggestions were responded to. From Christmas, 1898, his sexual life has been that of a vigorous normal man. There has been no relapse, and he is now the father of three children.

3. Insanity.—In 1889, Voisin reported amongst others the following successful cases, of which he had traced the after-history : (a) Melancholia with hallucinations, treated in 1885 ; (b) Melancholia with hallucinations, suicidal ideas, and attempted suicide, treated in 1885 ; (c) Acute mania with convulsive attacks, treated in 1886 ; (d) Melancholia with refusal of food, treated in 1884 ; (e) Sub-acute mania, treated in 1885 ; (f) Sub-acute mania, treated in 1888 ; (g) Acute mania, treated in 1885 ; (h) Melancholia, treated in 1888 ; (i) Melancholia, treated in 1888. Cases (h) and (i) relapsed after attacks of epilepsy ; the remaining seven continued well. Numerous other insanity cases, many of them equally interesting and successful, were reported by Voisin from time to time.

Dr. George Robertson, of Morningside Asylum, gives the following summary of the uses of hypnotism amongst the insane.

i. *As a Direct Therapeutic Agent.*—(a) Hypnotism sometimes succeeds in intractable cases of insomnia where narcotics have failed, and thus ought to be of great service where the brain nutrition is bad and depressing drugs specially undesirable ; (b) When the brain is highly unstable it may be of direct therapeutic value as a sedative, and thus prevent an outburst of excitement from passing into mania ; (c) It is useful in dispelling fleeting delusional states and minor psychoses.

ii. *For Purposes of Management.*—(a) Hypnotism may be used to overcome the morbid resistance of patients to the administration of food, medicine, etc. ; (b) It may be employed in cases of excitement and violence, instead of mechanical, chemical, or physical means of restraint.

4. Dipsomania and Chronic Alcoholism.—Nearly every medical man who practices hypnotism has reported successful cases of dipsomania and chronic alcoholism treated by suggestion, and some of my earlier ones have now remained over eighteen years without relapse.

5. Morphinomania and other Drug Habits.—Patients suffering from hysteria and neurasthenia frequently acquire drug habits ; the latter, however, are usually abandoned as soon as the insomnia and other morbid symptoms disappear under treatment. Still, this is true of ordinary hypnotic drugs only, and does not apply to opium and morphia. The treatment of patients addicted to the latter, especially where the drug is administered subcutaneously, presents many difficulties, and relapses are frequent. As far as I know, the best results have been obtained by Wetterstrand, of Stockholm : out of 41 cases he reported 30 as cured.

6. Vicious and Degenerate Children.—The following conclusions as to the value of hypnotism in the treatment of vicious and degenerate children were submitted by Bérillon to the International Congress of Hypnotism, Paris, 1889 : (a) Many carefully observed facts prove the therapeutic value of suggestion in the following diseases of children : incontinence of urine and feces, nervous twitchings, nocturnal terrors, onanism, blepharospasm, and other disturbances

of the nervous system of a functional character ; (b) So far no appreciable results have been obtained in cretinism, idiocy, or deaf-mutism ; (c) Suggestion constitutes an excellent auxiliary in the education of vicious and degenerate children, especially where there are habits of lying, cruelty, inveterate idleness, or cowardice ; (d) Suggestion should be confined to cases where the usual methods of education have failed, and medical men alone should employ it. It is not necessary to hypnotize normal children ; ordinary training ought to be sufficient for them. When, however, children are addicted to theft and other vicious and repulsive habits, and are afflicted with disgusting infirmities, we ought to try to cure them by hypnotism, especially when their parents are in despair owing to the failure of all other forms of treatment.

These conclusions were adopted unanimously by the Congress, and were transmitted to the Minister of Public Instruction and the Minister of the Interior.

7. Obsessions.—Many successful cases have been reported by Schrenck-Notzing and others. Personally, I have found treatment by suggestion yield better results in cases of obsession than in any other form of nervous disorder. In many instances, unless the obsessions can be cured, it means that the patient must abandon his business or profession. In one extreme instance the patient had been forced to give up work thirty years before I saw him, but after a few months' treatment he recovered.

I do not for a moment pretend that one can cure everything and everybody by suggestion, and agree with Braid in thinking that he who talks of a universal remedy is either a knave or a fool. Hypnotism is simply an additional weapon by which medical men can combat disease, and many cases have been cured or relieved by it which had previously resisted long, careful, and varied medical treatment. Further, the diseases which frequently respond to hypnotic treatment are often those in which drugs are of little or no avail. For example, what medicine would one prescribe for a man who, in the midst of mental and physical health, had suddenly become the prey of an obsession ?

In estimating hypnotic results it must not be forgotten, too, that the majority of cases treated in this way are extremely unfavourable ones. Since I came to London, patients have rarely, if ever, been sent to me when they first fell ill, and with most of them every form of treatment had been tried and had failed before hypnotism was resorted to. As the value of treatment by suggestion and its freedom from danger become more fully recognized, it will doubtless be employed in earlier stages of disease, and when that day comes the results will be still more striking.

Above all else, it should be clearly understood that the object of all hypnotic treatment is the development of the patient's control of his own organism. Many illnesses represent the culminating point in a life which has been characterized by lack of discipline and self-control. While attention is given to physical culture, the emotional side is too often neglected ; but much disease would be prevented if we could develop and control moral states just as an athlete does physical ones. One point is worthy of special notice. The results obtained by suggestion are due to the action of the patient's mind on his own body, and are free from the disadvantages sometimes associated with the use of drugs. Thus, the patient who is cured of insomnia by suggestion has really acquired the power of producing sleep at will, while he who obtains sleep by means of an ordinary narcotic has often added a drug habit to his original disease.

In this country those who practise hypnotism have to contend with greater difficulties than are met with at Nancy. There, as the result of Liébeault's thirty years' work, fear and prejudice have been almost entirely removed, while

here they not only exist, but are widely spread. For this, disgusting music-hall exhibitions, largely mixed with imposture, are much to blame.

The so-called Dangers of Hypnotism.—As far as my experience goes, the employment of hypnotism by medical men acquainted with the subject is absolutely devoid of danger. Professor Forel asserted that neither he, nor any other member of the Nancy school, had seen a single instance in which mental or physical harm had been caused by hypnotism. It is true that statements to the contrary still sometimes appear in the medical journals. The writers, however, are obviously unacquainted with the subject, and do not bring forward a single fact in proof of their statements.

It is to be hoped that the day will soon come when prejudice will disappear, and when treatment by suggestion will be employed by every general practitioner. It is not the specialist, whose practice is confined to unfavourable cases, who is likely to get the best results. It is the one who can choose suitable cases from amongst his own patients—patients whose confidence he has already gained.

No treatment can produce results equal to those claimed by Christian science, but those actually obtained by hypnotism and suggestion cannot be paralleled by any form of faith cure. Further, these results do not depend upon faith, superstition, or emotional conditions, and surely it would be better for medical men to treat suitable cases by suggestion, rather than allow them to fall into the hands of dangerous quacks.

J. Milne Bramwell.

HYPOPYON ULCER.—(See CORNEA, DISEASES OF.)

HYSTERIA.—This is one of the disorders of the nervous system in which no organic changes have as yet been determined to account for the symptoms. Nevertheless it is a definite disease, and if those affected by it are to be successfully treated, this truth must be recognized by all who are concerned in the management of the patient. To approach a case of hysteria in the belief that a condition akin to malingering is being dealt with, and to make it patent to the patient that this is the view taken, is to court failure. It is essential to successful treatment that such patients should be impressed with the belief that their condition is recognized as due to disease, and is being treated as such, so that any show of ridicule, or other indication that they are regarded as impostors, must be studiously avoided.

It is often difficult to refrain from showing impatience, or giving some other indication which may be interpreted by the patient as meaning that she is regarded as responsible for her symptoms, and could prevent them if so inclined. Behaviour of the kind should be carefully avoided if it is hoped that treatment is to be successful.

One of the best established facts in regard to hysteria is that the higher cerebral centres are in a very sensitive condition and most receptive to external impressions, a fact that should be carefully borne in mind and utilized in the treatment of such patients, rather than that this state of things should be permitted to frustrate the attempts that are being made to effect a cure. The subjects of hysteria respond to suggestion in a remarkable manner; so that, judiciously employed, we have in this a means of treatment the value of which cannot be over-estimated.

That instability of the nervous system underlies the manifestations of the affection is clearly established by all that is known with regard to the disease; and that this defect is in the main hereditary is evidenced by the fact that hysteria, or allied neuroses such as neurasthenia, mental disorders, and epilepsy, are usually to be traced in other members of the same family. This instability reveals itself by weakness of the higher centres which govern the will, but the

mind is nevertheless quite clear, and the condition cannot be regarded as a form of insanity.

The emotional centres are usually in a highly sensitive condition, so that they react to stimuli that should be inadequate to disturb them, and the response may be out of all proportion to the amount of the stimulus. In addition to this, the response may be so distorted that the opposite of what should obtain is forthcoming, e.g., something that should induce tears evokes laughter, and vice versa. In the sensory sphere, the disordered state of the centres may give evidence of an over-sensitiveness in which all sensory impressions are exaggerated in their effects, or the weakness of these centres may lead to a want of the power of perception of sensory stimuli, both in regard to common sensibility and the special senses. The same condition is evident in the motor sphere, where the instability of the neurons may be evidenced by an undue sensitiveness, which permits of spasms and convulsions, or a weakness which accounts for paralysis. It is, however, to disorder of the higher centres which initiate or conduct the movements, that we must look for the explanation of the paralysis of hysteria, rather than to the lower centres more directly concerned in the liberation of energy which results in the excitation of the muscles that causes them to contract.

It is thus clear that in hysteria it is the mind that is to be treated, and that although the affection is distinct from the various recognized forms of insanity, nevertheless it is a mental and not a physical disorder; and that while due regard must be paid to the physical condition of such patients, notably as to their general state of nutrition, it is to the mind that treatment is to be chiefly directed if a cure is to be effected. This does not imply that the physical condition is to be neglected, for a healthy physical state is so far conducive to a cure, that without this it may be impossible to exercise a beneficial influence on the mind.

Although hereditary instability of the nervous system underlies the manifestations of hysteria, there are many other proximate causes which are directly responsible for evoking the manifestations of the disorder. A careful search must always be made for such exciting causes, and measures calculated to correct them must form a part of the treatment.

Of the proximate causes, none is more common or effective than some form of mental emotion; and while a great shock, terror, sorrow, or anxiety may be responsible, the emotion may have been induced by an altogether inadequate cause, and nevertheless manifestations of the hysteria are forthcoming. The impressionability of such subjects makes them peculiarly liable to fall victims to imitation, so that there is a contagiousness about hysteria that has an important bearing on the prophylactic measures that are often needed if susceptible subjects are to be protected from this affection.

Although physical causes play a secondary rôle in the production of the malady, an impoverished state of general nutrition, anæmia, the debilitating effects of other disorders, and bad hygienic conditions of life, may be contributory factors which enable other exciting causes to prove effective, or which themselves permit of the exhibition of the symptoms of hysteria in one predisposed. It is especially important to remember that grave organic disease of the nervous system may play this part, and that hysterical manifestations may co-exist with, or may even mask, the symptoms of the organic malady.

Peripheral irritation, notably from the female generative organs, has been regarded as a potent cause; but there seems little doubt that this influence has been over-estimated, and that even when such disorders co-exist, the depressing mental effect engendered by the knowledge of their presence is the more potent agent in the causation of any hysterical manifestations that may result.

Of toxic agents, alcohol, morphia, and drugs of a similar kind, appear to exert the most baneful influence.

Prophylactic measures directed towards preventing the development of hysteria in those predisposed should include advice to neurotic mothers to avoid speaking of their symptoms in the presence of their children; not to show too much concern when there is anything wrong with the child, and especially to avoid making much of its every complaint, no matter how trivial. Removal of the patient from the home circle is a measure that may be required, not only for her own good, but to prevent other members of a susceptible family from falling victims by imitation.

Much good is also to be effected in prophylaxis by attention to the mental training, hygiene, and general nutrition of children in families in which hysteria and similar neuroses have claimed several members as victims. Wholesome food for mind and body, fresh air, and gymnastic exercises of various kinds, especially adapted to aid in the physical development of the child, are the measures to be chiefly recommended; while parents should be warned against the encouragement of precociousness and excitement in such children, and should be advised to guard them against undue mental and physical strain.

Cases of hysteria can rarely be treated with success in their own homes, so that the first thing to be secured is the removal of the patient to a good nursing home, or some other suitable place away from home influences, including that sympathy for which the hysteric craves, and which is meted out to her so lavishly by relatives and friends. Few things are worse for these patients than the gratification of this desire for sympathy; so that, without making the opposite mistake of ignoring their symptoms altogether, the less fuss that is made about them, and the more matter-of-fact the way in which their illness is treated, the better.

All who have to do with these cases must understand that they are dealing with a disease, and must make this clear to the patient. They must, however, be also careful to impress on the patient the fact that there is nothing wonderful in her malady, that many people are similarly affected, and above all things, that the condition is one from which she will make a complete recovery.

One of the most important elements, therefore, in the successful treatment of hysteria is the selection of a competent nurse, who, without being harsh and unkind, knows how to exercise that firm control over the patient which leaves no doubt in the mind of either as to which of them is to be mistress of the situation. The patient should be left, as far as possible, in the sole charge of the nurse, and the less other people have to do with her the better. The best of nurses may, however, prove of little avail if she be not well supported by the medical man in charge, who must know not only how to deal with his patient, but—what is equally important—how to manage her relatives, so as to prevent them from interfering with the nurse, and undermining her influence with her patient. The medical man must accordingly be quite sure of his nurse, and be in a position to trust her implicitly, if he is to give her the unqualified support that she needs.

It is also essential that the medical man should gain the complete confidence of his patient, and should duly impress her with his thorough knowledge of her case, and with his conviction that, under the treatment he is adopting, a cure will be effected. If he succeeds in thus establishing his position, he can effect wonders by the judicious use of suggestion, combined with whatever form of treatment he has decided upon.

Of the various methods of treatment that are available, none is more suited to most cases of hysteria than the Weir-Mitchell treatment (see NEURASTHENIA). The main object of this treatment is, however, very different when employed in

hysteria, for it is because it affords an admirable means of isolating the patient from the prejudicial influences of sympathetic relations and friends that it proves of such advantage in this affection. Moreover, the whole plan of treatment should be made as dull and monotonous as possible, with a view to making the patient tired of it, in the hope that this may be an incentive to her to try to get well, in order that she may be allowed to enjoy the pleasures of life again.

This being the case, the patient is not allowed to play games, read, or look at picture-papers, nor should the nurse be allowed to read to her. One by one these restrictions may be removed as rewards for any improvement in the symptoms; but the slightest sign of relapse must be the indication for enforcing the restrictions again.

With the same object, it may be advisable to make the diet monotonous, to the extent of keeping the patient on milk alone for a time. Solid food is then added as a luxury, and the patient is told that it has become permissible because there is an improvement in the symptoms, but that it will not be continued if there is any relapse. Due regard, however, must be paid to the patient's nutrition and digestion, which must not be allowed to suffer by any modifications in diet that are suggested as likely to exercise a moral effect in the treatment.

During a course of Weir-Mitchell treatment, or independently of this, various other methods may be employed with advantage, which are directed either towards improving the general nutrition and tone of the patient, or with a view to influencing some local manifestation of the disease. Hydropathy is especially valuable, notably in the spasmodic disorders, when the cold bath or douche may arrest a hysterical fit, and the douche, systematically employed as a local measure, may help to bring about relaxation of a spasm. Apart from this, the general tonic effect of the cold bath does good, and the cold douche to the spine is especially to be recommended, not only on account of its tonic effect, but also because it has a good moral influence, in view of the fact that many of the patients do not delight in it. The cold spray and needle bath are also effective.

Electricity is especially useful in the management of hysterical conditions, whether they be spasmodic or paralytic. A strong faradic current, applied by means of the wire brush, may be as successful in arresting the hysterical fit, owing to the pain which it engenders, as it is in bringing back movement in a part that is paralyzed. In making use of the electrical current to restore the power of movement, however, equally good results may commonly be obtained by applying a strong current by means of the ordinary pad electrode instead of the wire brush, when suggestion also may be made to play a part in the cure. The patient's attention should be directed to the fact that the electricity is making the muscles contract, and it should be impressed on her that this proves that the muscles are not dead, but are fully capable of doing their work if fresh life is put into them by means of the electricity. The movement of some part of the limb should then be evoked by the aid of the faradic current, and the patient should be induced to attempt to execute the same movement immediately afterwards. While she is attempting to perform the movement, a little moral persuasion should be employed by touching the limb with an electrode charged with a strong current. The part chosen for the application of this stimulus should be such that, in order to remove the limb from the unwelcome electrode, the patient must perform the movement which she has been previously unable to execute, and which she is being encouraged to attempt. By this means power may be rapidly or gradually restored to the paralyzed limbs.

Static electricity and high-frequency currents are also very useful. In both forms of treatment the drawing of sparks from the body does much to impress

upon the patient the value of the electricity with which she is so fully charged. The spasmodic disorders of hysteria are especially influenced by these methods of treatment. Electric baths also do good, but more from their general tonic effect than from any special local influence they exert on the disorder, whether it be spasmodic or paralytic. (See *ELECTROTHERAPEUTICS*.)

Massage, and Swedish and other forms of gymnastic exercises, are especially useful in the treatment of paralytic manifestations, quite apart from the place that massage occupies in the treatment of the malady as part of the Weir-Mitchell system.

The cautery, or a blister, may be employed locally with great advantage to the seat of pain or spasm, when either of these manifestations exists; but in addition, counter-irritation in this way to the back or other regions may aid in the restoration of the power of movement to the affected parts.

Metallotherapy, by the aid of a large magnet, is also most useful, but owes its efficacy to the element of suggestion which it serves to convey, rather than to any inherent virtue which the magnet imparts.

There is no measure in the treatment of hysteria for which so much can be claimed as suggestion. As has already been said, most of what is done with good result is tempered with a certain degree of suggestion; but cures may be effected by this means alone, and, it may be, with marvellous rapidity. So easily are such individuals influenced by suggestion that care is needed, when investigating a case, lest unguarded questions as to symptoms may induce phenomena which did not previously exist, and which have been unwittingly manufactured by the medical man in his zeal to discover whether this or that manifestation of the affection exists of which he may have read, or examples of which he may have seen. Suggestion, however, can effect much good, and does no harm when properly applied. (See *PSYCHONEUROSES*.)

The same cannot, however, be said of hypnotism. This is a most potent agent in the treatment of the affection, but labours under the disadvantage that it may be responsible for increasing the mental instability, and even for producing more serious mental derangement. It seems scarcely necessary to add that, dangerous as is the use of hypnotic treatment in the case of any female, it becomes doubly so when the patient is the subject of hysteria; so that the medical man who decides on employing it should safeguard himself by having at least one nurse in the room with the patient when the treatment is being carried out. (See *HYPNOTISM*.)

As in cases of neurasthenia, the patient should be sent away with a nurse to some bracing place in the country or by the sea, after a course of Weir-Mitchell treatment in a nursing home. In addition to this, such treatment is an alternative plan of dealing with patients suffering from this affection when the family cannot afford the expense of treatment in a nursing home, or when the hysterical manifestations do not appear to be sufficiently pronounced to call for as rigorous treatment. Indeed, climatic treatment as a whole is beneficial for these patients, owing to the improvement which may follow in their general condition where this is below par.

Drugs play but a minor part in the treatment of this affection, but valerian is certainly of service in many cases, and the out-patient departments of hospitals could ill afford to dispense with this remedy. It is not merely the unpleasant nature of the drug that effects the good, for favourable results are obtained when it is given in the form of a pill; but the best results are certainly obtained when valerian is given in the liquid form, and there can be little doubt that its unpleasant qualities exercise a good moral effect in many cases. Asafœtida may be similarly employed with advantage in the treatment of hysteria, and both drugs do good, irrespective of the precise manifestations of the disease.

Bromides may be employed with advantage when spasmodic disorders have to be dealt with, but they exercise little or no control over the hysterical fit, except when genuine epilepsy co-exists. It rarely happens that hypnotics are required in these patients, for, provided they be not told what they contain, cachets of sugar or some equally non-soporific substance will usually procure for them as excellent a night's rest as if the cachet contained one of the most active hypnotics. Similarly, analgesics are rarely required to relieve hysterical pain, which may be favourably influenced by cachets which contain no active ingredient, or by suggestion, or by counter-irritation or some other method of local treatment. Hypnotics and analgesics cannot be too carefully guarded against, as these patients very readily acquire the drug habit. Above all things, morphine must never be given, as it is pre-eminently the drug likely to prove most deleterious from this standpoint.

Tonics are commonly required, and iron is notably of advantage when the patient is anæmic. Aperients are habitually needed to counteract constipation; and in the forced feeding that forms part of the Weir-Mitchell system, medicines to aid the digestion may be called for. It is, however, a mistake to suppose that gastric symptoms of hysterical origin, such as pain and vomiting, can be influenced by drugs which have a direct action on the stomach, for the only good they can effect is through any influence of suggestion which they may impart. It is to the psychical condition that treatment must be directed, whether it be local or general, and whether a drug or some other method of treatment is employed. Thus it is that valerian, in a case of obstinate hysterical vomiting, may effect what each gastric sedative in turn has failed to accomplish, and that the cautery to the epigastrium may relieve a pain that has resisted every analgesic in the pharmacopœia that can be legitimately employed for its relief.

J. S. Risien Russell.

ICHTHYOSIS.—Although there are many grades of this disease, it is probable that they are all essentially of the same nature, though the severer the form the less amenable is it to treatment.

The principle of treatment is to supply to the skin that grease in which it is deficient, and this can be done, firstly, by doing everything possible to promote the patient's health and to encourage him to eat those things which tend to fat. Secondly, by a daily bath followed by the inunction of one or other kind of grease; perhaps lanolin is best of all. But in this, as in so many other directions, the skin shows marked idiosyncrasies, and experiments should be made with a number to discover which best suits the individual case. Lard, vaseline, eucerin, sesame, olive, and linseed oils are all worth trying. A young lady patient of mine found after a series of experiments that goose-grease gave her most relief. Unfortunately she had to give it up, as she found herself followed by all the dogs in the neighbourhood. Grease well applied from the outside, by lubricating the skin, diminishes the discomfort associated with its excessive dryness. Thirdly, the internal administration of thyroïdin in carefully regulated doses, or small doses of nitroglycerin, is followed by increased suppleness in the cuticle. Although arsenic is not generally indicated in ichthyosis, there are cases where it seems to be more useful than any other tonic in fattening the patient. It is most important in the management of a case of ichthyosis to make it clear to the patient from the outset that it is only amelioration and comfort, not cure, which one is able to promise him.

Norman Walker.

IDIOCY.—(See MENTAL DEFICIENCY.)

IDIOPATHIC DILATATION OF THE COLON.—(See CONGENITAL DILATATION OF THE COLON.)

IMBECILITY.—(See MENTAL DEFICIENCY.)

IMMUNIZATION.—(See SPECIFIC THERAPY.)

IMPETIGO CONTAGIOSA.—Few diseases are more amenable to suitable, or more rebellious to unsuitable, treatment than this very common disease. If the crusts are removed (either by starch poulticing or by oil soaks) and a weak antiseptic ointment (hydrargyri ammoniati gr. v, vaselini ʒj) constantly applied, even very extensive cases recover within a week or ten days. The secret of success is the thorough removal of the crusts, and the constant application of a *weak* antiseptic. In some cases a paste (hydrargyri ammoniati gr. v, zinci oxidi, vaselini, aa ʒss) is preferable to a simple ointment. It seems unnecessary to resort to vaccines in a disease which is so certainly cured by simple local measures. The frequent association of pediculosis capitis with this disease should be kept in mind.

Norman Walker.

IMPOTENCE.—Impotence, or the inability to perform the normal act of coitus, may be due to various causes, which may thus be tabulated.

1. **Organic Impotence.**—This form may be due to malformation of the genital organs, e.g., the large or rudimentary size of the penis; extreme degrees of hypospadias or epispadias; congenital curvature of the penis and shortness of the frænum; phimosis; gouty or gummatous deposits in the corpora cavernosa, causing curvature of the penis; large scrotal herniæ, vaginal hydrocele, and elephantiasis scroti; cryptorchism, and bilateral atrophy of the testes from syphilis, gonorrhœal epididymitis, or orchitis consecutive to mumps. Some of these conditions admit of relief by the employment of ordinary surgical measures, but when the development of the testes is at fault, or when their functional activity has been abrogated by disease, no treatment is of avail.

2. **Symptomatic Impotence.**—Here the condition may be due to injury, disease, or the habitual use of certain drugs; it may be present in cases of phthisis, Bright's disease, and diabetes, and in such cases the treatment of the cause may be productive of some benefit. Some cranial and spinal injuries, accompanied by cerebral or spinal concussion, give rise to impotence, in some instances temporary, in others of permanent duration. The prolonged administration of depressing drugs such as iodide or bromide of potassium, opium, morphia, or salicylic acid, lead-poisoning, or the abuse of alcohol or tobacco, may be responsible for this variety of impotence, which is usually susceptible of improvement by the removal of the cause and the administration of tonics.

3. **Nervous or Psychological Impotence** may be due to any of the varieties of sexual excess, and consequent exhaustion of the functional activity of the genital centre of the spinal cord; it may be caused by mental overwork and trouble, by a too strenuous business life, or by prolonged abstention from sexual exercise. These cases of nervous impotence are in many instances associated with varicocele, chronic prostatitis, and prostaticorrhœa. Cases of this nature are amongst the most difficult and trying that the practitioner may be called upon to treat, for this form of impotence is attended by an extraordinary degree of hypochondriasis, a condition which has been denominated sexual neurasthenia.

The treatment of this form of impotence will vary according to the cause, but must be primarily based upon the ordinary principles of sexual hygiene; these will include a cold morning bath, with cold douching of the perineum and scrotum; where cold is not productive of a healthy reaction, electric-light baths may be tried; a nourishing but not generous diet; stimulants only in very small quantities; active and well-regulated exercise; a hard bed with not too heavy coverings; careful regulation of the bowels; and galvanism or faradism

of the perineal muscles. If chronic prostatitis or prostaticorrhœa be present, the passage of a large silver sound, and the application of 20 min. of a solution of nitrate of silver, 10 to 20 gr. to the ounce, to the prostatic portion of the urethra by means of a Guyon's syringe, may be carried out twice a week. In cases in which impotence is caused by premature seminal emission, the above measures may be adopted, and at the same time abstinence from any attempt at sexual intercourse should be rigidly enforced. In a large number of cases of this nature the spinal genital centre is in an irritable condition, which may be improved by sedatives such as bromide of potassium, hyoscyamus, conium, camphor, and the fluid extract of *salix nigra*. Where the genital centre is inactive from prolonged disuse or from the excessive use or abuse of the sexual organs, aphrodisiacs may be resorted to. These drugs are mostly of the nature of nerve tonics, and act indirectly upon the sexual organs; amongst them may be mentioned phosphorus, either in pills or in the form of hypophosphites or glycerophosphates; extract of *nux vomica*; extract of *damiana* 2 gr.; hydrochloride of yohimbine $\frac{1}{10}$ gr.; muiracithin pills composed of extract of muira-puama wood and lecithin, four pills to be taken daily; the so-called "pil. potentin co." consisting of muira-puama extract and ovolecithin 1 gr. of each, three to six daily being the dose; a pill composed of:—

R	Extracti Damianæ	gr ij	Extracti Nucis Vomiceæ	gr $\frac{1}{2}$
	Lecithini	gr j	Yohimbinae Hydrochloridi	gr $\frac{1}{10}$
		Ft. pil., t.d.s.		

or testicular extracts, such as orchidin, spermin, or liquor testicularis, administered either by the mouth or subcutaneously. Cantharides was formerly held in some repute as an aphrodisiac, but is now for the most part discredited; it acts locally by irritating the mucous membrane of the genito-urinary tract, causing an influx of blood thereto, and erection of the penis, but if given in any quantity or for any length of time, it will produce strangury, cystitis, and hæmaturia. (See also HYPNOTISM (*Neurasthenia*) and STERILITY.) J. Ernest Lane.

INCONTINENCE OF URINE.—(See ENURESIS.)

INDIGESTION, INTESTINAL.—(See COLIC; DIARRHŒA; FLATULENCE.)

INFANT FEEDING.—In ordinary cases the hand-feeding of infants is a matter of little difficulty if only certain plain rules are attended to. No doubt children are met with from time to time who have a constitutional inability to digest cow's milk; and to rear such children successfully may tax to the utmost the skill and resource of the physician. But except in cases such as these, care and common sense, together with observance of the ordinary principles of infant feeding, will enable us to bring our task to a successful issue.

Our first care must be to keep the digestive organs in a healthy state; for a food, however carefully chosen, and however well adapted it may be to the digestive activities of the child, ceases at once to agree when the stomach becomes upset. Now infants are keenly sensitive to changes of temperature, and if they are bathed at inordinate length, are needlessly exposed after leaving the water, are allowed to lie with cold feet and legs, or are in any way exposed to chills, their digestive organs begin at once to suffer, and gastric or gastro-intestinal catarrh brings the work of the stomach, for the time, to a standstill. The first rule, then—one of paramount importance, and one which cannot be neglected without serious risk of disaster—is:—

1. *See that the infant is bathed as quickly as possible, and that his feet and legs are never allowed to get cold.*

In the next place we must remember that a hand-fed baby has to be reared

upon a food which is not his natural food, but only something like it. His digestive powers, therefore, require all the help we can give them, and experience gained from our own bodies tells us that one of the greatest helps to easy digestion is variety in the diet. The sucking infant will take his mother's breast morning, noon, and night, and want no change. In the hand-fed infant, on the contrary, the stomach is often quick to resent monotony of diet ; and to attempt, therefore, to bring up a child on one food, given continuously day and night, is wilfully to court the risk of failure. The second rule, then, is :—

2. *Take care that there is a sufficient variety of flavour in the various meals.*

In most cases it will be enough to order two differently flavoured meals to be given alternately in the daytime, and a third to be given in the night, but sometimes a still greater variety is required.

The next point regards the sanitary arrangements and cleanliness of the nursery. All feeding-bottles, jugs, spoons, etc., used in the nursery must be kept scrupulously clean ; all foods supplied to the infant must be absolutely fresh and good ; soiled napkins and sheets must be taken away at once, and the living room must be well ventilated, so as to keep the air he breathes as pure as possible. The third rule, then, is :—

3. *See to the cleanliness of the feeding apparatus, the freshness of the food, and the healthiness of the sanitary arrangements generally.*

These three rules govern the whole practice of infant feeding, and a breach of them is almost certain to involve the practitioner in difficulty, if it do not lead to more serious consequences.

In our choice of foods we must be guided by the digestive energy shown by the infant, and by what we notice of his special peculiarities. A food which is well suited to one child does not necessarily agree with another, and therefore we must be prepared to change at once any food which is not found to be completely satisfactory ; for it is useless to force upon a child again and again a food which makes him sick or fills him with wind.

Most infants do well upon a mixture of cow's milk and barley-water. The milk should be sterilized to destroy morbid germs, and should be mixed at first with 2 parts of fresh barley-water. This combination, of which $\frac{1}{3}$ is milk, must be given from a feeding-bottle at a temperature of 95° F. A new-born baby will take about 1 oz. of this mixture at a meal, but this quantity will very soon have to be augmented as his stomach increases in size. It is safe to let the child suck until he is satisfied, for any excess of food is regurgitated without effort soon after the meal. The food can be sweetened with white sugar, and, if the milk is poor, fresh cream may be added in the proportion of 1 teaspoonful to the bottle of milk. The baby may be fed at first every two hours. For the sake of variety, every alternate meal should be flavoured with Mellin's food or a little extract of malt, added in just sufficient quantity to make a change of taste ; and in the night it is well to give one of the desiccated milk foods, such as Allen & Hanburys' No. 1 food. This is to be mixed with the water only when the meal-time comes round ; indeed, no food should ever be kept standing ready mixed, but should be freshly prepared for each meal.

Instead of the above, milk and water may be given alkalized with $\frac{1}{3}$ part of lime-water, and many infants thrive upon this combination ; but in this case, too, some additional flavouring should be included in each alternate meal. If there is a tendency to flatulence or hiccup after the meal, 10, 20, or more drops of some aromatic water—according to the size of the meal—may be added to the feeding-bottle.

Sterilized milk should always be used. Of late an attempt has been made, both in the medical and lay press, to decry the practice of boiling or sterilizing the cow's milk used in the nursery, on the ground that by this means the

nutritive value of the milk as a food is very sensibly impaired. There is no doubt that sterilizing milk reduces its antiscorbutic powers, and that these must be supplied by other means; but the food value of the milk as a general nutritive agent is little if at all reduced. If the cooking process lessens the vitalizing element natural to the milk as it flows from the gland, it also destroys the many noxious organisms which often find their way into the fluid and are carried by its means into the nurseries with very serious consequences. After many years experience, I can say with full conviction that the prejudice attempted to be raised against the use of sterilized milk as a food for children is unreasonable and unsound, and that the omission of this safeguard in all cases where the milk is supplied by cows whose freedom from tuberculosis has not been established by inoculation, or from farms where the sanitary arrangements and precautions are not above suspicion, is a grave error in judgement which cannot be sufficiently deplored.

Infants vary greatly in their power of digesting cow's milk. An average new-born child will take without trouble $\frac{1}{3}$ part of milk as recommended above; but in exceptional cases we must give less, and in some babies the amount of milk allowed in the meal has to be changed frequently, according as the digestive capacity varies from day to day. It is in these cases that the plan of adding 1 gr. of citrate of soda to each ounce of the milk is so useful. As the child grows and gains strength, the quantity of milk in the meal must be increased; but the change should be made cautiously, and we must always be prepared to reduce the quantity should the gastric abilities seem to be overtaxed.

Up to the age of six months farinaceous foods should be avoided or used only with great caution, for the secretions necessary for the digestion of starch are wanting in the new-born infant, and develop only slowly. But by the time the child is six months old the diastasic power of the saliva and pancreatic secretion has advanced sufficiently to allow of a proportion of starch being added to the diet without disadvantage. It is best to begin with one of the many foods containing malt or other form of digestive. This must be prepared with milk and given at first once a day, but afterwards more frequently. Later on, the digestive may be omitted, and starch unguarded, such as Chapman's flour well baked, biscuit powder, rusk, etc., may be used. There is, of course, an infinite variety of infants' foods on the market, and any of these may be tried if a change in the diet seems desirable. At the same time it may be well to remind the reader that tinned foods and preserved or sterilized milks are not antiscorbutic, and in that respect are inferior in value to fresh cow's milk. The deficiency in this vitalizing element can be remedied by giving a teaspoonful of grape or orange juice once or twice in the day; and in any case if the slightest tenderness be noticed in the limbs of a hand-fed baby, or a reddish tinge of blood be observed in the urine, the energetic use of antiscorbutic remedies should be begun without delay. (See SCURVY, INFANTILE.)

At ten months old the child may begin to take broth. This should be made of veal, of the strength of $\frac{1}{2}$ lb. of the meat to the full pint of broth. It should be thickened with barley and strained, and may be flavoured, if desired, with turnip or carrot. At fourteen months old the child may have sole or plaice boiled or pounded. Mutton and chicken had better be withheld until he is eighteen months old. At first they should be pounded and strained through a wire sieve, and served up hot with a little gravy. They may be mixed with well-boiled cauliflower or vegetable marrow, when in season, and bread crumb.

In the matter of puddings, our great care should be not to overload the child's stomach with starch. An infant, during the earlier months of life, as has been said, has not the secretions needed for the digestion of starch. Later, when these have been established, his power of dealing successfully with farinaceous

matters is strictly limited, even when the digestion is in full working order. The slightest catarrh of the gastric mucous membrane materially reduces this faculty; therefore, starchy puddings, such as rice, sago, tapioca, etc., ought never to be allowed if the digestion is upset, and even in the healthiest subjects may usefully be varied with others made of flour, bread, or rusk. These are far more nourishing, as well as less likely to disagree.

Some children, as has been said, have a physical inability to digest cow's milk, but these are few in number. The large majority of infants in whom this disability seems to exist are those who, through prolonged bathing or careless exposure, have contracted a gastric catarrh a few hours or days after birth. These latter are met with only too often. In their case no time should be lost in treating the derangement. There will be vomiting or looseness of the bowels, or other sign indicating the nature of the disturbance, and the measures to be adopted are those described elsewhere. (See VOMITING and DIARRHŒA.)

In cases where the indigestion of cow's milk is a real disability and not merely a temporary incapacity, we can give help to the stomach by partially digesting the curd with Fairchild's zymine powders, and giving the milk largely diluted with barley-water. There is, however, another and better way of rendering the curd digestible to the child. The chief difficulty with which the infant has to contend lies in the composition as regards the protein constituents in the two milks. It has been estimated that in cow's milk there is about five times as much casein as albumin, while in human milk the proportions of the two are about equal. The difference may be corrected by the addition of a soluble form of milk albumin such as that which is sold under the name of "albulactin." When this is added to cow's milk in a quantity sufficient to equalize the proportion of casein and albumin, the chemical composition approaches closely to that of human milk, and the clot formed by the curd when coagulated is lighter and more finely divided. Some white cane-sugar should be added, and thus prepared the milk can usually be digested by the infant without serious difficulty. A grain of Finkler's papain added to the feeding-bottle still further reduces the work of the digestive organs. In cases such as these the practice introduced into this country from the United States of America of feeding the infant with a laboratory-compounded milk of stated strength is adopted by some. The modified milk is prepared from a prescription written by the physician, which sets down the exact amount of fat, sugar, and proteids to be taken in each meal. A serious objection to this practice is its cost, and I cannot say that I have found a proportionate value in the results obtained. One may write the prescription, but it is not so easy to get the milk so compounded to agree with the child. Personally I greatly prefer the old rule-of-thumb practice of adding to the milk barley-water, or other diluent, in such proportion as the effect of the last meal seems to render advisable. Moreover, by the latter method it is easier to give the variety of flavouring which I think so essential to the successful hand-rearing of infants in difficult cases. Not long ago the old plan of using milk soured by a lactic bacillus as a food for infants and others was brought again to the front. The employment of buttermilk as a food for infants had long been a recognized method of treatment, especially on the continent of Europe. It cannot be said ever to have fallen into disuse; but the recent study of bacteriology has thrown a new light upon many old practices, and a fresh impulse was given to the old plan by a claim that by the use of a special bacillus of Bulgarian origin, and by that means alone, the growth and development in the bowels of certain pathogenic organisms, notably the bacillus coli, the typhoid bacillus, and the ordinary putrefactive microbes, could be put a stop to with complete certainty. It was directed that the milk used should be fresh and pure and free from added preservatives. It was first

boiled to destroy germs, and was then cooled down to 105° F. Next, the lactobacilline powder was made into a paste with a few drops of the milk, and was stirred up with the rest of the milk; this was stood in a warm place for twelve hours or so until it set. It was then removed to a cool chamber until required for use.

For the success of this food, it was said, it must contain the true Bulgarian bacillus, for all other forms of the organism had been discredited; and it was to be used only in cases where the indigestion could be referred to the putrefaction of proteid elements, which was shown by the alkalinity of the stools. This is important, for the disturbance excited by the fermentation of starch, which gives rise to acid stools, will be only aggravated by the introduction of more acid bacilli. Now it has been asserted as the result of careful examination by many inquirers that very few of the advertised lactobacilline preparations contain the Bulgarian bacillus at all, and in none of them is this bacillus to be found in a state of purity. Few, if any of them, therefore, can be counted upon to be of real service, and for my own part, as a result of my experience of the method at the Shadwell hospital for children, I gave it up quickly, as productive more often of harm than of good.

If by no artifice of preparation we can succeed in rendering cow's milk digestible to the infant, it is best to lay it aside for a time and fall back upon unsweetened condensed milk or a desiccated milk food, diluting them with fresh barley-water. Sometimes, however, an infant can manage one meal of the prepared cow's milk in the twenty-four hours; sometimes he can digest easily $\frac{1}{8}$ part of milk, when double the quantity gripes him and fills him with wind. It is important to make every effort to enable the child to take the fresh milk, for the tinned substitutes are not a desirable food after the first few months have gone by. Sometimes the Clay Paget milk will suit an infant with whom other forms of milk have disagreed, but "humanized milk" I have rarely found satisfactory.

If, as sometimes happens, the tinned milks do not agree, but fill the child with wind and acid, they too must be dispensed with. Ass's milk is often well borne in these cases; but as its nutritive value is small, it is well to add to each pint of the milk 1 oz. of fresh cream and half a teaspoonful of Brand's chicken jelly. As an alternative meal we may give fresh whey and barley-water in equal proportions, with a teaspoonful of cream in the bottle, and flavour the whole with half a teaspoonful of extract of malt; or instead of the malt we may give the whey and cream fortified by 10 or 15 drops of bovine; or thin veal broth and barley-water with a teaspoonful of Mellin's food. It must be remembered, however, that in this, as in every case where a food disagrees and the infant's digestion is evidently upset, our first care should be to put a stop to the derangement of the stomach. The measures to be taken with this object are described elsewhere. (See VOMITING.) In every case our aim must be to get the child to digest a diet of cow's milk. Therefore, from time to time we should make a trial of a meal of the peptonized milk, freely diluted with absolutely fresh barley-water, or of some other preparation of the milk as already advised.

At first we must not be too exacting; often the amount of milk which can be borne has to be measured in the beginning by teaspoonfuls.

In conclusion, it is well to repeat that careful observance of the three simple rules for the successful rearing of infants by hand given in the earlier part of this sketch will go far to render the process an easy one. A healthy infant whose stomach is in a normal state is not difficult to feed. Any trouble which may arise comes generally from gastric catarrh. The practitioner should, therefore, keep a watchful eye upon the nursery arrangements, and as far as is possible see for himself that the directions which he has laid down are being strictly carried out.

Eustace Smith.

INFANTILE PARALYSIS.—(See POLIOMYELITIS.)

INFLUENZA.—It is most essential that the patient should be confined to his bed, or at least to his room, at the first symptom, however slight. The disease is most treacherous, and to neglect it is often disastrous. There is no specific for influenza; therefore symptoms must be treated as they arise. Much that is stated in the article **FEVERS, ACUTE INFECTIOUS**, will be found to be applicable to this disease. In many instances, the attack begins suddenly, with pyrexia and various aches and pains. The ammoniated tincture of quinine (B.P.) in 1-dr. doses every four to six hours is an excellent remedy for these symptoms; or salicylate of soda or salicin in 10- to 20-gr. doses at the same intervals. When there is headache, antipyrin 10 gr., phenacetin 5 to 10 gr., or acetanilide 2 to 5 gr., may be given. Should these remedies fail to relieve pain, Dover's powder (up to 10 gr.) or some other form of opium should be tried. Heart-failure is common in some forms of influenza; hence it may be inadvisable to employ baths or wet-packs for pyrexia; sponging, however, is seldom unsafe. For acute failure of the heart, strychnine is the best remedy, combined with quinine if the temperature is much raised.

For weakness of the heart, more or less persistent, whether following an attack of syncope or of gradual onset, digitalis and caffeine are invaluable. Rest, and careful observation of the circulatory system, are also imperative, as in the case of diphtheria (see **DIPHThERIA**). Bronchitis, and lobar and lobular pneumonia, are very common. The treatment appropriate to these conditions must be applied (see **BRONCHITIS** and **PNEUMONIA**). In lobular pneumonia, a mixture containing digitalis, chloride of ammonium, and nux vomica has in some cases proved very efficacious, as also has nitrite of sodium in 1- or 2-gr. doses. In the gastro-intestinal form, whey or peptonized milk should be given in small quantities frequently, and opium with some dilute mineral acid, e.g. :—

R Tincturæ Opii	℥iij	Syrupi Tolutani	℥j
Acidi Sulphurici Aromatici	℥vij	Aquæ	q.s. ad ℥j

An attack of influenza is the cause of acute mental disturbance in some patients, who will, therefore, require careful watching during convalescence. Severe neuralgic pain, localized to a definite spot, is not uncommon after this disease. If the usual remedies for neuralgia fail, a blister over the seat of pain should be tried.

The patient may be allowed to go amongst other persons as soon as he is well.
Quarantine period : if enforced, a week. E. W. Goodall.

INSANITY.—(See **MENTAL DISEASES**.)

INSOMNIA.—Cases of insomnia, as met with in practice, divide themselves naturally into two groups, namely, (1) *Symptomatic insomnia*, and (2) *Intrinsic insomnia*.

1. **Symptomatic Insomnia** attends a vast variety of morbid states, and is secondary to them, or is part of them. Pain, pyrexia, frequent coughing, and dyspnœa, are clinical conditions which may prevent or shorten sleep. In such and in similar instances the cause of the sleeplessness is obvious, and the consequential character of the insomnia—that is, its dependence upon a distinct and sufficient cause—is clear. We may control sleeplessness of the kind in question either by the exhibition of remedies which directly cause sleep—hypnotics or soporifics—or by the employment of measures which combat the cause of the insomnia, by removing pain, by reducing pyrexia, quelling cough,

relieving cardiac disturbance and dyspnœa, and so on ; or by using in conjunction hypnotics and remedies for the removal of the causes of the sleeplessness. The treatment of secondary insomnia is part of the treatment of a large number of diseases, and is given in other articles. If a hypnotic drug be needed in such a case, one of those described later may be selected. It must always be remembered that preparations of opium are contra-indicated, as a rule, in renal diseases and in bronchitis.

2. Intrinsic Insomnia.—These cases fall naturally, as to their causes, into three divisions, the *psychic*, the *toxic*, and the *senile*. In psychic insomnia, some severe mental shock or long-continued mental strain (such as financial worry or hard reading for an examination) has excited or kept up such relative cerebral hyperæmia, that insomnia results. In toxic insomnia, some ingested agent, as in alcoholism, or in excessive smoking of tobacco or snuff-taking, or as in the drinking of strong tea or coffee near bedtime, or some autogenetic poisons such as arise in the gouty diathesis, in renal insufficiency, or in habitual constipation, keep up sufficient cerebral hyperæmia for the production of insomnia. In senile insomnia, the broken and short sleep is the result of senile degeneration of the smaller cerebral arteries. In such degeneration, those blood-vessels are less elastic and contractile than in health, and they may become dilated, so that the blood supply to the cerebral cortex is with difficulty reduced enough to permit of sleep.

Patients who are sleepless without physical discomfort, are usually those of nervous temperament, and their impressionability as to insomnia is determined by psychic or toxic causes, or by senile changes in the cerebral blood-supply, or by these conditions in various combinations.

TREATMENT.—As a rule, successful treatment follows the discovery of its cause. A hypnotic should be prescribed only in exceptional cases, and when its exhibition cannot be avoided. A removable cause of insomnia should never be allowed to continue. In the severer forms of psychic insomnia, the prompt use of a hypnotic will soon restore to the brain the power of sleeping, without further aid from drugs.

Potassium bromide is the best hypnotic in well-nourished patients and in the slighter cases generally. It produces nervous calm, is a direct brain sedative, and quite safe. It must be given in a full dose after getting into bed, 30 to 60 gr.* dissolved in half a tumblerful of water.

Bromural and *Adalin* are excellent mild hypnotics which, while considerably more powerful than the bromides, are also relatively non-toxic and non-cumulative. They are very useful in cases of mild insomnia from worry or excitement, and may be given in doses of 10 gr. at bedtime or on waking during the night. Their effect passes off in about four hours.

Opium, or one of its hypnotic derivatives, may be given, especially when pain prevents sleep ; but is contra-indicated in children, in bronchitis, and in renal disease ; it is unsuitable for habitual cases, and its exhibition should not be long continued, or its dosage much increased. In severe psychic cases it may act well, thus prescribed :—

R Pilulæ Saponis Compositæ (B.P.) gr iiss
Ft. pil. One or two to be taken at bedtime.

Chloral is the hypnotic most used, and it is certain in its action. Its disadvantages are that sometimes it is a gastric irritant, it is a cardiac depressant, undesirable in heart disease or with a low blood-pressure, and the habit of taking chloral, which is a prevalent vice, may be induced. The syrup of chloral hydrate is a good preparation. Each fluid drachm of the syrup contains 10·9 gr. of chloral hydrate. From $\frac{1}{2}$ to 2 dr. of this syrup may be given at bed-

* The doses recommended are not devoid of danger.—AMERICAN EDITOR.

time in a wineglassful of dill, peppermint, or other aromatic water, and repeated in a half dose in two or three hours, if necessary.

A combination of hypnotics is sometimes more successful than any of them singly ; in such combination each acts better in a smaller dose than otherwise. Chloral and bromide of sodium or of potassium may be given together ; or both may be combined with opium, thus :—

R. Tincturæ Opii	℥iij-vj	Chloralis	gr. v
Potassii Bromidi	gr. x-xx	Aquæ Menthæ Piperitæ	q.s. ad ʒ iss
M. Ft. haust. To be taken at bedtime.			

Chloral formamide is especially recommended in insomnia complicating disease of the heart. In such cases Dr. Hale White advises 25 gr. dissolved by stirring in 1 oz. of brandy, adding water to taste, taken about one hour before bedtime. On account of its disagreeable taste it is sometimes proposed to administer chloral formamide in capsules ; but if the drug be given as a powder, it may be very slow in its action, and cause a drowsy day after a sleepless night.

Sulphonal, and its chemical allies, *tetronal* and *trional*, are powerful hypnotics, which do not depress the heart or irritate the stomach. None of them is safe if the kidneys be diseased, as each may cause hæmatoporphyria. Each has the disadvantage of being comparatively insoluble in water, and their insolubility may retard their effect for some hours after they have been taken by the mouth. None of them should be administered for more than a few nights consecutively. While one of them is being taken, 20 to 30 gr. sodium bicarbonate should be given during the day, to prevent the urinary hyperacidity which these hypnotics cause by their action upon the blood. Each of these drugs is best given in a cachet, washed down with a little hot water, one hour before bedtime. The dose of sulphonal is 10 to 30 gr. ; tetronal, 10 to 20 gr. ; trional 15 to 30 gr.*

Paraldehyde is a good hypnotic. It is a colourless liquid with ethereal odour and pungent taste, soluble 1-8½ of water. It is best given emulsified with yolk of egg. It acts quickly, and does not depress the heart. The dose is from ½ to 2 fl. dr. It has an unpleasant after-effect. For days after a single dose, a disagreeable smell is given to the patient's breath.

Veronal is a good hypnotic. It is a white crystalline powder, comparatively insoluble in water (1-160). It is cautiously given in cachets and in pills, for which latter, syrup of glucose is a good excipient. The dose is 3 to 15 gr.*

Medinal is sodium-barbitone. Its action and dosage are the same as that of barbitone, but it is much more soluble, and can be administered if necessary by the rectum.

In many cases of chronic wakefulness from prolonged mental strain, the patient is anæmic. The insomnia cannot be cured unless the anæmia be cured. Hæmatinics are indicated, of which the best are iron and arsenic, singly or combined. The diet must be generous, containing plenty of fish, meat, and eggs.

The prescription of alcohol as a remedy in disease is often difficult and sometimes dangerous. To many people a "nightcap" of toddy is a superfluous, perhaps hurtful, luxury. It gives, however, perhaps better than anything else, rest and sleep to the worried brain of feeble persons whose blood is poor. Alcohol is the best hypnotic in many cases of chronic psychic insomnia, when the patient is worried and weakly, sorrowful and anæmic. When alcohol is prescribed in the form of any of the fluids which contain it, in the treatment of insomnia, the reasons for the employment of the remedy should be explained, and it should be discontinued when the conditions which called for its exhibition have disappeared.

In the toxic kinds of insomnia, if the cause be the consumption of tobacco, alcohol, tea, or coffee, such consumption must be stopped or lessened, as the

* The doses recommended are not devoid of danger.—AMERICAN EDITOR.

case may be. In the toxic insomnia of gout, or of chronic kidney disease, with a pulse of high tension, the following combination is useful :—

R. Magnesii Sulphatis	℥ss	Sodii Citro-Tartratis Effervesc.	
Sodii Potassii Tartratis	℥j	(B.P.)	℥ss

M. Ft. pulv. One or two teaspoonfuls to be taken in half a tumblerful of water every morning, before breakfast.

In the toxic insomnia which sometimes accompanies habitual constipation and undue fæcal retention, and of which such fæcal retention may be the whole cause, the cure of the habitual constipation must be aimed at. If laxative drugs be necessary, the following modification of Marshall Hall's pill is useful :—

R. Aloes Barb.	Extracti Taraxaci	
Theriaceæ	Saponis Mollis, singulorum	
Extracti Glycyrrhizæ		partes æquales

Solve in aqua, et calore lente inspisse; deinde divide in pilulas, pondere 2½ gr. One or two pills to be taken at bedtime.

As a mild laxative, the following combination of remedies has proved excellent :

R. Magnesii Ponderosi		Mellis Depurati	℥j
Olei Ricini	āā ℥ss		

M. Ft. conf. One teaspoonful to be taken at bedtime.

Senile insomnia is very obstinate. One of the hypnotics before mentioned may be given, with exceptional caution as to dosage. In many cases the bromides, with full doses of hop or of henbane, afford the most efficient and least harmful medicinal means of relief. (See also BRONCHITIS, ELECTROTHERAPEUTICS, GOUT, HEART, ETC.)

James Sawyer.

INTERMITTENT CLAUDICATION.—(See CRAMP.)

INTESTINAL OBSTRUCTION.—(See also INTUSSUSCEPTION.) The general heading 'intestinal obstruction' includes such different conditions as strangulation of a loop of intestine in an intraperitoneal fossa, obstruction by a foreign body, and stricture the result of carcinoma. The one feature in common is the necessity for early recognition, followed by immediate surgical treatment—there is no medical treatment of intestinal obstruction. Long-standing constipation alone will not produce symptoms which will mimic an obstruction calling for surgical interference.

In primary acute intestinal obstruction, the patient is suddenly seized by violent colicky abdominal pain; this comes on in paroxysms and is accompanied by vomiting. In the early stages, between the attacks of pain, the abdomen appears normal, but during the attack a writhing coil of gut may sometimes be made out. Distention, fæcal vomiting, severe shock, are all late symptoms. Among the acute obstructions are strangulation by bands (including Meckel's diverticulum, and the appendix), intussusception, volvulus, obstruction the result of gall-stone impaction, internal hernia.

Chronic intestinal obstruction may reveal itself by increasing difficulty in getting the bowels to act, with attacks of colicky pain particularly in the right iliac fossa, with continuous diarrhœa, or alternating diarrhœa and constipation, all of which may be due to malignant disease of the large intestine. In others, repeated attacks of abdominal pain, with distention and visible peristalsis, may point to obstruction in the small intestine, the result of kinking by adhesions, or of tuberculous or other stricture. If not operated upon, all these cases tend to terminate acutely. In rare instances of carcinoma of the colon, the first symptoms noticed by the patient are those of acute obstruction.

In every case it is important to diagnose the cause of the condition, if possible. Infinitely less harm will be done by delaying operation ten minutes than by spending an extra ten inside the abdomen because the diagnosis was not made before operation. A careful history may enable this to be done, eliciting previous abdominal illnesses, pointing to the possibilities of strangulation by band or obstruction by gall-stone. In examining, the whole abdomen must be uncovered and the hernial orifices seen. Careful abdominal and rectal examination may reveal a gall-stone in the ileum, or a malignant growth may be felt.

Acute intestinal obstruction usually affects the small intestine, and apart from the common form in children—intussusception—it is generally due to adhesions from pre-existing disease or operation. These adhesions are usually the result of the neglect of surgical treatment at the most favourable time. Appendicitis is a fertile cause. If this disease were treated on modern lines—operation within the early hours of an acute attack, or even by forestalling its onset—many cases would be prevented. The acute obstruction due to volvulus of the sigmoid could be prevented if the preceding constipation had been effectually treated.

The sudden onset of severe abdominal pain, accompanied in many cases by vomiting and by rigidity, is most often due to a cause only relievably by surgical means. To consider an attack of this sort as due to biliousness, indigestible food, or faecal accumulation, is one of the gravest of mistakes. Every surgeon could tell of dozens of useful lives lost through this practice. In many instances the patient is given an aperient or, if vomiting is a prominent feature, sedatives such as bismuth and opium, and a surgeon is not sent for until time has rendered the surgical nature of the case so evident that the most favourable period for operation has passed. In every case of severe abdominal pain, associated with abdominal rigidity, vomiting, or both, or in any abdominal case about which the slightest doubt exists, *no drugs or food* of any kind should be given. If the patient is very thirsty, water may be taken, but every effort should be made to keep the intestine at rest. If any doubt at first exists, a few hours' watching will reveal the nature of the case and enable prompt surgical intervention to be carried out. No harm will result from the delay of a few hours if neither drugs nor food are given. In acute intestinal obstruction, diagnosis rests on the history—the sudden onset of colicky pain and vomiting. In cases of abdominal emergency an enema should never be given before operation; when faecal accumulation causes chronic intestinal obstruction, we use it as *treatment*.

When the diagnosis has been made, operation should be carried out without loss of time. Few preparations are necessary. In late cases of intestinal obstruction, in which faecal vomiting has supervened, the stomach should be washed out before operation; lives are lost through neglect of this precaution. With regard to the anæsthetic, ether on an open mask, preceded by an injection of morphia and atropine, is ideal in the early cases. In the late ones, a combination of local and general anæsthesia, gas and oxygen with 1 in 400 novocain, is preferable; or if this unobtainable, intraspinal analgesia.

Except when the disease has been located to the left side of the abdomen, or in the case of malignant disease of the descending colon or sigmoid, or of duodenal hernia, the incision should be made just to the right of the mid-line, below the umbilicus; the inner edge of the rectus should then be defined and pulled outwards. The strangulating agent—band, Meckel's diverticulum, appendix—should be dealt with, and the condition of the gut investigated. If distention is great, it will be wise to open the gut, after protecting the abdominal cavity, and allow the stagnating contents to escape. If the bowel recovers its tone after this has been done, the opening may be closed in the usual way. If in doubt, a glass tube should be inserted for drainage.

If a coil of gut has become snared, its condition must be carefully investigated after removal of the obstructing agent. If it is unlikely to recover, resection should be carried out, remembering to do this through healthy gut. In most cases immediate anastomosis, end-to-end or lateral, may be carried out, but occasionally the condition of the patient will not admit of this, and a tube should be tied in with catgut.

When the obstruction is due to the impaction of a *gall-stone* in the lower ileum, it should be gently brought back to a healthy portion of gut and removed through a longitudinal incision. The same rule with regard to drainage applies here. If the condition of the patient is so bad that no search can be made, the most distended coil should be opened and drained by a small Paul's tube.

Tuberculosis is most commonly met with in the sigmoid, but may occur rarely in the ileocaecal region. In the sigmoid, after the obstruction has been reduced, colostomy should be performed. No attempt should be made to resect the affected coil. Reduction alone usually fails.

In acute obstruction due to *malignant growth*, resection is unjustifiable. The intestine should be drained central to the obstruction. When this is in the most common position—the sigmoid—if the growth is removable, it should be so placed that at the following operation it can be included in the abdominal incision. Caecostomy should only be performed in the late cases in which patches of gangrene are seen, or when it is on the point of giving way. When the malignant disease is at the splenic flexure, it is often safe to do a lateral anastomosis between transverse and descending colon such as can be used after later resection of the growth. When at the caecum, it may be possible to do an ileocolostomy to the transverse colon.

After operation for acute intestinal obstruction the patient should be nursed sitting up in bed. Nothing should be given by the mouth, and if vomiting continues the stomach should be washed out and kept empty. Salines should be administered per rectum.

With regard to *aperients*. No attempt should be made in the early hours to obtain an action by the use of irritating drugs. After the intestine has had time to recover by rest, turpentine enemata, with or without a preceding injection of pituitary extract if distention is great, should be given. The return to food must be gradual. Secondary operation, when necessary, can usually be undertaken in from ten to fourteen days.

James Sherren.

INTESTINAL WOUNDS.—(See ABDOMINAL INJURIES.)

INTRACRANIAL HÆMORRHAGE.—(See HÆMORRHAGE, INTRACRANIAL.)

INTRACRANIAL TUMOURS.—Earlier diagnosis, and more accurate topographical localization, are gradually making the treatment of intracranial tumours more and more promising—in that they afford the patient, at a more favourable moment, the opportunity of relief, and in some instances of cure, which surgery has to offer.

Unfortunately, the majority of cerebral tumours are of a malignant character; so that cure is rarely to be expected. On the other hand, the relief that can be afforded is in the majority of cases as great, or greater, than that offered by merely palliative operations in almost any other part of the body. Blindness can be averted; the agonizing headache, for which drugs are useless, can be entirely removed; the distressing vomiting can be abolished; life can be prolonged for many months, and in some instances for many years. Non-operative treatment avails nothing, and when once the diagnosis of an intracranial tumour has been made, the treatment belongs to surgery just as certainly

as that of cancer of the bowel. Unfortunately, the nature and extent of a cerebral tumour cannot be foretold, and in many instances its exact position cannot be diagnosed with certainty. Operations, therefore, must necessarily often be of an exploratory character.

The operative treatment is either radical or palliative. Non-malignant tumours, such as meningeal endotheliomata, which do not infiltrate the brain, may be removed; so also may certain syphilomata and tuberculous masses. Some of the firmer gliomata may occasionally be removed successfully; and cysts may be evacuated or enucleated.

Removable tumours, however, are comparatively uncommon; the majority are, either from their nature or situation, not capable of removal, and it is for these cases that palliative measures alone can be employed.

The methods of approach to an intracranial tumour are: (1) The osteoplastic flap; (2) Removal of bone; (3) A combination of the two. The osteoplastic flap is suitable for those cases in which removal of the tumour is contemplated. If, on exposure, the tumour proves to be irremovable, the operation can be converted into a simple decompression, by taking the piece of bone from the flap, or cutting away more bone elsewhere at some more convenient site.

The essential aim of a simple decompressive operation is to afford complete relief to the increased intracranial tension without causing loss of function in any part of the brain. Herniated brain does not lose its function if the opening is large enough to allow it to protrude without any interference whatever with its circulation. Moreover, when an opening inadequate for the complete relief of tension has been made, the herniated and consequently partly-strangled cerebral tissue is not the only part of the brain to lose its function. The selection, therefore, of a so-called "silent area" of the brain, without regard to the position of the tumour, is a mistake; and it is better not to operate at all than to make too small an opening. The opening should be made as close to the tumour as possible, or at least over that intracranial compartment which contains the tumour. When even that elementary degree of localization is impossible, the bilateral subtemporal opening of Cushing affords a useful way out of the difficulty. This, in brief, consists in removal of the bone beneath the temporal muscle without disturbing its peripheral attachments; the muscle being split in the direction of its fibres, and retracted during the craniectomy. For tumours situated below the tentorium, a similar submuscular operation is available, the floor of the occipital fossa being removed so that the thick mass of the suboccipital muscles afterwards forms a protective covering to the cerebellar hernia. The free opening of the dura mater forms an essential part of any decompressive operation. Without this step, the craniectomy, save in a few rare instances, affords no relief of pressure and is quite useless. In every decompressive operation the scalp flap should be much larger than the bony opening, so that the suture line is placed at a safe distance from the herniated brain. If this is not done, fungus cerebri is apt to result, and to be followed by the almost inevitable consequence of meningitis. The flap should be most carefully and accurately sutured, so as to avoid any chance of leakage of cerebrospinal fluid, an accident which is apt to be followed by disastrous results.

Another palliative operation, applicable to certain cases in which a tumour is so situated as to produce its pressure effects chiefly by causing ventricular distention, consists in establishing a drainage track between the lateral ventricle and the subarachnoid space (see *HYDROCEPHALUS*).

Lumbar puncture, as a means of relief of intracranial pressure in tumour cases, has only to be mentioned to be condemned. It is liable to cause sudden death from herniation of the medulla and cerebellum into the foramen magnum. When, in a suspected tumour case, an examination of the cerebrospinal fluid

for diagnostic purposes is required, only a very small quantity should be withdrawn by lumbar puncture.

Treatment by x rays and radium has been tried in some instances, the bony opening allowing of comparatively easy penetration of rays. Hitherto no marked improvement has been reported as having followed this line of treatment.

INTUBATION.—(See DIPHTHERIA.)

Percy Sargent.

INTUSSUSCEPTION.—Operation should be carried out directly the diagnosis is made or reasonably suspected. It is unjustifiable to waste time in attempts at reduction by rectal injections. In the majority of cases a sausage-shaped tumour can be felt, but its absence does not contra-indicate operation.

The incision should be made just to the right of the middle line, and the lower part of the rectus muscle pulled outwards. The intussusception should be sought and as much reduced by manipulation inside the abdomen as possible. The last portion should be reduced outside the abdomen; it should be done by squeezing and not by traction; if, however, it is difficult, it is justifiable to try gentle traction.

If it is irreducible, much will depend on the condition of the child. If the small intestine above is very distended, temporary drainage should be used. If the condition of the patient admit, the mass should be rapidly resected, and the end of the ileum united to the ascending colon end to side.

Feeding should be begun as soon as possible after the operation; if the child is breast-fed, the mother should continue to feed it.

James Sherren.

IRITIS.—The iris and ciliary body together form the anterior part of the uveal tract. Anatomically they are continuous structures, and have a common blood-supply; it is therefore not surprising that they are frequently involved in the same inflammatory processes, though not necessarily to an equal degree.

The chief dangers which may arise in iritis are twofold:—

1. *Posterior Synechia* (adhesion of the posterior surface of the iris to the anterior lens capsule). When these adhesions involve the whole circumference of the pupil (*total annular synechia*), the normal circulation of the ocular fluids is interfered with and glaucoma results.

2. *Lymph in the Pupillary Area* obscuring vision (occlusion of pupil).

The ciliary body, on the other hand, is the main nutritive organ of the eye, and supplies the aqueous and nourishes the lens and vitreous body. In cyclitis, therefore, the chief dangers with which we have to contend are:—(1) Opacities in the vitreous; (2) Opacities in the lens (cataract); (3) Organization of the inflammatory products thrown out into the vitreous, which may lead to: (4) Detachment of the retina; and later, (5) Disorganization and shrinking of the globe (phthisis bulbi).

The treatment of iritis and cyclitis have so much in common that they will be discussed together, and considered under the headings: (1) General, (2) Local.

General Treatment.—This consists in rest, dieting, purgation, and diaphoresis. In every case of acute iridocyclitis the patient must be confined to the house or bed. The diet during the height of the attack should be restricted to milk and easily-digested foods, but as soon as the severity of the symptoms have passed off the patient may be allowed to resume his ordinary diet; stimulants are, as a rule, best avoided. In every case the treatment should be commenced by free purgation, and care taken to procure a daily action of the bowels.

There can be little doubt that profuse diaphoresis is of great importance in the treatment of acute iridocyclitis, relieving pain, enhancing the action of

mydriatics, and tending to cut short the attack. The best means of securing a free action of the skin is the hot-air bath or the hot pack, combined, if necessary, with the subcutaneous injection of pilocarpine nitrate, $\frac{1}{12}$ to $\frac{1}{3}$ gr. If there is much pain and sleeplessness, five grains of Dover's powder, repeated if necessary, will often give great relief, and at the same time encourage the skin action.

Many ophthalmic surgeons recommend mercurial inunction in every case of iridocyclitis, irrespective of causation; but the administration of the drug should be chiefly limited to cases intimately associated with syphilis, and to cases of sympathetic ophthalmitis.

Various diatheses play so important a rôle in the etiology of iridocyclitis that it is necessary, in discussing the general treatment, to refer to them somewhat fully. No attempt, however, will be made to deal with the detailed treatment of these constitutional disorders; but, in passing, brief mention will be made of the drugs which we have found most generally useful.

Syphilis is the causal factor in more than one half of all cases of iridocyclitis, either in the hereditary or the acquired forms of the disease.

Salvarsan or neo-salvarsan should be given as soon as possible, and the dose repeated in the course of a fortnight. When this cannot be obtained, mercury is the best remedy, and its physiological effect must be obtained as quickly as possible, inunction being a convenient form of administering the drug. In the later stages, and in the more chronic forms, potassium iodide is of the greatest value, and must be pushed to large doses (if necessary to 90 gr. per diem).

Gonorrhœa.—In this disease the eye affection generally shows itself in the gleet stage, and is often associated with joint affections. It is hardly necessary to point out that the urethra must receive careful attention; this, together with the administration of potassium iodide and quinine, combined with local treatment, will, as a rule, rapidly alleviate the symptoms. In the severer and more intractable forms of gonorrhœa, with marked constitutional symptoms, the injection of the gonococcal vaccine, controlled by the estimation of the opsonic index, may be found of great value.

Rheumatism, especially in the chronic articular, rarely the acute, form, is undoubtedly a frequent predisposing factor in inflammation of the iris and ciliary body. Without attempting to discuss the general management of rheumatic affections, we may mention that acetyl-salicylic acid is frequently of very great value in the more acute eye affections. In the more chronic forms potassium iodide is especially valuable.

Gout.—In rare instances the gouty diathesis is the exciting cause of the eye disease. In addition to local treatment, the diet must be regulated, stimulants given with caution, and a visit to a suitable spa is to be recommended.

Tubercle.—This form of iridocyclitis is most usually of the chronic type, and frequently, but by no means always, associated with nodules in the iris. The treatment must be directed to the improvement of the general health, and cod-liver oil should be given. In addition, carefully regulated injections of tuberculin should be tried. In some cases these are very useful, but unfortunately in the more severe cases a large proportion fail to respond to this or any other form of treatment; the sight is lost and the eye has to be removed.

Diabetes Mellitus may be the direct cause of a chronic form of iridocyclitis; and it is important to test the urine in every case where there is any doubt as to the causation. With local and general treatment these cases do well.

Metastatic.—A purulent form of iridocyclitis is not infrequently met with associated with some specific disease, e.g., cerebrospinal meningitis; or with some septic focus in other parts of the body, e.g., discharge from the ear. As a rule, the case develops into a panophthalmitis, with loss of sight and shrinking

of the globe. In addition to local treatment, the primary source of infection must be eradicated as far as possible. If the panophthalmitis is acute, and pain a marked feature, and if the patient's general condition is otherwise satisfactory, the eye should be removed. Usually, however, the disease runs a more chronic course, free from pain, in which case the eye should not be excised.

Chronic Iridocyclitis.—For the most part the cases which fall under this heading have few symptoms beyond gradually failing sight; there is little or no pain, circumcorneal injection is never marked and often absent, while posterior synechiæ are frequently not found. The main signs are punctate deposits on the back of the cornea (keratitis punctata) and opacities in the vitreous. The keratitis punctata is often so fine that it will not be recognized without a magnifying glass and the use of a brightly focussed light. A great deal of work has been done of late to try and elucidate the etiology of these cases. They run a course strongly suggestive of infection, but when tubercle, syphilis, gonorrhœa, and chronic rheumatism have been excluded, a large number still remain unaccounted for.

Pyorrhœa alveolaris is found in a high percentage, as would be expected from such a prevalent disease, and with the cure of the oral sepsis a certain proportion of the cases, differing considerably with various observers, get rid of the iridocyclitis; which shows that the pyorrhœa is either the direct cause, or at any rate an important factor, in interfering with the general nutrition. The pyorrhœa should therefore undoubtedly be treated thoroughly, by scaling and regular brushing of the teeth, cleansing the sockets, or, if necessary extraction.

Chronic constipation, or some form of colitis, is also a common associate of iridocyclitis, and may be a cause of toxæmia or direct infection. It should be treated energetically.

A bacteriological examination of the urine for tubercle or bacillus coli should be made, and a careful search for some infective focus in any other part of the body, such as suppuration in the air sinuses communicating with the nose, in the middle ear or mastoid, or an inflamed pile or fistula, etc., and if such a focus be found it should as far as possible be removed.

But often even after a careful search for local or general infection no cause for the iridocyclitis can be assigned, and therefore no specific treatment is practicable. In this case the cyclitis must be treated on general lines. Protection must be given from cold winds and glare by wearing protecting tinted goggles, and a warning must be given not to ride in open carriages or motors, or on the tops of omnibuses, etc. A very limited use of the eyes for close work should be allowed, weak atropine drops given to keep the pupil semi-dilated and the ciliary muscle at rest, counter-irritation to the temple, and hot bathing of the eye at bedtime.

A general tonic is advisable, such as malt, strychnine, phosphate of iron, or Tweedy's pill (quinine sulphate gr. i, calomel gr. $\frac{1}{8}$ to $\frac{1}{4}$, extract of belladonna gr. $\frac{1}{8}$, confection of roses q.s.; t.d.s., p.c.). In some cases injection of neo-salvarsan, even when syphilis can be excluded, has proved of great use.

Malaria and Relapsing Fever.—Quinine and arsenic are especially useful.

Traumatic.—(See EYE, INJURIES OF.)

Sympathetic Ophthalmia.—(See OPHTHALMIA, SYMPATHETIC.)

Local Treatment.—This consists in protecting the eye from light, by means of a pad and bandage or dark glasses; the use of atropine, hot applications, leeching, and blistering. Atropine is our sheet anchor in the local treatment of acute iridocyclitis, its action being threefold: (1) It dilates the pupil, thus preventing or breaking down posterior synechiæ; (2) It paralyzes the ciliary muscle, and places the eye at rest; (3) By contracting the vessels of the

inflamed iris and ciliary body, it tends to relieve pain and reduce the inflammatory process. In a recent case of acute iritis it should be used in the form of ointment,* 4 gr. to the ounce, every two hours until the pupil is fully dilated; but once that object is attained, every four hours is quite sufficient.

It is always well to combine hydrochlorate of cocaine with the atropine in the proportion of 3 to 1, as by so doing we induce a maximum dilatation of the pupil, and at the same time increase the analgesic effect. Should, however, the pupillary margin become firmly adherent to the lens capsule, and refuse to yield to the weaker applications, the strength of the atropine must be increased to 8 gr. to the ounce to endeavour to break down the adhesions; it is seldom wise to use a stronger ointment than this, or alarming symptoms of atropine poisoning may arise, e.g., dryness of mouth and fauces, fever, rash, hallucinations, and delirium. Should these symptoms unhappily occur, they must be met at once by stopping the atropine, by the injection of morphia, and the administration of strong coffee.

The use of the strong (8-gr. ointment) atropine should not be continued for more than two or three days, and at the end of that time we must return to the weaker (4-gr.). If adhesions have not yielded to this energetic treatment, they must be left; but it should be remembered that many pupils, which have apparently resisted all treatment, may dilate in a week or longer under the influence of the fourfold battery of atropine, hot bathing, leeching, and purging.

Substitutes for Atropine.—The use of atropine may lead to a marked local irritation, such as eczema or erythematous swelling of the lids and even the whole side of the face, with chemosis of the conjunctiva. In such cases a substitute for the atropine must be used; hyoscine hydrobromide, 1 to 2 gr. to the ounce, is the best; but if this also gives rise to irritation, duboisine sulphate, 2 gr. to the ounce, may be tried. The application of ung. zinci oxidi or ung. calaminæ to the inflamed skin may be found especially valuable.

Hot applications, either in the *moist* or *dry* form, are of the first importance. If the former be preferred, frequent hot boracic bathings answer admirably.† If the latter, covering the eye with a pad of absorbent wool, previously heated by contact with a can containing boiling water, or the use of the Japanese muff-warmer, with a pad of gauze between it and the eye, are both convenient and efficient forms for its application. Maddox's electric pad is a light and extremely ingenious invention which also works well when obtainable.

If the pain is acute, two leeches applied to the temple, not nearer the eye than the margin of the orbit, will give the greatest relief, and, moreover, assist the atropine in dilating the pupil. The leeching may be repeated at intervals if the pain is a marked feature and the general condition of the patient one in which local depletion is not contra-indicated. Should the natural leech be objected to, or unobtainable, a satisfactory depletion may be brought about by artificial means, e.g., Heurteloupe's leech.

In the more chronic cases, counter-irritation by blistering the temple is often extremely beneficial. Treatment must be continued until all signs of inflammation of the eye have ceased; and even after the eye is white the use of

* Ointment is preferable to drops, being more powerful locally, and less toxic generally.

† *Hot bathing*, to be effective, must be carried out thoroughly. A small bowl with some boracic lotion, a good-sized pad of cotton-wool, and a kettle of boiling water are required. The boiling water is added to the lotion, and the wool wrung out in this and applied over the closed eyelid. As soon as the pad becomes cool it is wrung out and heated again. As the lotion becomes cool, half is thrown away and more boiling water is added, and so on, keeping the pad as hot as can be borne, the strength of the boric acid being unimportant. Often the eye will stand greater heat than the fingers, and the pad can then be applied by means of a wooden spoon. Hot bathing should be carried out for at least twenty minutes "by the clock," and between the bathings the eye must be kept hot by means of a dry pad of wool, with or without the muff-warmer.

atropine must be kept up for at least a fortnight; otherwise recurrence is extremely probable.

Operative Treatment.—The most serious complication in iritis is the occurrence of glaucoma. If glaucoma supervenes with a deep anterior chamber, and without complete binding down of the pupil to the lens capsule, a paracentesis must be performed to relieve the increased tension; and this can be repeated every second or third day if necessary.

If glaucoma with *total annular synechia* occurs in the acute stage, atropine must still be pressed in order to break down the adhesions; but if this fails, we must make some opening in the iris to restore the intra-ocular circulation. An iridectomy in the acute stage will probably become closed by lymph, and a less severe procedure is advisable, viz., Fuchs' quadruple puncture, which should be followed by iridectomy when the eye is quiet. After several attacks, when the pupil is nearly blocked, an iridectomy is indicated in the interval between the attacks, to prevent the occurrence of a complete posterior synechia and secondary glaucoma.

Again, when the pupil has been occluded by lymph, an optical iridectomy may be indicated to improve vision.

Ilbert Hancock.

ISCHIORECTAL ABSCESS.—(See ABSCESS.)

ITCH.—(See SCABIES.)

JAUNDICE, CATARRHAL.—(See BILE-DUCTS, CATARRH OF.)

JAW, DEFORMITIES OF.

Deformities of the jaws and dental arches are frequent accompaniments of adenoids. The deformed jaw or arch is practically always subnormal in size, especially the maxilla, where the want of growth accompanying adenoids is more obviously felt. Treatment should begin early. The time for growth once past, increase in that part practically ceases. Except for the fullness added by the erupting canines, the anterior part of the maxilla is hardly increased after ten, and is certainly finished by fourteen years. This means that the earlier adenoids or nasal obstructions are removed, the better for the patient's jaws and beauty; and that where possible, "regulation" should be undertaken early. (See ADENOIDS).

Joseph Geo. Turner.

JAW, FRACTURES OF.

1. The Inferior Maxilla.—Fractures of the inferior maxilla are generally the result of direct violence; but occasionally, in cases of sepsis or tumour, a spontaneous, or nearly spontaneous, fracture may occur.

(a). *The Canine Fossa.*—The fracture is more or less vertical, and runs either directly through the canine fossa or through the mental foramen. The deformity will be most marked when the condition is bilateral. In such cases the posterior fragment is pulled upwards and forwards, but soon coming into contact with the teeth of the upper jaw, it is not markedly displaced; the anterior fragment is, however, drawn downwards and backwards to a considerable degree. In the unilateral cases the larger fragment will be drawn downwards and backwards in its anterior part. In all cases the muco-periosteum, which alone covers the inside of the bone, is torn, and hence the fracture becomes compound. There will be bruising and laceration of the soft tissues, with abnormal mobility, crepitus, and alteration in the line of the teeth, while a certain amount of bleeding will occur into the mouth cavity. There is very grave danger of sepsis spreading from the mouth.

TREATMENT.—These cases should, wherever possible, be treated with the aid of a dentist. The oral cavity must be made as aseptic as possible, any carious stumps being removed and the rest of the teeth attended to. A model of the lower teeth is then taken, either in two portions corresponding to the two fragments or, if the deformity be first overcome, in one portion. From the model a cap is made to fit accurately over the whole of the lower teeth. When this cap has been made, a certain amount of specially prepared cement is poured into it and the cap is fitted over the teeth whilst the cement is yet soft. These manipulations require an anæsthetic. By this means the two fragments are firmly fixed together. The jaw can be freely opened so that the mouth can be kept thoroughly cleansed, and the patient is enabled to bite soft foods on the surface of the cap. This is kept in position for three weeks, after which the cement will be sufficiently loosened for it to be removed without difficulty. If there be no teeth, a cap is made to fit over the alveolus, and is fixed by means of wires which, leaving the angles of the mouth, pass round the outer sides of the cheek and are fixed by a bandage running round the head. As a temporary means of treatment, the two fragments may be brought into apposition with the

Fig. 45. — Four-tailed Bandage applied to a Fractured Mandible.

teeth of the upper jaw, and fixed in this position by means of a four-tailed bandage applied in the manner shown in the figure (*Fig. 45*). If the services of a dentist cannot be obtained, this four-tailed bandage may be replaced by one of a similar shape cut out of poroplastic splinting, which is then moulded to the jaw. Such an apparatus, however, suffers from the serious drawback that it does not permit of thorough cleansing of the mouth; and thus sepsis at the site of the fracture is very prone to take place, and be followed by localized necrosis of the bone, while at the same time the diet will have to be limited to fluids. Under no circumstances is it advisable to unite the fragments by means of wires passing round a few or all of the teeth in the lower jaw, for by this means sepsis is increased and there is a tendency for the teeth to be loosened.

(b). *The Alveolus.*—Portions of the alveolus may be broken off, either by the careless extraction of a tooth or by a blow which knocks out or loosens a tooth. As a general rule the separated portion is small and but little trouble ensues. If larger, it can usually be replaced in position, and is maintained there by the surrounding soft tissues. If the mouth be kept clean and the diet limited to soft food the fragments will usually unite; but if sepsis ensues, they will be loosened and come away.

(c). *The Angle.*—This is a much less common variety of fracture than the preceding one. It is always caused by a direct blow over this portion of the jaw. Owing to the wide attachments of the internal pterygoid and masseter muscles there is little or no displacement. There will be pain, swelling, and bruising, the pain being increased on biting. As a general rule the fracture is simple; but occasionally it may reach sufficiently far forwards to tear through the mucous membrane behind the last molar tooth, the fracture in this case being compound. Owing to the lack of displacement, this variety is more likely to be overlooked than the others. If, however, the anterior fragment be grasped firmly, movements will be associated with pain referred to the angle.

TREATMENT.—When the fracture is simple, a four-tailed bandage should be applied for a week, so as to prevent undue mobility of the fragments. At the end of this time any support may be dispensed with, but the patient must only be allowed soft food for another two weeks, so that contraction of the masseter and pterygoid muscles is prevented. If the fracture be compound, careful oral antisepsis must be added.

(d.) *The Coronoid Process.*—Fractures of this portion of the bone are very uncommon.

TREATMENT.—If there be no separation, the jaw should be kept at rest as in a case of a fracture of the angle. When the coronoid process is separated, an open operation should be performed, the fragments drawn into position, and fixed with a small silver-wire suture.

(e.) *The Condyle.*—Fractures in this position may occur from direct violence, or less commonly by blows upon the chin. Either the neck of the bone is fractured, or the condyle itself splintered. There will be little or no displacement in either case, but in both there will be limitation of movement, and pain.

TREATMENT.—Operation will generally be required; otherwise there will be a tendency for ankylosis of the joint to take place. If the neck be fractured, it may be possible to fix the two fragments by means of a small wire suture; but if this fails, or if the condyle be fractured, it will be better to remove the condyle, to round off the remaining portion of the bone, and to turn in a small portion of the capsule or aponeurosis to prevent bony union.

2. The Superior Maxilla.—Fractures may involve either one or both of the superior maxillary bones. They are most commonly caused by falls on the face, but may also occur from gunshot wounds, or the alveolar process may be separated during the extraction of a tooth. One or both bones may be separated as a whole from the rest of the face; in that case the nasal bones usually accompany the superior maxilla, but the malar bones maintain their normal attachments. Under such circumstances there is little or no deformity, but the whole front of the face is bruised, and may be freely movable, with crepitus. It tends, however, to fall back in its normal position, and if kept there by means of a bandage, union may rapidly take place. The oral and nasal cavities should be kept thoroughly cleansed by means of antiseptic washes. If there be any deformity, this should be reduced by manipulation under a general anæsthetic.

If a portion of the alveolus be fractured, the muco-periosteum may be also torn, the fracture then becoming compound. The fragment can, as a rule, be readily replaced, and should never be removed unless completely detached. If kept clean it will frequently unite, and should necrosis occur the fragment may be removed at a later date.

The anterior wall of the antrum may be driven inwards, this at times occurring as a result of fracture and downward displacement of the malar bone. If unassociated with injury of the malar bone there will, as a rule, be little deformity, and treatment should be limited to maintaining asepsis of wounds of the skin or mucosa. If the malar bone be affected there will be marked deformity, and it will be necessary to replace this bone. A small incision should be made in the fornix, the anterior wall of the antrum laid bare, and attempts made to disimpact the malar bone by means of a periosteum elevator. If necessary, an opening may be made into the antrum, and the elevator inserted through it beneath the malar bone. When once disimpaction is carried out, the fragments can readily be replaced, and show but little tendency to leave their normal position. The wound in the fornix can then be closed and the mouth kept clean. In rare cases, involvement of branches of the infra-orbital nerve may give rise to neuralgia, which will require operation to free the nerve. *Albert J. Walton.*

JAW, NECROSIS OF.—Necrosis of the jaw may be due to many conditions, and the amount of bone may vary from a small superficial sequestrum to the whole thickness of the jaw; so that in severe cases there may be a spontaneous fracture of the lower jaw, or extensive destruction of the upper jaw. The condition is more common in the inferior maxilla. The causes may be divided into (1) *Infective* and (2) *Chemical*, the former being much more common than the latter.

1. *Infective.*

(a). *Compound Fractures.*—If the wound becomes infected, the underlying bone will participate in the sepsis, and necrosis will occur. This may be so slight in amount that no portion of bone is separated as a sequestrum. If more extensive, there may be destruction of a varying amount of bone, which may separate later. In the minor degrees it may be sufficient simply to maintain oral asepsis until the sequestrum is free. If a local abscess forms it should be incised, but even if dead bone be felt it is generally preferable not to remove it until it is quite loose, lest the recently united fracture be again broken down. In more severe cases, a large portion of the bone may be destroyed, and owing to the amount of surrounding sepsis a more vigorous line of treatment will have to be carried out. A general anæsthetic being given, the mouth must be freely opened and the site of the fracture cleansed as far as possible. A free incision is made down to the bone through the mucosa, and if necessary other incisions made through the skin. Drainage tubes are inserted wherever pus has collected, and fomentations applied. Oral antisepsis must be thoroughly carried out in the after-treatment. Owing to the amount of destruction of the bone, it is important to keep the fragments in as good a position as possible, so that when new bone is formed there will be little resulting deformity. If a dental plate has been used in the treatment of the fracture there will be little difficulty in this, whereas if only a four-tailed bandage has been employed considerable displacement may occur. No attempt should be made to remove the dead bone until a new sheath of bone has been formed. If necessary the progress can be investigated by *x*-ray photographs, and when the involucrum is formed the dead bone may be removed. It will generally be found, however, that by this time there are loose sequestra which may be removed either from within the mouth or through one of the openings that have been made in the skin. In the case of the lower jaw the new bone formation is rapid, and a very serviceable jaw may result, although several teeth may be lost in the process. When the upper jaw is affected the sepsis is generally less extensive, and it may be possible to provide adequate drainage by means of incisions in the mouth. If the pus spreads up to the antrum, this structure will also require drainage. In this position sequestra are not so extensive as a rule, but the amount of new bone formation is relatively slight, and repair may indeed be only fibrous.

(b). *Alveolar Abscess.*—When the condition follows an infection of the tooth socket after removal of the tooth, the pathological changes will be identical with those occurring in a case secondary to infective stomatitis, and will require the same treatment. When the tooth is *in situ* the amount of destruction will be very variable. In the less extensive cases there will be a swelling of the soft tissues over the infected tooth, which, if the tooth be not immediately removed, will soon be followed by pus formation. When pus is formed it may be sufficient, in the early stages, to incise the swelling from the mouth and to administer antiseptic mouth-washes. In such cases no actual sequestrum may separate. In more advanced cases the pus will pass through the periosteum and involve the surrounding tissues, so that a subcutaneous abscess is formed. By this time a larger area of bone has usually undergone necrosis. It will now be necessary to open the abscess externally, or the pus will spread widely into the submaxillary

tissues or even into the neck, and one or more disfiguring sinuses may form. The longer the condition is left unoperated upon, the more extensive will be the separation of the periosteum and the necrosis of bone. If necrosis has taken place, the sinus will continue to discharge, and the separation of the sequestrum take several months to be completed. In all cases of persistent sinus the tooth should be removed, as a carious tooth may be sufficient, without the existence of a sequestrum, to prevent its closure. If a sequestrum be present it is not advisable to remove it at once, for not only will it be difficult to determine the limit of the dead bone, but fracture of the jaw, with consequent deformity, is likely to occur owing to the absence of the new sheath of bone. In removing the sequestrum, which is generally dense and well defined, the operation should, if possible, be carried out through the mouth, so as to limit the subsequent scar deformity. If the infection is situated near the angle of the jaw, care must be taken that contraction of the masseter and pterygoid muscles, leading to closure of the jaws, does not ensue. In the case of the upper jaw, an extensive abscess may form on the palatal surface without bone destruction; but especially in the case of infection of the bicuspid or first molar there is, as in the previous variety, danger of infection of the antrum of Highmore.

(c). *Secondary to Stomatitis*.—Any form of stomatitis, whether following one of the exanthemata or any septic wound of the mouth, may be associated with necrosis of the jaw. With the exception of very severe cases the lesion is usually limited to the alveolus, the condition starting round the tooth sockets. If no treatment be carried out, or if the condition fail to react to treatment, the ulceration around the teeth will extend more deeply, portions of the alveolus will be seen to project as greyish or black hard spicules, and later, as the teeth fall out, these small irregular portions will separate, the ulcer of the gums then healing. In the more extensive cases the infection may spread down so as to surround the bone and destroy the periosteum. Or in other cases there will be extensive superficial gangrene which will lay bare a large area of the bone; there is, in fact, a condition of cancrum oris. In either case, more active treatment will have to be carried out. If there be a deeper infection, the tissues must be freely opened and the mouth thoroughly cleaned mechanically whilst the patient is under an anæsthetic. Drainage must be maintained, and if the condition abate, the sequestrum should be removed at a later date when the involucrem has formed. In the case of cancrum oris, the usual lines of treatment for that condition are carried out; and if the patient survive, again the sequestrum is removed at a later date.

(d). *Pyæmia*.—An infection of the jaw through the blood-stream is rare. Free incisions must be made both internally and externally down to the bone, and portions of the outer wall of the bone should, unless the whole structure is dead, be removed. The wound should be freely drained and the mouth kept as aseptic as possible. It is sometimes advocated that the dead bone be removed at once, an apparatus being inserted between the two remaining portions to maintain the shape of the jaw until the involucrem has formed. Under such circumstances, however, it is very difficult to maintain the normal position, owing to the amount of surrounding sepsis. It is therefore preferable to leave the sequestrum in position until sufficient new bone is formed. Provided that there be adequate drainage, which is best secured by removal of portions of the outer wall of the mandible, there need be no hurry to remove the remaining portion. Later, when the sequestrum has separated and there is sufficient new bone, the dead portion may be removed through an incision in the mouth, when the cavity will rapidly close if the mouth be kept clean.

(e). *Syphilis*.—Syphilitic necrosis occurs in the tertiary stage. It is more

common in congenital syphilis, and usually affects the hard palate. A gumma forms on the muco-periosteum, and the underlying bone is destroyed, either gradually, so that a perforation appears without separation of a sequestrum, or a large irregular piece of bone may be separated, leaving a hole passing through to the nasal cavity. In the early stages antisyphilitic treatment should be carried out, and destruction of the bone may thereby be prevented. In the later stages the sequestrum may require removal, this being often followed by alteration in the speech owing to the loss of structure. When a perforation is present, it may be closed either by a plastic operation or by the wearing of an obturator.

(f). *Tuberculosis*.—Tuberculous disease of the jaw is very uncommon. It occurs more frequently in the upper jaw, usually spreading from the face or nose. Occasionally it may affect the lower jaw, and then usually commences at the symphysis, but even in these cases it rarely gives rise to the formation of a definite sequestrum. Even if perforation of the palate takes place, the bone is usually destroyed by a gradual process of ulceration. Treatment should be carried out on general lines, but if there be a localized focus it may be possible to remove this by operation.

(g). *Actinomycosis*.—The lower jaw is one of the commonest sites affected with actinomycosis. In the early stages treatment will consist in removal of any carious teeth which may be the source of infection, and in the administration of large doses of potassium iodide. Later, when sinuses are present, it will be better to scrape them thoroughly with a sharp spoon, the wounds being then lightly plugged with iodoform gauze. (See also ACTINOMYCOSIS.)

2. Chemical.

(a). *Mercury*.

TREATMENT.—If a patient, whilst being treated with mercury, complains of pain around the tooth sockets, with tenderness on biting, and the breath becomes foul, the mercury should be stopped immediately. The mouth should be thoroughly cleansed, and iodide of potassium may be administered. Should it arise after intramuscular injection of an insoluble mercurial salt, the same lines of treatment should be carried out. The area of injection, which still contains a considerable amount of unabsorbed mercury, should be excised entirely. If any portion of the bone has become carious, it should not be removed until a new involucrum has been formed, the mouth being kept thoroughly cleansed in the meantime.

(b). *Phosphorus*.—This condition only occurs amongst those who work in factories where phosphorus is largely used, the yellow phosphorus being alone accountable for the condition. It is believed that the phosphorus merely predisposes to the entry of pyogenic organisms or tubercle bacilli.

TREATMENT will consist in removing the patient from the phosphorus fumes, the local condition being then treated on the same lines as a pyogenic infection.

(c). *Arsenious Acid*.—This material is used for devitalizing the pulp of the tooth. Should it escape upon the gums, or through the apical foramen, it may give rise to a localized necrosis of the alveolar process.

TREATMENT consists in localized cleanliness and in waiting for the sequestra to separate.

Albert J. Walton.

JAW, TUMOURS OF.—Tumours of the jaw may be of many varieties; for not only may they arise from the bone and periosteum: but the periosteum and mucous membrane being in certain areas in close relationship, tumours peculiar to this latter structure may invade the substance of the bone. The jaws also contain the teeth and the antrum of Highmore, from either of which tumours may arise. It will be found convenient to classify these tumours according as they affect the following parts: (1) *The muco-periosteum*; (2) *The*

jaw proper ; (3) *The palate* ; (4) *The antrum of Highmore* ; (5) *The dental tissues*.

1. **The Muco-periosteum.**—These tumours, which are often loosely grouped together under the term *epulis*, are of many different varieties, and may occur in either the upper or lower jaws. The majority of them arise in association with the tooth sockets, generally springing from the periodontal membrane, and are often associated with pyorrhœa alveolaris.

(a). *Angiomata*.—This condition, which is sometimes described as a vascular epulis, is identical with the angiomata found elsewhere in the skin or mucous membrane.

TREATMENT.—If small and pedunculated it may be found possible to excise them entirely ; which treatment, as in the case of cavernous nævi elsewhere, will give the most satisfactory results. In other cases, where they are too extensive for this form of treatment, a cure may be brought about by electrolysis or multiple punctures of the galvano-cautery. Such form of treatment may leave a fibrous mass which it may be necessary to excise later.

(b). *Papillomata*.—These tumours form soft wart-like masses, generally situated close to the teeth. They are best treated by snipping off with a pair of scissors. Any resulting bleeding may be controlled by the aid of a styptic.

(c). *Granulomata*.—These are one of the common forms of epulis, and often can only be distinguished from the fibrosarcomata by microscopical examination. In nearly all cases they occur in association with carious teeth.

TREATMENT.—Owing to the fact that these tumours arise from the periodontal membrane, it is necessary not only to extract the carious tooth, but thoroughly to remove the affected portion of the membrane. Excepting in the very early cases it is doubtful if this can be successfully accomplished by scraping out the tooth socket. Moreover, it is often impossible to determine accurately whether the tumour is granulomatous or sarcomatous. For these reasons it is better to extract the teeth on either side of the tumour, and with a small chisel to remove thoroughly the affected portions of the alveolus, together with the periosteum.

(d). *Fibrosarcomata*.—These commence in the same position as the granulomata. The majority of cases of so-called fibrous epulis are in reality cases of fibrosarcoma.

TREATMENT.—In the early stages the tumour will be removed by the same method as that in use in the case of granulomata, and if the alveolus and periodontal membrane be freely taken away there is but little likelihood of recurrence. In the later stages it will be necessary to remove the jaw much more freely. If the tumour has not yet involved the body of the bone, it may be possible, in the case of the lower jaw, to leave a bar of bone at the lower border of the mandible so that the contour of the jaw is maintained. If, however, there is doubt as to the safety of this procedure, or if the tumour has been rapidly growing, the whole thickness of the jaw should be removed. Before doing a partial excision of the jaw it is necessary, in the case of the lower one, to have a plate or obturator made, so that it can be inserted at the time of the operation, and the two remaining fragments be thus maintained in their normal position until sufficient new bone has been formed. Such an operation should always be carried out by an external incision. It is not wise, for the sake of avoiding a small and insignificant scar, to take the risk of not cutting sufficiently wide of the tumour.

(e). *Myelomata*.—This condition is more common in young people. It commences, also, as an enlargement of the process of gum lying between two adjacent teeth. It grows rapidly, and forms a soft, dark, purple mass which tends to ulcerate and bleed readily. It was formerly known as a malignant epulis.

TREATMENT.—If small, the adjacent teeth should be removed, the tumour with the affected portion of the alveolus then being excised with a chisel, it being generally necessary to take out a much larger portion of the alveolus than is the case with the other varieties. In later cases, owing to the extent of the tumour, it may be necessary to extract several teeth.

(f). *Epitheliomata*.—Epithelioma of the gums may arise as a primary condition, or secondary to a lesion of the tongue or floor of the mouth.

TREATMENT.—If seen early it may be possible to remove only a portion of the lower jaw, the operation being then carried out on the same lines as that indicated in the case of fibrosarcoma, but at the same time the lymphatic glands in the submaxillary region should be thoroughly extirpated. In later cases, if the glandular involvement is not too extensive to forbid operation, it is better to remove the affected half of the horizontal ramus of the lower jaw; or if the upper jaw be affected, to take away the whole of the superior maxilla.

2. The Jaw Proper.—These tumours correspond to those arising in bone elsewhere, and may therefore be innocent or malignant.

(a). *Osteomata*.—These more commonly arise from the superior maxilla, and are then usually seen springing from the outer surface, especially from the nasal processes. In other rare cases the condition is diffused over the whole surface of the face, and is then described as leontiasis ossea. Apart from these cases, which are possibly inflammatory, osteomata are rare; but they may occasionally occur as small bony outgrowths on the alveolar processes, whilst on the lower jaw they are more common at the angle and at the region of the mental foramen.

TREATMENT.—The tumours situated on the anterior surface of the nasal processes will, owing to the deformity, usually require removal. They will generally be situated too high up for removal by an incision in the fornix, and hence they must be exposed through an incision made in the labio-nasal fold. The excess of bone may be removed either with a chisel, a dental drill, or a small saw.

(b). *Myelomata*.—Apart from the doubtful myelomata growing from the muco-periosteum of the alveolar processes which have been described already, true myelomata originating from the centre of the bone may occasionally be found. They are more common in the lower jaw, and have all the characteristics of the myelomata of the long bones elsewhere.

TREATMENT.—If these cases are diagnosed early, before they have led to destruction of the inferior maxilla, they may be removed by a local operation. It is unnecessary to do even a partial resection. The surface of the bone may be laid bare, preferably by an incision running in the submaxillary region. The outer wall is then chiselled away and all the tumour material thoroughly scraped out. Any hæmorrhage into the cavity should be carefully stopped, and the walls swabbed with pure carbolic acid. If sufficient of the outer wall is removed, the soft tissues on being returned to their normal position may eradicate the cavity. If the cavity is large, it may be either plugged with gauze and allowed to granulate up, or filled with one of the absorbent stoppings.

(c). *Sarcomata*.—These may be either periosteal or endosteal, the former being the more common. They are either of the round or spindle-celled type.

TREATMENT.—In all these cases it is probably better to remove the whole of the affected half of the bone. Any attempt at local removal is almost certain to be followed by recurrence. Even if the whole of the affected part of the lower jaw be removed, it is very probable that metastasis will occur, this being one of the most malignant types of growth.

3. The Palate.—Tumours in this portion of the jaw are uncommon.

(a). *Adenomata*.—These are generally regarded as being the commonest tumour of the palate.

TREATMENT.—The tumour should be removed by an elliptical incision, the edges of which are sutured together.

(b). *Papillomata*.—These may occur on the soft palate in the neighbourhood of the uvula. They are slow-growing and usually soft, owing to the moisture of this position. Occasionally they may ulcerate, and in older people may be the starting point of epitheliomata.

TREATMENT.—If giving rise to trouble, they should be excised, and the edges of the wound sutured together with catgut.

(c). *Epitheliomata*.—Epithelioma generally occurs in the palate owing to direct spread from the tonsils.

TREATMENT.—If seen in the early stages it may be possible to eradicate the disease by operative means. For this purpose a modification of Mickulicz's operation may be employed. In this method, the affected tissue is reached by a curved incision beneath and behind the angle of the jaw, this portion of the bone being itself removed, if necessary, to give a better view. The glands of the neck should be dissected out at the same time.

(d). *Sarcomata*.—These tumours are rare in the palate, but occasionally may occur as a rapidly-growing round-celled variety.

TREATMENT.—If there is any doubt of the nature of the tumour, a portion should be removed for microscopic examination, as it is only in the early stages that successful operative measures can be carried out. If a positive diagnosis be made, a partial resection of the superior maxilla on the affected side must be performed, the orbital plate being left, but as much as possible of the affected half of the soft palate being taken away.

4. **The Antrum of Highmore.**—Tumours in this position are very complex in nature. They all tend to lead to distention of the cavity, and to be relatively far advanced before diagnosis is made.

(a). *Myxomata*.—These arise from the epithelium lining the antrum. They tend to undergo degeneration, and hence are often described as cysts of the antrum.

TREATMENT.—The condition is often diagnosed as a chronic inflammatory change, with obstruction of the orifice. In such a condition, however, the affected side will be more opaque to transillumination, and an exploratory puncture will show the presence of pus. Under these circumstances an opening should be made in the outer wall through the superior fornix. The myxomatous tissue should be evacuated, and the lining membrane of the cavity thoroughly scraped out. This will lead to destruction of the epithelium, and hence it is wiser at the same time to make a free opening into the corresponding nasal cavity for the purpose of drainage.

(b). *Sarcomata*.—Of the two varieties of malignant growth occurring in this situation, sarcoma is the more common. It may occur in relatively young people, and start from the sub-epithelial tissue or from the bone.

(c). *Epitheliomata*.—If primary within the antrum, this tumour is usually of the villous and columnar-cell type, and tends to occur in rather more elderly patients. It has already been mentioned that an epithelioma starting elsewhere may pass upwards and invade the antrum.

These two tumours cannot, as a rule, be distinguished from one another until microscopic sections are taken.

TREATMENT.—When a diagnosis has been made, and if the tumour be still confined to the superior maxilla, an excision of that bone should be carried out. The whole of the affected maxilla, including the orbital plate, should be removed, and care should be taken to see that no portion of the growth be left in the region of the sphenomaxillary fissure. A preliminary laryngotomy should always be performed and the pharynx plugged, so that all growth can be

thoroughly removed from the deeper areas. If microscopic sections show that the tumour is an epithelioma, the glands of the neck should be removed at a second operation.

5. The Dental Tissues.—These are rare tumours; the following are the more usual types:—

(a). *Epithelial Odontomes, or Fibrocystic Disease of the Jaw.*—These tumours are generally believed to arise from persistent remnants of epithelium connecting the enamel organ with the common enamel germ. They are most commonly seen in the lower jaw. They are generally encapsulated, and are composed of a multitude of small cystic spaces, the septa between which may occasionally be ossified.

TREATMENT.—If the tumour be small, and near the alveolus, access may be obtained by means of an incision through the oral cavity. If larger, an incision through the skin will be necessary. An opening should be made into the tumour, and all the diseased tissue thoroughly removed with a gouge and chisel. Care must be taken to remove every portion of the tumour, leaving only a smooth bony lining to the cavity. The resulting defect in the jaw is plugged with gauze and the cavity allowed to granulate up.

(b). *Follicular Odontomes, or Dentigerous Cysts.*—These always occur in association with an unerupted tooth. The tooth is one of the permanent set, and the lesion is more common in the lower jaw of young adults.

TREATMENT.—An incision should be made down to the swelling, if possible through the mucous membrane. The outer bony wall of the cavity is removed, the unerupted tooth extracted, and the epithelial lining thoroughly scraped out. The resulting cavity is packed with gauze and allowed to granulate up.

(c). *Fibrous Odontomes.*

TREATMENT.—The mass should be laid bare as in the previous conditions, and the whole fibrous tumour dissected out from the bone, the resulting bony cavity being plugged with gauze.

(d). *Dental Cysts.*—These are always found in association with a carious tooth. The sacs are not uncommonly bilateral, and may be multiple. They are more commonly attached to the bicusps and molars, and in the upper jaw may be sufficiently large to invade the antrum.

TREATMENT.—The smaller cysts are usually removed whole when the carious tooth is extracted. Larger sacs which have led to enlargement of the bone should if possible, be opened through the mouth, the fluid removed, and the cavity thoroughly scraped out with a sharp spoon. The opening is then plugged with gauze until it has granulated up, the mouth meanwhile being kept clean with antiseptic mouth-washes.

Albert J. Walton.

JOINTS, ANKYLOSIS OF.—(See ANKYLOSIS OF JOINTS.)

JOINTS, TUBERCULOUS DISEASE OF THE.—It makes no difference what the joint is; if it is the subject of tuberculous disease it must be kept at rest, and it must be kept at rest until the inflammation has quite passed away. It is better that a joint which has been inflamed should be kept for too long a time at rest than that it should too soon be granted its freedom. As to when this freedom may be granted without risk, reference will be made further on.

Effect of Prolonged Rest upon an Inflamed Joint.—The question is likely to be asked of the practitioner whether there is not a risk of the joint being left permanently stiff if it is locked in a splint for month after month. The answer is that it is *inflammation* and not *rest* which leaves a joint stiff, and that the first thing necessary towards getting rid of the inflammation is to obtain perfect

rest. That if a limb were, by mischance, kept at rest long after the inflammation had passed off, the worst that could happen would be the occurrence of some fibrous adhesions which could easily be got rid of. But that if the inflammation continued, a growth of granulation-tissue would destroy the softer part of the joint and the ends of the bones themselves, and that these granulations might grow into solid bone and weld the joint into a single mass. Through the whole field of surgery runs the unvarying principle that the first thing necessary for an inflamed organ is to rest it.

The question will probably be asked also if massage or electricity, or the two together, might not be of service to the wasting limb. But inasmuch as a limb cannot be subjected to massage unless it is taken out of a splint, handled, and moved about, massage must not be advised so long as a remnant of inflammation is left. Nature begins her treatment of a diseased joint by starving the muscles into a condition of feebleness and inactivity; a surgeon would be flying in her face, as it were, by having them roused and excited. But when the tuberculous inflammation has passed away, the help of these useful measures may well be sought. And that will be the time also for gentle passive movements, and for the carrying out of well-considered exercises, either in or out of a gymnasium. But such treatment is too often resorted to before the proper time. Tuberculous inflammation of a joint cannot be hurried.

When may the Joint be set free?—After a joint has been for some time fixed in a splint, and all cause for alarm has passed away, the question arises as to when the patient may have free use of the limb once more. If the surgeon was wise at the beginning of the treatment, he made no promise as to when the joint should be set free, and he is, therefore, less likely now to be hurried into doing something which he might afterwards regret. He takes off the splint and has a look at the joint, which, because of the wasting of the muscles, may now seem strangely large. Everything has been going on well: there is no spot where bulging has taken place—which might mean that the joint still held some “water,” or, worse, that a cold (tuberculous) abscess was forming. If the joint is still inflamed, the skin over it is hotter than it should be; but the surgeon must remember that if a splint and bandage have only just been taken off, the skin is sure to be warmer; he gives it time to cool down, therefore, and afterwards, by comparing with the other side of the body, satisfies himself that there is no unnatural warmth. Then he presses upon those parts of the joint which are nearest the surface, or gently squeezes them between his finger and thumb. As a rule the tender places are in the grooves between the bones forming the joint. In the case of the knee, the tender spot is almost certainly over the internal semilunar cartilage, a spot which is found by gently bending the leg and feeling for the hollow beneath the front of the internal condyle. If there is no flinching when this part is pressed, it is unlikely that any inflammation remains. In the case of the *hip*, the surgeon makes gentle pressure upon the front of the capsule, which is in the crease of the groin behind the femoral artery. He also thrusts his finger into the space between the ischial tuberosity and the great trochanter, so as to reach the back of the joint. Tenderness in the *shoulder-joint* would be found by pressing round the globular head of the bone beneath the acromial process. In the *elbow* it would be best made out where the synovial membrane comes close up to the skin around the head and neck of the radius, just below the outer condyle of the humerus. The *wrist-joint* is examined by pressing with the finger and thumb sideways between the styloid processes of the radius and ulna and the first row of the carpal bones. This is sure to find out any tenderness in the radio-carpal joint, and a gentle squeeze through the middle of the wrist reveals inflammation in the large synovial membrane of the carpus. If the surgeon grasps the forearm with one hand and with the

other gently pulls on the patient's hand, or if he thrusts the wrist-bones against the lower end of the radius and ulna, and there is no complaint, he may be sure that all is going on well.

If the skin is not warmer than it should be, and there is no bulging about the joint, and if no tender spot is to be made out by pressure, the chances are that the trouble has passed off, and that movements may be restored to the joint. So the surgeon cautiously imparts a gentle movement of flexion to the joint. But the return to freedom and activity must be gradual. It would not do to say, "Now you are all right; throw away the splint and use the joint." This is what the ignorant "bone-setter" is apt to say; it is part of his ritual; and in the case of tuberculous joints it is liable to involve sad distress. At first the splint should be left off only at night, after the patient is in bed, and it should be put on again before he gets up in the morning. Then, if all goes well, it may be taken off in the evening and not put on again till next day. Then it need be worn only when he is going out of doors, and so on, a little more freedom being allowed each week, and the surgeon keeping his eye on the joint the while. It is necessary for the surgeon to have the patient under his close supervision when the joint is being granted its freedom, so that in case of there being any return of trouble he may at once order the re-application of the splint. During this time, judicious massage will be helpful in bringing back tone and strength to the muscles of the limb. And, perhaps, day by day, a little movement may be given to the joint, so as to help on the return of activity and freedom; but this should be done with much care and gentleness. No risks must be run; far better is it that the limb be allowed to "shake itself loose," as Hugh Owen Thomas used to say.

Plaster-of-Paris and other Splints.—Splints made of common house-flannel, hardened by plaster-of-Paris, are very useful in the treatment of tuberculous joints. The flannel having been duly cut into shapes and laid ready, an inch or so of water is poured into a basin, and fresh plaster is shaken in until it forms a little island in the middle; then it is quickly stirred in until a creamy mixture is made with which the flannel is to be soaked. It is well to have two pieces of shaped flannel on each side of the limb, one of which has a surface daubed with the cream on one side only, the dry side being placed next to the bare limb, and on the outside of this is laid the piece which is thoroughly soaked with the cream. A nurse or other assistant holds these two pieces close against one side of the limb, whilst the surgeon quickly fixes them in place by a few turns of a muslin roller. Without any loss of time the other side of the limb is similarly treated, only in this case the splints are put on outside the muslin bandage which held the other pieces in place. If the splints have been put on nicely, there will be a space running up the front of the limb between their borders which is covered in simply by muslin, and then, or next day, the surgeon may run the scissors up this gap, take off the splints, trim their edges, and re-apply them.

There is one great advantage with regard to these splints: they can be made at a moment's notice and of any length. It may happen that if they are being fitted on a tall man, or a very large limb, the first side will not be finished off before the plaster in the basin has become as hard as a rock, so that a second mixing in a fresh basin will be needed. The plan of winding plaster-laden bandages round and round a limb, without any provision for their prompt removal in case of need, is unsatisfactory and obsolete—even dangerous.

But of all ways of fixing an inflamed joint, there is none so good as that of leather side-splints. These splints are made of undressed cow-hide, shaped to a paper pattern, and soaked in hot water and vinegar. Thus treated, the leather becomes as limp as wet brown paper, and after being bandaged on the

limb in two side-pieces, it is left on for twelve or twenty hours to harden, and it may afterwards be lined with wash-leather, and fixed with straps and buckles.*

GENERAL TREATMENT.—It may be said that cream, butter, bacon, and other fatty foods are all good for tuberculous patients; but there is probably nothing quite so valuable as cod-liver oil. And if a patient says that he cannot swallow or digest the oil, he may often be tricked into taking it by giving it with sardines. As soon as the sardine-box is opened, the preservative cotton-seed oil should be emptied away and the box filled with fresh cod-liver oil. For a tuberculous infant, systematic inunction with cod-liver oil, every evening after the warm bath, is useful, the infant lying on the flannel apron as the nurse sits in front of the fire. The smell is apt to be objected to, but when the child is found to be improving in weight and appearance this objection is disregarded. It need hardly be said that fresh air and sunshine are of prime value in the treatment of the tuberculous patient. In recent years we have learnt that the greater the amount of phagocyte corpuscles which can be brought in the blood-stream through the inflamed tissues, the greater the chance of the early destruction of the tubercle bacilli which are the cause of the disease. It is for this reason that the Bier treatment is so valuable (p. 103). Thus also is explained the value of the actual cautery, of liniments, of douchings of hot and cold water, of gentle massage, of the application of tincture of iodine to the surrounding skin—all these measures increase the circulation of blood through the area of disease. But the systematic production of engorgement of the joint by circular constriction of the limb above the joint with an elastic band, as described in the Bier treatment, gives the most satisfactory results. The constriction, of course, must not be so vigorous as to check the arterial flow, or the object of the treatment would be frustrated.

In those cases of tuberculous invasion which are hanging fire under the ordinary lines of treatment, it will be advisable to call in the help of the "bacterio-therapeutist," who, by investigating the power of resistance of the blood to the bacillary invasion, may by his methods so increase its strength as to enable the colourless corpuscles to carry on a completely successful warfare against the bacilli. Should the case be one of those unhappy ones in which septic micro-organisms have found entrance to the joint and have joined with the bacilli of tuberculosis in the attack, he may give very material help by his vaccination or inoculations with specially prepared sera.

The Shoulder-Joint.—When the shoulder-joint is the seat of tuberculous disease, the forearm and hand should be supported by a broad sling, and a poroplastic or leather splint should be moulded over the shoulder, reaching to the mammary and to the scapular regions, and extending half-way to the elbow. The arm and hand should be fixed to the chest by a binder and secured beneath all the clothes; it could not be brought through the sleeves without harmful disturbance. When the acute attack has passed off, the hand may perhaps be set free, but the elbow must still be fixed to the side. No oils or liniments applied to the skin are likely to be of any service, and the practitioner must be content to see the muscles of the shoulder-blade and arm steadily wasting without wishing to try the effect of massage or electricity. As it is easy to keep the shoulder-joint at rest, the disease generally proves amenable to treatment.

If the joint-pains are very severe, menthol may be gently rubbed over the neighbouring skin, or leeches may be applied.

If the disease quietly continues, and the tuberculous granulation-tissue breaks

* The illustrations in this article have been made from leather splints which have been applied to various diseased joints by Messrs. Spratt & Brooke, of 5, Brook Street, Hanover Square, W.

down, a chronic "abscess" forms in the joint, and it will be likely to find its escape through the cuff of synovial membrane which passes out with the tendon of origin of the long head of the biceps, or it may point anywhere else along the borders of the deltoid, especially near the coracoid process. The collection must not be allowed to break through the skin, lest septic germs should enter the joint, but it should be removed by aspiration or by direct incision, as described under the heading *HIP-JOINT* (*vide infra*). In due course the cartilage disappears, and granulations, finding their way through the articular layer of bone, render the adjacent surfaces of scapula and humerus rarefied, as is shown by the Röntgen rays. But if the health remains good, and the arm is still kept at rest, the disease may completely clear up, the bones becoming solidly joined together as in the welding of a simple fracture. With this result the surgeon may fully be content, for, as the scapula plays easily over the chest wall, the movements of the limb will not be very seriously hindered. But if the disease continues, in spite, may be, of antibacterial vaccination, and if the skiagram shows steady advance of the process of disintegration, and the general health seems unable to cope with the persistent discharge, excision should be no longer delayed, and the cavity should be thoroughly scraped, flushed, and dried. This operation gives a freely movable and useful limb. I have never met with a case of tuberculous disease of the shoulder or elbow which called for amputation.

Fig. 46.—Leather splint applied to a tuberculous elbow-joint.

The Elbow.—The forearm must at once be bent to a right angle, and the limb secured in a splint reaching three-quarters of the way up to the shoulder and almost down to the wrist (Fig. 46); for a splint which occupies only about the middle third of the limb does not suffice to keep the joint absolutely quiet. If after the evacuation of a tuberculous abscess a sinus persists, Bier's hyperæmic treatment should be tried, as described on page 103. Should the disease prove intractable, excision may be done. Excisions of the shoulder and the elbow give excellent results.

fingers should be fixed and worn in a sling. A wooden splint is not convenient, as it shifts its place, and the plaster of Paris answer, as it is hard and uncomfortable, and is apt to become cracked and soiled. Nothing does so well as a moulded splint of undressed leather, as shown in Fig. 47. It can be made to fit as close as a glove, and if it is covered with black kid it may be made to look quite smart.

The Wrist-Joint.—The hand and fingers should be fixed and worn in a sling. A wooden splint is not convenient, as it shifts its place, and the plaster of Paris answer, as it is hard and uncomfortable, and is apt to become cracked and soiled. Nothing does so well as a moulded splint of undressed leather, as shown in Fig. 47. It can be made to fit as close as a glove, and if it is covered with black kid it may be made to look quite smart.

Fig. 47.—Leather splint applied to a tuberculous wrist-joint.

A splint for the wrist should be long enough to reach from half-way to the elbow down to the middle of the fingers, for if the fingers and thumb are left free the hand cannot get its full measure of rest, and unless this is secured the trouble may persist indefinitely. The use of the splint must not interfere with the methodical employment of the Bier congestion-treatment to which reference has been made on page 575.

Tuberculous disease of a **Finger-Joint**, or of the thumb, is apt to come on after a sprain or blow. The trouble is apt to be persistent unless it is thoroughly well looked after. It is best treated by a leather splint (*Fig. 48*), the hand being worn in a sling.

Hip-joint Disease.—The patient must at once be placed flat on his back and the limb secured against all movement. This may be done by a stirrup and weight; but if there is already persistent flexion, so that when the thigh is brought down flat upon the mattress the loins become arched, *the traction must be made in the line which the thigh takes when the loins are flat and the pelvis is squared.* Thus, if when the loins are flat the thigh is found flexed and adducted, as is likely to be the case, the traction must be in an elevated direction and across the opposite limb, the thigh being supported on an inclined plane of firm pillows. But if a Thomas's splint of the correct size for the case is at hand, it should at once be adjusted and applied; this is far better than the stirrup, and I allude to the stirrup treatment first only because it can be arranged at a moment's notice, and used whilst the Thomas's apparatus is being got ready. The stirrup and weight do not pull asunder the inflamed tissues of the joint—that is mechanically impossible—they merely fix the limb and protect it against muscular startings and accidental disturbances: Thomas's splint does exactly the same thing. The faulty position of the thigh is kept up by the effusion which has taken place in the capsule of the joint, and as it undergoes absorption so does the thigh come down. Gradually, therefore, under the influence of the stirrup and weight or of the iron splint, the surgeon is able to bring the limb down flat and straight without causing the loins to arch.

If, as the result of acute effusion into the joint, the pains are unusually severe, they may be relieved by the introduction of a small cannula and trocar into the bulging capsule. In a more advanced stage, acute pains are likely to be due to ulcerated surfaces of the bones being irritated by muscular contractions. Possibly these may be lessened by fomentations or by the readjustment of the splint.

One great advantage of the treatment by a Thomas's splint is that as soon as the thigh has been brought down flat and the acute pains have passed off, the patient can be allowed out of bed, can be carried out of doors, and, due precautions being taken, can be permitted to walk on crutches—the foot of the sound side being raised by a four-inch patten or a thick-soled boot. It is highly important that the subject of tuberculous disease be out in the open air, and with the use of a Thomas's splint this can generally be arranged.

Hip-joint "Abscess" is the result of the breaking down of tuberculous granulation-tissue with the addition of serous exudation. This is not an abscess in the usual sense of the word, in that it contains no pus: as a rule it forms quite quietly, and, tracking forward, is apt to point in front of the great trochanter. It may, however, bulge in the gluteal region, near Poupart's ligament, or at some distance down the thigh. The surgeon should constantly be on the look-out for such collections, and he must not allow them to break spontaneously, lest septic organisms should enter the joint and the patient should sink under the double infection. The abscess should be treated by aspiration, the puncture being made through healthy, unthinned tissues, after the surface has been sterilized. The aspiration may have to be repeated several times, and the needle should be large enough to allow the easy passage of thickish material. Inoculation by

Fig. 48.—Leather splint applied to tuberculous disease of the first metacarpo-phalangeal joint.

sterile culture of the particular germs may be undertaken if suppuration has occurred, and discharging sinuses may be dealt with by Bier's method.

If, notwithstanding the repetition of aspiration, fluid collects and the thinning skin threatens to give way, either a free incision should be made, the cavity being scraped out and flushed with iodine water and then tightly closed, or else the head of the femur should be excised and the joint and the abscess-cavity thoroughly scraped over, dried, and firmly closed by deep suturing.

Excision of the Head of the Femur for tuberculous disease would rarely be called for if the disease were diagnosed promptly and efficiently treated; but unfortunately many of these cases are allowed to drift. Some surgeons advocate very early resort to excision in order that the tuberculous focus may be entirely removed. But experience has abundantly shown that if the limb is kept at rest and the general hygienic conditions are maintained, Nature may be trusted to effect a cure in her own quiet way. A child with tuberculous disease of the hip-joint may make as complete a recovery as a child with tuberculous disease of the spine, and one does not talk about the radical treatment of a tuberculous vertebra. Nature may be trusted, but she needs a little help. Probably those surgeons who have had most experience with Thomas's splint in hip disease will be least inclined to endorse the treatment by early excision. Excision is fully justified, however, when long-continued discharge from sinuses suggests that extensive ulceration (and possibly necrosis) of the femur or of the acetabulum has occurred; when the shortened and inverted condition of the limb, with other signs, shows that the head of the femur has been dislocated upon the dorsum ili; when digital examination by the rectum reveals the fact that perforation of the acetabulum has taken place and that an abscess is bulging towards the pelvis; or when, together with long-continued suppuration, the mutual contact of ulcerated surfaces of bone is wearing out the patient with distressing pain.

Resection of the Head of the Femur may be conveniently done through an incision over the anterior and outer part of the joint, and especially so if the operation is resorted to before septic sinuses have formed. The neck of the femur having been divided and the head of the bone brought out, the cavity should be scraped clean and dried, and the wound sewn up tight. But if staphylococci as well as bacilli are already infecting the joint-cavity, it is probable that the resection may be accomplished by enlarging one of the sinuses or by joining two of them so as to obtain more room. If the attack is made from behind, through the gluteus maximus, heed must be given that the great sciatic nerve is not injured. And if, as is probable, tuberculous softening has implicated also the os innominatum, the affected surfaces must be thoroughly scraped over, and the sharp spoon must also be used for the removal of the granulation-tissue which lines the sinuses and fills the crevices about the bones. The area should then be dried with swabs of gauze, and finally washed over with a solution of chloride of zinc of about 10 gr. to the ounce. A large drainage tube should be left in for a few days, the hip being packed around by pads of absorbent wool firmly bandaged on.

If, after the operation, the local and general conditions improve only to a certain extent, it may be advisable to open up the wound and scrape the surfaces once more, draining again, or leaving the cavity open and packed with antiseptic gauze. But if there is no favourable response, if the suppuration persists, and the continual absorption of small doses of septic material renders the patient cachectic and anæmic, the liver, perhaps, becoming large and the urine albuminous, the question arises whether it may not be needful to remove the wasted, hopeless limb through what is left of the hip-joint. This is the only treatment for some of these old-standing cases: if one watches and waits too long, the child

is at last carried away with what the old practitioners called colliquative suppuration and diarrhœa; whereas, after amputation, rapid and complete recovery may ensue, the albuminoid changes steadily clearing away.

Amputation of the Hip-Joint is most conveniently performed (after a preliminary ligation of the common femoral vessels) by cutting straight across the thigh a little above the middle, and by enucleating the remaining part of the femur through an incision running down to the bone from the top of the great trochanter. The shell-like femur being taken from its loose periosteal investment, a rudimentary piece of thigh-bone may eventually be developed in the core of the stump.

The Knee-Joint, on account of its liability to sprains and direct hurts, is often the seat of tuberculous disease. Immediately that the knee is found hot, swollen, or tender, the patient should be placed in bed and a splint of house-flannel and gypsum should be applied, as described a few pages back. As a rule, splints for an inflamed knee are not made long enough. A splint, for instance, which reaches a third of the way up the thigh and a third of the way down the leg does not absolutely prevent the knee from moving: it should reach nearly up to the groin and almost down to the ankle (*Fig. 49*). The complete rest thus obtained may promptly cure the disease; but if it does not, a Thomas's knee-splint should be ordered, so that, with a raised sole or patten beneath the other foot, the patient may be allowed to walk out. He certainly should not be kept in bed, or even indoors. If, when the case first comes under treatment, the leg is more or less flexed upon the thigh, and possibly rotated outwards, no attempt should be made forcibly to straighten it under an anæsthetic, as this would be apt to cause a separation of the upper epiphysis of the tibia. The limb must be fixed up in the faulty position, and as the inflammation quietly subsides and the intra-articular swelling diminishes, so will it become possible to get the limb straighter. Bier's hyperæmic treatment should be resorted to as recommended under the head of *general treatment*, p. 575. If the pains in the joint are very severe, the application of a few leeches, a small blister, or even of a hot iron may prove useful. If the disease continues and sero-synovial fluid collects in the joint, it may, if thought advisable, be removed by aspiration, but it generally becomes absorbed under the combined influence of compression and rest. If "tuberculous abscess" forms, it must be incised before the skin is reddened, and the joint having been washed out with weak iodine water, the wound should be closed by sutures. In those advanced cases in which septic micro-organisms have joined the bacilli of tuberculosis in their attack upon the joint, and in which, in spite of rest on a splint, the use of antiseptic lotions, and the adoption of every local and general measure which might prove helpful, the joint is steadily getting worse, some operative procedure may be necessary. Probably the Röntgen rays have already shown advanced disorganization of the ends of the bones, with, perhaps, the existence of local necrotic areas. But even without these evidences it is obvious, from the failing condition of the child, the displacement of the head of the tibia, and the painful state of the articulation, that something active must be done: arthrectomy and excision may therefore be considered.

Arthrectomy (Erasion).—It may suffice that the joint be opened by a free semilunar incision, that the swollen pads and granulations of the synovial

Fig. 49.—Leather side-splints applied to a tuberculous knee, with a hinged attachment to the heel.

membrane be dissected out and scraped away, that the surfaces be washed over with a strong antiseptic solution, that the wounds be closed, and the limb be readjusted on the splint. The best result that is then attainable is a straight, synostosed knee; no attempt should be made to impart movement to the joint.

Excision.—But if, on opening the joint, the destructive changes are found much further advanced than was suspected, as is likely the case—if, for instance, the crucial ligaments are soft and useless, or if ulceration of the cartilages has extended far backwards, or deeply into the tissue of the femur or tibia,—complete excision will have to be undertaken, implying, of course, thorough erosion of all the affected tissue.

Amputation.—Lastly, there are certain intractable cases of tuberculous disease of the knee in which, either with or without the invasion of septic micro-organisms, the joint is so large, the limb so wasted, and the patient in such a miserable physical condition, that neither of the two operations just mentioned can be recommended, and to allow the patient to remain unrelieved is to court disaster. It may be, indeed, that there is already some tuberculous manifestation in the lung or skin, or in some other joint, or that the urine is albuminous, or that the patient is rapidly wasting. In these conditions amputation through the lower third of the thigh is likely to effect a change as instantaneous as it is happy.

The Ankle-Joint or Tarsus.—The first thing to do is to fix the foot at a right angle in some retentive apparatus (*Fig. 50*); if a Thomas's knee-splint is used with a patten the patient can be allowed to walk about. The Bier treatment, rest, time, and patience work wonders, and there need be no haste to resort to incision or erosion. In certain intractable cases, however, a Syme's amputation is called for, which is far better in the circumstances than any partial amputation of the foot.

Fig. 50.—Tuberculous disease of the ankle-joint treated by leather side-splints. The foot is not sufficiently dorsiflexed, but possibly this was the best position obtainable at that time.

Sacro-iliac Disease is a very serious manifestation of tuberculosis; it does not allow of the patient being up and about during treatment, and there is nothing for it but to keep him continuously in the horizontal position. Tuberculin injection may be tried, and everything should be done in a general way to improve the health and

vigour. Tuberculous "abscess" may be dealt with as mentioned in the paragraph upon hip disease, and trephining and erosion of the joint may be called for. But there should be no haste on the part of the surgeon to perform a radical operation on the joint: the wound may never heal. If, as is too likely to happen, the area becomes septic, antiseptic vaccination must be tried; but the outlook is very unhappy.

Edmund Owen.

KERATITIS.—(See CORNEA, DISEASES OF.)

KERATOCELE.—(See CORNEA, DISEASES OF.)

KIDNEY, MOVABLE.—The efficient treatment of movable kidney is intimately dependent upon the proper diagnosis. Four distinct classes of cases will be met with:—

1. Patients with a symptomless movable kidney.
2. Patients with movable kidneys where the other abdominal organ are also

loose, and where there are well-developed signs of neurasthenia, but no severe renal pain.

3. Patients with recurrent attacks of renal colic, with or without hæmaturia, which are obviously due to mobility of the kidney.

4. Patients with movable kidneys which are the seat of intermittent hydronephrosis, of stone, or of other disease.

In *Class 1* no treatment is necessary; nor is it advisable to acquaint the patient with the undue mobility of the organ, if she is unaware of the abnormality.

In *Class 4* the treatment is operative, and the difficulty lies chiefly in the diagnosis.

In a clearly-defined example of *Class 2* the treatment is non-operative, while in a pronounced case of *Class 3* nephropexy is indicated.

The intermediate cases between the last two classes give rise to difficulties in diagnosis, and account for many failures in treatment.

Non-operative treatment should be tried in all cases which come under *Classes 2 and 3*.

The treatment of neurasthenia should be carried out; the increase of the body fat should be encouraged by diet, cod-liver oil, and milk in spare subjects, and an abdominal belt should be worn. The belt should support the abdominal wall, and press upwards and backwards. It may either be a separate structure, or a specially made attachment to a well-fitting corset. The latter is preferable when it can be carried out, for then there is no need for the irksome perineal straps which are necessary to prevent the detached belt from working upwards. Kidney belts are made of many materials, and the details of their structure may be left to a good instrument maker, or a corset maker guided by the surgeon. They should have an insertion of strong elastic webbing at either side, and are better laced than buckled, since the latter method of union is more bulky. They should be stiffened by one or two vertical supports of whalebone.

Pads of various kinds have been used. No form of pad can press with sufficient force or precision to maintain the kidney in place without at the same time causing troublesome pressure upon the colon and other abdominal organs. A pad in some degree restrains the movement of the abdominal wall on the side of the movable kidney, and in this way gives a sense of comfort and support. The best form of pad is a flat indiarubber bag, which is distended with air or glycerin, and fits into a pocket in the proper position on the inside of the belt. The belt is worn over a well-fitting under-vest, and is discarded at night, but reapplied before rising from the recumbent posture.

The patient with a movable kidney should avoid sudden and violent movements. Horse and other vigorous exercise should be interdicted. The danger is, however, more frequently of the opposite nature, and these patients should not be allowed to indulge in a semi-invalid existence, spending their lives upon the couch or bed.

Operative treatment consists in nephropexy, and there are many varieties of the operation, dependent upon the individual taste or experience of the surgeon.

Operation is indicated in all cases where genuinely severe symptoms can be focussed on the movable kidney, where enteroptosis is not a marked feature of the case. It is likely to be followed by complete relief where definite crises of renal pain are present, where hæmaturia attends these attacks or follows exertion, and where signs of intermittent hydronephrosis, even of a slight degree, can be elicited.

Operation is imperative where hydronephrosis, although intermittent, is marked, and where stone or other renal disease has been diagnosed. (See also GASTROPTOSIS and NEURASTHENIA.)

J. W. Thomson Walker.

KIDNEY WOUNDS.—(See ABDOMINAL INJURIES.)

KNEE-JOINT, INTERNAL DERANGEMENT OF THE.—The semilunar fibro-cartilages are connected by their extremities with the head of the tibia, whilst their thick convex borders are attached to the margins of its tuberosities by the coronary ligaments. The convex border of the internal cartilage is closely connected with the internal lateral ligament, but attachment of the outer disc to the external lateral ligament is prevented by the intervening tendon of the popliteus, lubricated by the articular synovial membrane. Thus the internal fibro-cartilage is firmly fixed, whilst the other follows the movements of the tibia and femur. It is almost always the fixed or inner disc which causes the trouble; the outer one, being able to glide from pressure, escapes damage.

It does not follow that because a man has a loose semilunar cartilage his knee-joint must be opened. It should first be seen if the wearing of an apparatus may not render the knee comfortable and trustworthy. The illustration (*Fig. 51*) represents the sort of splint which may be tried. It is made by Montague, of New Bond Street, and it limits the movements of the joint to flexion and extension, entirely checking that rotatory inclination with which the slipping of the cartilage is usually associated. But if after fair trial it is found ineffectual, the advisability of resorting to an operation must be considered.

If the splint proves successful, it ought to be worn whenever the individual is

Fig. 51.

likely to run the risk of imparting rotatory movements to the tibia, as these are the usual cause of the slipping of the fibro-cartilage. At first he should always wear the splint; but later, when he has learnt to keep a constant watch against irregular and harmful movements of the leg and foot, he need wear it only when about to take part in such exercises as golf, dancing, or riding on horseback. As to football, hockey, and cricket, and other such sports and games which make for happiness in a young man, they must be given up temporarily, as they are almost certain to involve a twist of the leg.

In the event of palliative treatment proving unsuccessful, the loose part of the cartilage had better be resected, or, at any rate, as much of the cartilage as is in front of the lateral ligament. The plan of suturing the cartilage to the head of the tibia is not to be recommended: it is not sufficiently thorough.

Preparation for Operation.—The patient should be lying up for at least three days before the operation. During this time his urine is examined, and laxatives are given. He is ordered a light diet, and is put into strict training for a fortnight's close confinement to bed. His limb is shaved, and cleansed with turpentine. No water is to be used for the cleansing, or the antiseptic influence of the weak tincture of iodine which is to be applied before the operation would be interfered with. A leather splint is moulded on to the limb, so as to be in

readiness for application subsequently to the removal of the wooden splint on which the limb is placed after the operation. This leather splint is not absolutely necessary, but it is very convenient for application after the first dressing. The thorough painting of the inner side of the knee with weak tincture of iodine once more before the operation, as well as after the closure of the wound by sutures, should be done.

The skin in the neighbourhood of the incision is to be rendered as free of likely sources of contamination as it is possible to make it; it is as impossible to render the skin "absolutely aseptic" as it is to obtain, theoretically, a perfect vacuum under the air-pump. It is advisable that sterile indiarubber gloves be used for this operation; there can be no doubt that the risk of infecting the joint is thereby lessened, for the surgeon cannot make his hands absolutely sterile.

The swabs and gauze—which no one touches but the surgeon and his assistant—are duly sterilized, as are also the instruments and the sutures, and the less the interference with the interior of the joint the better. Certainly the naked finger should not be introduced into it.

Operation.—A three-inch vertical incision is made a little to the inner side of the patella, and, all bleeding having been arrested, the synovial membrane is opened, when, as likely as not, the fibro-cartilage is seen lying across the top of the internal tuberosity of the tibia, and perhaps detached to a considerable extent from the internal lateral ligament. This being the case, the knee is flexed, the cartilage is cut across as far back as possible, and the loose part removed. Sometimes the cartilage is found broken, twisted, or curled up.

There is often a large amount of bleeding, and every vessel should be clamped before the synovial membrane is opened. Sometimes the torn or crumpled cartilage is found far behind its normal position; but whether this is so or not, it ought to be firmly gripped in a strong pair of clip-forceps and then cut across as far back as possible. If, after its removal, there is much bleeding into the joint, the cavity may be washed out with warm carbolyzed water, 1-80. Some surgeons would be content to use "normal saline" solution for this purpose, but I would advise the operator who is not too proud to call himself an *antiseptic* surgeon, as opposed to *aseptic*, to put the more recent principles on one side for this operation, and to hold on to the old, well-tried, and faithful antiseptic method of Lister.

Some surgeons write of removing the internal cartilage as if they took the entire crescent away. This, however, is not required, or, I think, quite practicable; it is the anterior part which gets caught between the bones and does the harm, and it is only this anterior part which need be resected. However, if the disc is actually detached from the internal lateral ligament, it may be pulled well forwards, and then be divided posterior to the ligament—as far back, indeed, as possible. It may be cut by a strong, narrow-bladed knife or by a pair of scissors.

The wound in the synovial membrane is closed by fine silk sutures, and the incision in the skin is stitched up with silk or silkworm gut. Catgut would answer well if only one could be *absolutely certain* of its being aseptic. The region of the operation is then painted over with weak tincture of iodine (B.P.).

A drainage tube may be left in for twenty-four hours, its end being secured by a skin stitch. After the gauze dressing is applied, the limb is placed on a long back-splint with a foot-piece, and raised on a pillow. On the sixth day after the removal of the drain, and the seventh day after operation, the surface stitches are taken out, a collodion dressing is applied, and the limb is fixed up in the moulded leather splint which was prepared some days before the operation—the sort of splint which is shown in *Fig. 49* on page 579.

A few days later the patient is allowed to shift himself from the bed to the

sofa, and in another week he is permitted to walk about the room, the limb being protected by the leather splint.

It sometimes happens after the operation that the joint becomes distended even when the tube is still in position, a collection of sero-synovial fluid taking place in the sub-crural pouch of the synovial membrane. In these circumstances an incision should be made without delay through the quadriceps, in such a way that the distention may be thoroughly relieved, a drainage-tube being left in for a day. I have had several cases in which I have had to resort to this treatment. The tension being removed, the temperature comes down, and the patient is rendered comfortable and able to sleep. From the fluid which I thus removed in a rather anxious case of this sort, a culture of *Staphylococcus albus* was obtained; nevertheless, everything went quite well subsequently to the joint having been irrigated with a weak antiseptic lotion.

Should a joint become septic after the operation, with local redness and swelling, and should creamy, blood-stained fluid ooze from it, which the bacteriologist shows to be teeming with foul micrococci, a consultation should at once be held as to the course of action. Probably the best thing would be to give an anæsthetic and make free incisions in well-planned situations, and having washed out and dried the cavity, to paint every area over, first with pure carbolic acid, and afterwards with absolute alcohol, so as to limit the cauterizing effect of the acid. The cavity should then be stuffed with mercuric gauze, and the limb placed on a back-splint. Either with or without an examination of the patient's blood having been made, the increase of his resistance to the attack of the septic organisms in question should be sought by the injection into his tissues of a sterile culture of the particular organism indicated. If in these anxious and disquieting circumstances the treatment is prompt and thorough, there is hope for recovery of the patient with a good working joint. But one has heard whispers of cases in which synostosis has followed septic invasion of the joint, and of others in which the surgeon has been compelled to amputate through the thigh in order to save the patient's life.

There is this about the operation for the removal of the loose fibro-cartilage: it is completely successful. I have met with no cases in which the result has been mere *improvement*, or anything but an unqualified success. (I am not alluding here to the risks attending the operation, but am speaking only of the actual result of the removal of the loose body so far as the mechanics of the joint are concerned.)

I know nothing in the whole range of operative surgery which could cause a surgeon such distress as a knee-joint which is inflaming and becoming painful after an operation for internal derangement—an operation which is generally resorted to in the case of a strong, vigorous individual in the very prime of life—an operation, moreover, that was not of absolute necessity. The worst, as a rule, that could be said for the knee was that it was not “trustworthy”: that it was apt to throw the individual down on the rink, in the field, the street, or the ball-room; that when an apparatus was worn the knee generally behaved fairly well, though even then a slipping or locking sometimes occurred; that the condition was perhaps nothing worse than “vexatious,” or inconvenient, but that as the individual knew of exactly similar cases in which a perfect result had followed operation, he or she would like it done, and was prepared to take all risks in connection with it. But patients do not always know what risks they are running when they submit themselves to operations. I think I have said enough to make the warning clear that the opening of a healthy knee-joint is an operation that is not to be lightly undertaken; and I do not believe that any hospital surgeon who has had his fair share of these cases will think that I have made too much of it. With due care the cases may be expected to go right:

they almost invariably do so ; but I hold the opinion that no one ought to consider himself qualified to undertake this operation unless ample personal experience has proved to him that he may confidently trust himself and his methods. There is not an operation in the whole field of surgery which can be performed with "no risk," nor is any surgeon ever justified in saying or implying to the contrary—not even with the proper desire of inducing a patient to screw up his courage for an absolutely necessary treatment. And in the class of cases under consideration the surgeon must proceed with the very utmost care and circumspection.

Edmund Owen.

KNOCK-KNEE.—This is the name applied to a deformity where the tibia and fibula form an abnormal lateral angle with the femur, the apex being inwards. There are two varieties: one is associated with general rickets; the other, occurring from twelve to eighteen years, is static in origin. A flattened or everted foot generally co-exists. Knock-knee is often mechanically produced. If a plumb-line be dropped from the head of the femur it will drop outside the centre of the knee-joint. This is, of course, more marked in women than in men. The external condyle of the femur, therefore, and the external tibial facet transmit more weight than the inner side, because the centre of gravity is to the outer side of the joint. Folk tired from overstanding, instead of using their muscles to stand erect, substitute their ligaments. They do this by extending their knees and everting their feet. As a result the external condyle is atrophied.

There are three chief deformities associated with knock-knee: (1) Obliquity of the line of articulation; (2) Difference in the condyles of femur and tibia; (3) Bending of the shafts above or below the joint.

In rickets the deformity is often associated with bowing or anterior curving of the tibia.

TREATMENT.—If knock-knee is associated in a very young child with active rachitic manifestations, it is best placed in a double Thomas's hip-splint, with head-piece attached, and two lateral bars to which the knees must be bandaged. The child must be carefully dieted and kept in the sun until the bones have hardened. He may then be massaged and exercised, and allowed to walk. It is most important not to allow these children to crawl or walk, and correction during recumbency effectually solves the problem of treatment. Cod-liver oil is almost a specific.

It has been observed that quite a large proportion of patients recover without treatment; but as it is impossible to foretell which cases will recover, it is wise to treat every case. In very mild cases recumbency, massage, open air, and manipulation will suffice. With one hand the surgeon will press upon the lower part of the femur outwards, and with the other the lower end of the fibula inwards.

As walking with the feet turned out stretches the internal lateral ligament and increases the deformity, the child should be taught to walk with inturned or parallel feet. For the same reason the heels of the boots should be raised on the inner side. These simple procedures may suffice to check and correct a genu valgum.

Mechanical Treatment.—Knock-knee at any stage may be cured by proper splints, but such treatment in later adolescence is not justifiable, because of the time occupied and the weakening of ligamentous structures.

Many surgeons, and all instrument-makers, supply jointed splints for the correction of knock-knee. These are quite useless. To succeed, one must apply lateral pressure while the knee is fully extended. As soon as flexion begins, the corrective pressure-strain of the splint is relaxed and soon disappears. All

knock-knee deformity disappears long before voluntary flexion reaches 90° ; therefore, when any degree of corrective pressure is applied by splints having an antero-posterior joint at the knee, the patient flexes his legs slightly and all pressure is removed.

The simplest splint for the treatment of knock-knee is a bar of iron running into the heel of the boot, placed to the outer side of the limb and reaching as high as the great trochanter. A posterior bar reaches well above and below the knee (*Fig. 52*). The knee is first bandaged to the posterior bar to keep it fully extended, and afterwards to the outer bar to correct the lateral deviation. During the night, shorter splints may be applied to keep up the improved position; later, the day splints can be discarded and only the night splints used.

The test of recovery by which we know whether we may discard the splint is important, and is not referred to in books. So long as the ligaments are stretched, lateral movement with the knee straight can be passively produced

by the surgeon. The splints cannot be discarded till this lateral movement disappears. Even then it is well to let the patient wear the altered boot, and walk with parallel feet.

When knock-knee is complicated by bow-legs, as is often the case in rickets, care must be taken not to correct the latter, or knock-knee would be increased.

Treatment by Manipulation.—Many surgeons advocate the manual rectification of knock-knee, and the procedure seems to be free from risk. Fracture sometimes occurs through the condyle, sometimes above, but very rarely are the ligaments torn. The knee is fully extended, and the lower end of the femur

is grasped in one hand, while with the other the lower end of the tibia is forced inwards. The limb usually straightens following a greenstick fracture. It is necessary to keep the leg in splints for six weeks.

Treatment by Osteoclasis.—In cases which will not yield to the hand, a Thomas or a Grattan osteoclast may be applied. If the deformity is in the upper part of the tibia, the fracture may be produced there. If in the femur, the ploughing blade of the osteoclast may be placed above the condyles.

Treatment by Operation.—This will consist in an osteotomy of the femur or in the removal of a wedge from the tibia. The osteotomy may be done with a chisel from the inner side (Macewen), or, as practised by the author, with a protected subcutaneous saw from the outer side.

Robert Jones.

KRAUROSIS VULVÆ.—For the treatment of this condition, see the article on PRURITUS VULVÆ. If milder measures fail, it may be necessary to remove all the affected skin and mucous membrane. An additional argument in favour of operation may be found in the fact that carcinoma sometimes supervenes on this condition.

H. Russell Andrews.

Fig. 52.—The Thomas Knock-knee Brace.

LACRYMAL APPARATUS, DISEASES OF.

Acute Inflammation of the Lacrymal Gland (Dacryo-adenitis).—It has only recently become recognized that this disease is by no means uncommon. The symptoms are acute: great swelling of the lids and conjunctiva, tenderness, with brawny thickening over the lacrymal gland, enlargement of the preauricular gland, pain, and general febrile symptoms.

Hot fomentations, leeches to the temple, purgation, and antiphlogistic treatment will generally subdue the inflammation in a few days. Should, however, the gland suppurate, it may be necessary to divide the external canthus with a pair of scissors (canthotomy), and having everted the upper lid, incise the abscess. This, however, is seldom necessary, for the abscess almost invariably bursts into the conjunctival sac, when the symptoms are at once relieved. Rarely, the pus escapes into the orbital tissues, giving rise to an acute orbital cellulitis; or through the skin, when a troublesome fistula may result.

Lacrymation and Epiphora.—These terms, both used to imply an overflow of tears, have a widely different significance.

Lacrymation implies an excessive secretion of tears, which flow over on to the cheek owing to the inability of the normal excretory passages to cope with the increased flow. The treatment of this symptom is therefore described under the various injuries and diseases of the eye which cause a reflex hypersecretion of the lacrymal gland.

Epiphora, on the other hand, signifies an overflow of tears brought about by some imperfection in the excretory passages (puncta, canaliculi, lacrymal sac, or nasal duct).

In the treatment of epiphora we may first classify the conditions which give rise to this symptom: (1) *Stenosis or eversion of the punctum* (including ectropion). (2) *Obstruction of the canaliculus*. (3) *Obstruction of the nasal duct*.

1. *Stenosis or Eversion of the Punctum* (including ectropion).—This most frequently results from chronic ciliary blepharitis. Should repeated dilatation with a Lang's dilator, with treatment of the diseased lids, fail to relieve the epiphora, the canaliculus must be slit up for its outer two-thirds. This is often more successful if combined with removal of a small portion of the inner wall of the canaliculus. The inner wall is picked up with a fine pair of forceps, and a quadrilateral portion is excised with scissors. (For method of dilating the punctum, and slitting the canaliculus, see CHRONIC DACRYOCYSTITIS, *infra*.) Rarely we meet with cases of congenital occlusion of the punctum resulting from a membranous pellicle—it is only necessary in such cases to rupture the membrane with the dilator. Eversion of the lower punctum, so frequently met with in old people, and resulting from loss of tone in the orbicularis muscle, is one of the commonest causes of epiphora, a very slight displacement being sufficient to give rise to this symptom in a distressing degree. For milder cases an astringent application, e.g., zinc sulphate drops, 1 gr. to the ounce, or painting the conjunctiva with 2 per cent silver nitrate solution twice a week, may be all that is necessary. Failing this, after the application of a few crystals of solid cocaine, an oval area, 4 mm. by 2 mm., of the conjunctiva immediately behind and below the punctum, should be cauterized with the fine point of the actual cautery. By the contraction of the cicatrix thus formed, the everted punctum becomes restored to its normal position. Should epiphora continue, the canaliculus should be divided, and a quadrilateral portion of the inner lip excised. In facial paralysis, eversion of the punctum from sagging of the lower lid, with distressing epiphora, is a prominent symptom. If the paralysis is permanent, it becomes necessary to slit up the lower canaliculus to make a gutter for the reception of the tears, and in some cases to shorten the lower lid by an appropriate operation.

2. *Obstruction of the Canaliculus*.—The lower canaliculus may become blocked by cicatricial contraction, or rarely by a foreign body, e.g., eye-lash or concretion.

In cicatricial contraction, if epiphora exists, the canaliculus must be divided by a Stilling's knife, which must be passed right on into the sac. A style is then inserted, and worn for several months. Foreign bodies must be removed, if possible through the dilated punctum, but failing this, by a small incision in the long axis of the canaliculus.

3. *Obstruction of Nasal Duct* (see ACUTE and CHRONIC DACRYOCYSTITIS, *infra*).

Acute Dacryocystitis.—Acute inflammation of the lacrymal sac (acute dacryocystitis) most commonly follows a chronic obstruction in the nasal duct, as shown by the frequent history of long-standing epiphora. Occasionally it may result from a syphilitic or tuberculous periostitis, very rarely from secondary infection from the conjunctival sac.

In the earliest stages, continuous hot fomentations, purgation, and antiphlogistic treatment will sometimes cut short the attack. If, however, the symptoms do not subside in a few days, an anæsthetic (nitrous oxide or ethyl chloride) must be given, and an incision, one inch in length, made through the thickened tissues right down to the sac. The wound should then be packed with a narrow strip of gauze, and kept open until the discharge has ceased, fomentations being applied and continued until all the swelling has subsided. Later, the case should be treated as in chronic dacryocystitis.

Chronic Dacryocystitis.—In this disease, which commonly results from a stricture of the nasal duct, the lacrymal sac becomes distended with muco-pus, forming a swelling immediately below the tendo oculi (mucocoele). The disease is one of the most intractable with which we have to deal, and its successful treatment necessitates the exercise of great patience on the part of the sufferer and the surgeon. It may be laid down as a general rule in the treatment of this condition that the simpler methods should be exhausted before we resort to cutting instruments or the passage of probes.

The different methods which we may find it necessary to adopt should be carried out in the following order: (1) Syringing; (2) Passage of probes; (3) Wearing a style; (4) Excision of the lacrymal sac.

We commence the treatment by ascertaining if the lacrymal passages are permeable to fluids, and to do this we must first dilate the lower punctum.

Method of Dilating the Lower Punctum.—With the patient seated in a chair, the lower lid is slightly everted and at the same time rendered tense by being gently drawn downwards and outwards. A Lang's canaliculus dilator is then passed in a vertical direction until the point is well engaged in the lower punctum, when it is turned through a right angle and made to pass horizontally, until the opening is sufficiently enlarged. Having thus dilated the punctum, the nozzle of the lacrymal syringe filled with boracic lotion is inserted and passed along the canaliculus into the lacrymal sac. If, on gently emptying the syringe, the fluid does not regurgitate through the upper or lower punctum, but passes freely into the patient's nose and throat, we may hope to cure such a case without either probing or slitting the canaliculus.

The sac should be freely syringed every second day with boracic lotion, 10 gr. to the ounce, followed by astringent lotion, e.g., zinc sulphate, 2 gr. to the ounce, or protargol, 25 gr. to the ounce. After syringing with protargol it is always well to wash out the sac with boracic lotion before the patient is allowed to go. The patient should be directed to empty the sac frequently by pressure with the finger, and if there is any suspicion of rhinitis, a saline nasal douche should be used night and morning.

In the use of the lacrymal syringe, the greatest gentleness should be exercised, as too great force may lead to an extravasation of the septic fluids through the

diseased wall of the sac, with disastrous results, e.g., orbital cellulitis and optic atrophy.

Should we find it impossible to syringe fluids into the nose, the same treatment should be persevered with for two or three weeks, in the hope that the inflammation may subside, and the normal channels again become patent; but if at the end of that time we are still unsuccessful, an attempt must be made to dilate the stricture by means of probes.

If the lid is sufficiently lax, a small probe may often be passed down the nasal duct without dividing the canaliculus; but if any difficulty is experienced, either from rigidity of the lid, or in finding the passage, the outer two-thirds of the lower canaliculus should be divided before attempting to dilate the stricture.

Slitting the Canaliculus.—A drop of 2 per cent cocaine is instilled into the conjunctival sac, and a few crystals of solid cocaine are placed along the line of the proposed incision. The surgeon stands behind the patient, who is seated in a chair with the head thrown well back and comfortably supported. Usually the lower canaliculus is the one selected, as being more convenient for subsequent probing or for wearing a style. The lower lid is everted and drawn downwards and outwards in order to make the parts tense. The punctum is now dilated, and a Tweedy's canaliculus knife, with the cutting edge directed upwards and backwards, is passed in the same way as the dilator (*vide supra*) along the canaliculus, until the point is distinctly felt to impinge against the lacrymal bone. The knife is now raised until the canaliculus is divided for the outer two-thirds of its extent. It is most important that the incision should lie on the conjunctival surface and not on the free border of the lid, as the latter renders satisfactory drainage impossible. After the little operation is completed, the lips of the wound will speedily unite unless special care is taken to keep them apart for a few days by the passage of a small probe, or the same result may be obtained by snipping off a small quadrilateral portion of the posterior lip of the incision.

Passing a Probe.—The position of the patient and surgeon are the same as for opening the canaliculus. The smaller sizes of Couper's bulbous-pointed probes are the most generally useful, and to alleviate the pain and facilitate the passage of the probe, its end should be well coated with a 2 per cent cocaine ointment. With the probe held lightly between the finger and thumb, it is passed horizontally along the opened canaliculus and into the sac until it is *distinctly felt to strike the lacrymal bone* and there is no dragging of the lid. It is most important that careful attention should be paid to this detail; otherwise a false passage will almost certainly result. Keeping the point of the probe pressed gently against the lacrymal bone, the hand is raised until the probe points downwards and slightly outwards and backwards. Gentle pressure is then exerted, when the probe will be felt to pass down the nasal duct. The amount of force to be used must depend to a great extent upon the experience of the surgeon, and it is only necessary to point out how extremely easy it is to make a false passage. Having passed a small probe (No. $\frac{1}{2}$ or 1), we proceed at intervals of a few days to dilate the stricture with larger probes, but it is seldom necessary to go higher than a No. 4. This probe should be passed once a week for some months, until regurgitation and epiphora have entirely ceased. On no account should probing be immediately followed by syringing, or disastrous results may ensue, e.g., orbital cellulitis.

Continuous dilatation of the stricture by wearing a style, a form of treatment much in favour with some surgeons, should be preferred to probing under the following conditions: (1) When probing is too painful; (2) When regular attendance is impossible; (3) When the stricture again contracts rapidly after dilating.

Unfortunately there are many cases of chronic dacryocystitis in which conservative treatment either fails or becomes impossible from the demands upon the patient's time. In such cases we must excise the lacrymal sac. This operation, which until recent years has been done but little in England, gives the most admirable results, and contrary to what might be expected, the resulting epiphora is slight, and frequently only noticeable in a cold wind.

Excision of the Lacrymal Sac is indicated in the following conditions: (1) When the sac is distended; (2) When conservative treatment has failed; (3) When a spreading ulcer of the cornea associated with a mucocele progresses in spite of the ordinary treatment; (4) When an urgent intra-ocular operation is indicated, e.g., glaucoma. In the less urgent operations, e.g., cataract extraction, it is generally wiser to excise the sac some weeks before doing the extraction; (5) When the sac is tuberculous; (6) When there is necrosis of bone.

Congenital Lacrymal Obstruction.—Not infrequently we meet with cases of lacrymal obstruction associated with dacryocystitis (acute or chronic) in the newly-born, resulting from the nasal duct being blocked by epithelial débris. These cases, as a rule, can be cured by frequent syringing; but failing this, the passage of a No. 1 Couper's probe down the duct through the dilated punctum seldom fails to bring about a complete cure.

Fistula of Lacrymal Sac.—This condition is a not infrequent sequela of acute dacryocystitis. The treatment consists in excising the fistulous tract and restoring the patency of the lacrymo-nasal passage, or excising the sac and the fistulous tract at the same time.

Ilbert Hancock.

(*Revised by W. T. Lister.*)

LARYNGEAL OBSTRUCTION.—The causes of laryngeal obstruction from intrinsic changes in the larynx may be broadly classified into (1) Diphtheritic; (2) Non-diphtheritic affections. In the latter group are included acute simple laryngitis, syphilitic and tuberculous laryngitis, acute purulent perichondritis, œdema of the larynx, neoplasms of the larynx, and the impaction of foreign bodies.

1. Diphtheritic Laryngitis.—In its *primary* form this is an exceedingly rare disorder, and indeed the condition can be absolutely identified only by obtaining a culture of the Klebs-Loeffler bacillus from the interior of the larynx. *Secondary* diphtheritic laryngitis is easily identified by finding evidence of the primary infection in the pharynx or the nose.

When the swelling in the larynx is so great as to seriously impede the entry and egress of air, the air-passage must be kept patent by artificial means. (This is merely an adjunct to the routine treatment of DIPHTHERIA, which see.) The two means at our disposal are intubation and tracheotomy. When the child can be kept continuously under the immediate supervision of a medical man, the former method has many advantages over the latter. Intubation can be performed quite soon after the onset of obstructive dyspnoea, since the risk of injuring the larynx is exceedingly slight. No anæsthetic is required. The formation of an open wound in the neck, with the associated risk of infection, is entirely avoided. The inspired air is warmed and filtered by passing through the normal channels for respiration, which is not the case after the performance of tracheotomy. Lastly, experience has shown that in cases of diphtheritic laryngitis the mortality is less after intubation than after tracheotomy. The great disadvantage of this method is the need for the continual presence of a medical man, since the replacing of a tube that has been coughed out cannot as a rule be performed by a nurse, and death may ensue from suffocation before help can be obtained. It is thus a mode of treatment that must be limited almost entirely to cases in a hospital. (For further details of the operation, see under DIPHTHERIA.)

If the dyspnœa is not relieved after intubation has been performed, then *tracheotomy* must be resorted to. The directions for performing this as a leisurely surgical operation are too well known to need repetition, and may be found in any text-book. The opportunities for performing it under such conditions are, however, far fewer than those for an emergency operation. Under such conditions, as a rule, it has to be performed with great rapidity in cases of extreme urgency, and the following method will be found to be a safe and reliable one.

A sharp scalpel and a pair of Spencer Wells' forceps are the instruments required. Place the child in the recumbent position, with a sand-bag under its shoulders, so that the head and neck fall backwards, with the skin more or less tightly stretched over the front of the neck. Identify the lower border of the cricoid cartilage by running the finger up the middle line of the neck. With the index finger and thumb of the left hand grasp the trachea firmly on either side immediately below this point, and do not release it until air is entering freely through an opening in its anterior wall. With the trachea thus fixed, cut boldly from above downwards in the centre of the space between the thumb and finger. The anterior surface of the trachea is thus rapidly exposed. Then grasp the blade of the scalpel near to the point and incise the trachea freely from below upwards. Insert the tip of the forceps into the opened trachea and separate the blades. By this means the opening is made to gape, and the trachea can be steadied in the wound. Not until this has been done should the hold on the trachea by the left hand be released. A piece of ordinary rubber drainage tube can be inserted as a temporary substitute for a proper tracheotomy tube. In making the incision in the soft parts of the neck with the trachea thus fixed there is no necessity—and frequently no time—to search for the interval between the infra-hyoid muscles, to identify the isthmus of the thyroid gland, or to avoid the distended veins which are described as a likely source of danger. Hæmorrhage, as a rule, is unfortunately only too scanty, since a free flow of blood would be a welcome relief to a badly distended right side of the heart. Moreover, the entry of blood into the trachea can be averted easily by pressing back the soft tissues on both sides of the wound with the thumb and finger at the same time as the opening into the trachea is mopped by wool. The tube must be kept clean by spraying at short intervals with an alkaline lotion, and when necessary the inner tube must be removed for a more thorough cleansing. Feathers or other bodies must never be thrust down a tube to clean it. The outer silver tube should be changed at the end of twenty-four hours after operation, and a rubber tube may be substituted for a silver one within about three days.

2. Non-diphtheritic Affections.—Either or both of the foregoing methods of treatment may be necessary in cases of *non-diphtheritic origin* after other measures have failed.

In *acute simple laryngitis* the bed must be drawn up alongside a window widely open at the bottom. The child must be covered by blankets, and the head and hands protected by a warm cap and gloves. Hot-water bottles must be kept in the bed. Glycerin of belladonna fomentations or ice-bags should be applied to the front of the neck, and plenty of hot drinks administered. By these means the maximum amount of pure air is ensured to the child, and in many cases after a short time the patient falls into a quiet sleep. Preliminary measures of treatment have so frequently been directed towards keeping the child in a stuffy room, and thereby directly aggravating the symptoms caused by an imperfect supply of oxygen, that the adoption of the above methods often affords instantaneous and permanent relief. But when these measures fail after a short trial only, intubation must be performed. (See also CROUP.)

In *œdema of the glottis* as a secondary condition in renal disease, or following a scald or burn, intubation is useless on account of the *œdematous* tissue which overlaps the opening of the tube, and because of the extensive ulceration that the tube causes in these cases. Tracheotomy must be performed at once. But recurrent attacks of laryngeal obstruction due to *œdema* of the aryteno-epiglottic folds may occur in subjects otherwise healthy. The *œdema* is part of a generalized congestion of the mucosa of the pharynx in their immediate neighbourhood, due to the presence of septic embedded tonsils. No relief is afforded by intubation, and examination by Brünings' tubes shows that the upper end of the intubation tube is occluded by the swollen aryteno-epiglottic folds. Immediate removal of the tonsils by dissection affords instant relief and effects a permanent cure. If this is not done, tracheotomy must be performed—a very undesirable alternative, as it treats only the symptom of obstructed respiration without affecting the cause of it.

New growths of a simple nature, and foreign bodies, must be removed by intralaryngeal operations, if possible. A solitary papilloma lends itself well to this form of treatment, but multiple papillomata tend to recur so frequently after intralaryngeal removal that the writer has finally abandoned this method. For multiple cases a thyrotomy should be performed and then the whole of the papilloma-bearing area removed by dissection. The wound in the larynx and neck is then closed in the usual manner, and a large-sized intubation tube, well greased with ung. iodoformi or any other simple ointment, is introduced into the larynx through the mouth. This should be removed for purposes of cleaning at the end of forty-eight hours, and then replaced. Daily removal should then be begun, but the tube must be used for about a month or six weeks. At the end of that time the interior of the larynx should be completely healed, whilst any tendency to narrowing of the larynx by the formation of bands or adhesions has been prevented by the presence of the tube. A final inspection with Brünings' tubes will exclude any recurrence of the growth having occurred. Treated in such a way, these otherwise troublesome cases do well, and the power of speech appears to be very slightly impaired after about a year's time from the date of operation. Other methods of treatment that have recently been introduced with advantage are the direct application of radium to the growth, and "desiccation" by means of high-frequency currents.

The detection of foreign bodies may be aided by *x* rays. Laryngoscopic examination should be attempted in all cases, and under a general anæsthetic when necessary. But by far the most valuable method of examination in all doubtful cases—and the only possible one in children—is the direct-vision method by the aid of Brünings' tubes. For this a general anæsthetic is advisable, and in children is a necessity.

In frequently recurring attacks of laryngeal obstruction without any obvious cause, *syphilis* should be suspected and antisyphilitic remedies used. In advanced cases of *tuberculosis* with secondary involvement of the larynx, tracheotomy may have to be performed for the relief of obstruction. (See also LARYNGITIS, and FOREIGN BODIES IN THE AIR-PASSAGES.) George E. Waugh.

LARYNGEAL STRIDOR (Congenital).—Although in most cases due to malformation of the epiglottis, which causes obstruction to respiration, this complaint may sometimes depend on want of co-ordination between the muscles which close the glottis and those which are otherwise concerned in respiration. Whether the defect is of the higher cortical centres, or of those in the bulb, is unknown. In many cases the affection subsides towards the end of the second year. It is however, persistent in some, but these are usually the subjects

of congenital spasticity or other forms of birth-palsy. Special treatment, unless nasal obstruction by adenoids or catarrh be present, is unnecessary.

Leonard G. Guthrie.

LARYNGISMUS IN CHILDHOOD (Laryngospasm, Laryngismus Stridulus).

This is commonly associated with tetany, convulsions, and rickets (*q.v.*). Intermittent spasm of the glottis (laryngismus) should be distinguished from congenital stridor, from the various forms of laryngitis, from dyspnœa due to laryngeal obstruction by a foreign body, and from dyspnœa dependent upon intrathoracic causes.

Laryngismus occurs under excitement, on suddenly waking, and on exposure to cold draughts. Hoarseness, continuous stridor, clanging cough, and pyrexia are absent in uncomplicated cases.

TREATMENT.—For the immediate relief of laryngismus, sponges wrung out of hot water should be applied to the front of the neck, and the chin should be drawn forwards. By the time a hot bath can be prepared, the spasm is usually over, or the infant is dead. But death from simple laryngismus is rare. When fatal, it is usually in association with enlargement of the thymus, and the so-called "status lymphaticus." Dangerous symptoms are sudden blanching, cessation of struggling and attempts to breathe, and wide dilatation of pupils. On their appearance, artificial respiration should be at once employed, and parents and nurses should be instructed in this method of restoration in all cases of laryngismus, in case necessity for its use should arise. Children in these dangerous conditions are too often hurried to the nearest chemist, doctor, or hospital, and are dead by the time they arrive. During artificial respiration, smelling salts may be held under the nostrils, but not whilst struggles for breath continue, for ammonia may increase spasm.

Very few cases of laryngismus resist treatment by suitable diet, and by castor oil suspended in mucilage, with rhubarb and bromide of potassium. Belladonna or chloral hydrate may be added, especially if convulsions have occurred.

Leonard G. Guthrie.

LARYNGITIS.—(See also CROUP, DIPHTHERIA, LARYNGEAL OBSTRUCTION, and MEASLES.)

1. Acute Laryngitis.—Primary acute laryngitis when it occurs in the adult is usually met with in males who have been indulging too freely in alcohol and tobacco, or over-using the voice. It also occurs in the course of the acute and infectious diseases, but more frequently in influenza, when the patient has persisted in using his voice during the attack.

TREATMENT.—Without treatment the attack will probably pass off in a few days and may leave no ill-effects behind, or it may become chronic. It is generally those who have to use their voices professionally who seek for advice, and often with the earnest request that they may be cured at once in order to fulfil an engagement. The risk of injuring the voice permanently in such cases is so great that it is best not to undertake them at all unless the patients will give up the engagement, for three or four days' complete rest of the voice is the essential element in treatment.

The patient should be put to bed, and given a mercurial purge. The windows should be kept open, and if the weather be cold, a fire lighted. If the patient complain of cold, a light Shetland shawl should be put over the head. Alcohol and tobacco should be strictly forbidden.

Internally, acetyl-salicylic acid (10 gr.) or pyramidon salicylate may be given thrice daily, especially if there be any fever, but if the temperature be very high, as occasionally happens in very nervous subjects, half-drop doses of tincture of aconite may be given every hour until it falls to 100° F.

Liquor ammoniæ acetatis in $\frac{1}{2}$ -oz. doses combined with 7-min. doses of spiritus ætheris nitrosi may be given every two hours, followed by hot weak tea or large draughts of hot barley-water, until perspiration occurs. Vapour in the form of 1 teaspoonful tinct. benzoin. co. to a pint of hot water should be inhaled at a temperature of 150–140° F. for ten minutes three or four times a day. The following prescription the writer has found very efficacious:—

R Sodii Bicarbonatis		Acidi Carbolici Puri	gr xv
Sodii Benzoatis		Glycerini	$\frac{3}{4}$ iss
Sodii Boratis	āā 3ij	Aquæ Destillatæ	q.s. ad $\frac{3}{4}$ viij

One part of this should be mixed with one of cold water, and put into the tumbler of a Siegle's steam spray. The spray must be so arranged on a table or chest of drawers that the patient's mouth is exactly opposite it and on the same level. If necessary the patient can be put on a chair and raised with books or pillows.

The patient should then put a large bath-towel round his neck and shoulders, and, taking hold of his tongue with one corner of the towel, pull it well out whilst sitting so that the funnel of the spray is not more than two inches from his open mouth. He should then, while keeping the tongue well out, inhale the vapour deeply into his lungs for five or ten minutes at a time—including also the nose, when there is catarrh of that organ—and then get back to bed and roll his head up in the shawl. This can be repeated three or four times a day.

When there is much pain, a mustard leaf will be found very soothing. It should be applied as follows: Cut it in half lengthways, and apply one half to the larynx just below the chin, and the other half below that, so that it forms a long narrow strip down the front of the neck. The leaf should be allowed to remain on for twenty minutes by the clock. On removing it, a little vaseline should be rubbed over the reddened surface, and some cotton-wool applied to it and kept on by a bandage.

A carbolio-acid compress will also be found very soothing. A doubled piece of lint about three inches wide, and long enough to go half round the neck, should be wetted with a solution of carbolio acid (1–60). This should be applied to the neck and covered with a piece of guttapercha tissue large enough to extend at least two inches beyond it on all sides. This should be kept on by applying cotton-wool and a bandage. Guttapercha tissue is preferable to jaconet or oil-silk, as it clings to the skin better, and prevents the evaporation of the carbolio acid. This can be kept on for twelve hours and then renewed.

From the very beginning it is of the utmost help to have the neck properly massaged for twenty minutes night and morning, and the use of an electric vibrator, such as Barker's, will be found a great adjuvant to the treatment, and will greatly help to prevent the disease becoming chronic, i.e., if the voice has been rested during the attack.

In patients with a rheumatic diathesis, ionic medication with 2 per cent salicylate of soda is useful both in relieving the pain and removing the hoarseness.

It is best not to begin tonics until the acute symptoms have passed off, and then the following mixture may be given:—

R Ferri et Ammonii Citratis	3ij	Ammonii Chloridi	3iv
Liquoris Strychninæ Hydrochloridi		Extracti Glycyrrhizæ	$\frac{3}{4}$ j
(1 per cent)	3i	Infusi Senegæ	q.s. ad $\frac{3}{4}$ vj

One-twelfth part thrice daily after meals in a wineglassful of water.

When the patient is fit to go out, the hot inhalations should be stopped, and the following spray be used four or five times a day :—

R Mentholis	gr xij	Olei Gaultheriæ	āā ℥ij
Camphoræ	gr vj	Olei Cinnamomi	℥iv
Olei Eucalypti		Olei Adepsin	q.s. ad ℥j

To be sprayed into the nose and throat four or five times a day by means of a De Vilbiss spray.

2. Acute Œdematous Laryngitis, when it occurs primarily, may be set up by the sting of a wasp, the impaction of foreign bodies, or the drinking of corrosive or scalding fluids. Sometimes it occurs in patients of a well-marked rheumatic diathesis without any apparent exciting cause. It may also be secondary to septic inflammation of the pharynx from infection by some pyogenic organism.

TREATMENT must be based on the cause. In a great many cases the feeling of choking, even when there is not much œdema, frightens the patient so much that he will not allow any examination to be made. In that case large doses of bromide of potassium should be administered, and, if necessary, $\frac{1}{2}$ gr. of morphia should be injected, and the throat sprayed with a mixture of 20 per cent cocaine and 1–2000 adrenalin. A large dose of calomel should be given as soon as possible, and if there be any rheumatic history, salicylates in full doses.

Locally, the œdema must be reduced by scarifying the inflamed tissue by means of Mackenzie's laryngeal knife; this, however, must not be done in a haphazard way, but by means of the laryngeal mirror. If the operator is not expert in its use, it would be advisable for him to perform tracheotomy or laryngotomy, or intubation. (See LARYNGEAL OBSTRUCTION and DIPHTHERIA.)

3. Chronic Catarrhal Laryngitis.—In most cases this is due to an acute attack which has not completely resolved, but it may result from an extension of disease downwards from the nose, or upwards from the trachea. In both cases there is constant cough from an endeavour to get rid of mucus. It also occurs very frequently in gouty, rheumatic, and dyspeptic subjects, and in those who suffer from liver complaints or uterine troubles. It is also a concomitant of syphilis, tuberculosis, lupus, and some cases of paralysis.

TREATMENT will depend to a great extent upon the cause, but in every case rest of the voice is essential to success. This is the great difficulty in curing professional voice-users, to whom such vocal rest is often impossible. The use of alcohol and tobacco should be forbidden. For those who can afford it—especially if gouty or rheumatic diathesis be present—it is best to begin treatment by a course at Aix-les-Bains, Mont Dore, or Salsomaggiore, where the local treatment is thoroughly carried out. In no English spa (that the writer knows of) is the local treatment so well done, however good the general management of the cases may be. At home, the treatment recommended under acute laryngitis must be persevered with, but in the writer's experience the greatest good is obtained from skilful massage of the neck and larynx combined with massage, vibration, and ionization. In most cases of professional voice-users, the voice has been badly produced from the beginning and is extremely "breathy": it is sometimes very difficult to get patients out of their old habits, which is so necessary in these cases before they can learn to produce their voice with a wide-open pharynx, and therefore without "pinching" or "squeezing."

4. Hypertrophic Laryngitis.—This is only a more marked form of the condition just considered. Treatment is not satisfactory, but when the hypertrophy is situated in the interarytenoid space, it may sometimes be of advantage to

pinch out a piece of the hypertrophied mucous membrane with forceps. Ionization may also be tried.

5. **Atrophic Laryngitis** is generally associated with the same condition in the nose and nasopharynx, and should be treated on the same lines as these.

6. **Subglottic Laryngitis**.—Owing to the swelling taking place below the glottis, and therefore in a restricted space, this is a more dangerous form than any of the others previously mentioned. If the case is at all severe it should be kept under constant supervision, because at any time tracheotomy may be necessary.

7. **Chorditis Tuberosa**.—This is generally called “singer’s nodules,” but it more often occurs in teachers than in singers. It is in all cases due to a wrong method of voice-production, and it occurs more frequently in females than in males, because the former are more liable to anæmia, and so force their voice by using it when the larynx is anæmic, and because they have the smallest children to teach and have to speak in a higher pitch in the endeavour to make their voice heard over the din.

In all cases *absolute* rest of the voice must be secured, and if the nodule or nodules be not large this may be sufficient, combined with cold astringent sprays. But if the nodules be very large, the quickest way to get rid of them is by removal with forceps, which of course must be very cautiously done, especially in the case of a singer.

The “coup de glotte” has often been supposed to be the cause of the formation of these nodules, but it is only the case when the “coup de glotte” is improperly carried out, and when it is combined with abdominal or diaphragmatic breathing.

George C. Cathcart.

LARYNGITIS, CATARRHAL.—(See CROUP.)

LARYNX, FOREIGN BODIES IN.—(See FOREIGN BODIES IN THE AIR-PASSAGES AND ŒSOPHAGUS.)

LARYNX, MALIGNANT DISEASE OF.—Malignant growths in the larynx are nearly always squamous epithelioma, and their treatment depends chiefly on their situation. An intrinsic growth is one wholly within the larynx, that is, involving either the ventricular bands, the vocal cords, or the parts below. An extrinsic growth is one involving the epiglottis, the ary-epiglottic folds, or the arytenoids. Intrinsic growths grow slowly, and do not infect the lymphatic glands. Extrinsic growths are inclined to grow rapidly, and the glands are involved, often on both sides of the neck, almost from the commencement.

Intrinsic Growths.—These most commonly affect the vocal cords, and can usually be recognized at a very early stage. Whilst the growth remains intrinsic, shut up as it were in a cartilaginous box, the prospect of cure by free removal is most favourable, probably 70 to 80 per cent of cases remaining free from recurrence. Therefore operation may invariably be recommended, unless the patient’s general condition is such as to preclude any severe surgical procedure. The operations to be considered are thyrotomy, and total extirpation of the larynx. Removal through the mouth is not to be recommended, although occasional successes have been reported. Removal of half the larynx must also be condemned; if a growth is too extensive for thyrotomy, total extirpation is best.

Thyrotomy.—When a growth is limited to one vocal cord, or affects the anterior parts only of both cords, thyrotomy should be carried out. If the growth is so extensive that the soft parts of both sides of the larynx have to be cleared out,

it is certain that laryngeal stenosis will follow, and better results will probably be obtained by complete extirpation. Thyrotomy consists in opening the larynx through a vertical incision in the median line of the neck extending from the hyoid bone to within a finger's breadth of the sternum. The thyroid and cricoid cartilages and the upper rings of the trachea are carefully exposed by dissection, and all bleeding being arrested, the tracheal rings are divided and a Hahn's tube inserted. This is a tube covered by compressed sponge, which swells up when wet and completely closes the trachea, so preventing any blood entering. The larynx is now opened by dividing the thyroid cartilage and the soft tissues within it, precisely in the middle line. The two halves of the larynx are held apart by retractors, the growth carefully examined, and its extent determined. The interior of the larynx is painted with a solution of cocaine and adrenalin, which abolishes the laryngeal reflexes and greatly facilitates the subsequent procedure. The growth, with a sufficient margin of healthy tissues, is surrounded by an elliptical incision which is carried down to the cartilage, and then dissected off the cartilage with a blunt dissector, and removed in one piece. Hæmorrhage is arrested and all oozing stopped by applying a strong caustic, or a paste made by rubbing powdered tannic acid with a few drops of water. The edges of the thyroid cartilage are accurately approximated by one or two catgut stitches, passed through the lining mucous membrane as well as the cartilage. The skin wound may be partially closed, and the tracheotomy tube removed at once, or better, left in for twenty-four hours. The patient should take nothing by the mouth for the first twenty-four hours, after which cautious attempts at drinking should be tried. The tracheotomy tube being removed, the patient should sit up, leaning slightly forward, and swallow sips of boiled water. If the water enters the larynx it will come out by the wound, and the attempt must be at once discontinued. If the patient swallows properly, other fluids such as milk, beef tea, and jellies may be given. It should always be carefully noticed if these give rise to coughing, or if they return by the wound in the neck. This may occur at any time during the first four or five days, although the patient may be able to swallow on the first day. If swallowing is impossible, the patient must be fed two or three times daily through a soft feeding tube, which can be passed gently through the mouth, and the patient encouraged to swallow it. After seven or ten days the patient can usually swallow well, and healing is merely a matter of time.

As regards results, the operation is attended with no great danger, provided the patient is not too feeble and has no serious complications. The ultimate results as regards life are excellent when the operation is done in well-selected cases; many operators can claim 80 per cent of lasting successes. When one vocal cord only is removed, after three or four months it becomes replaced by a fibrous band which looks and acts very like a cord, and the patient can generally speak in a loud if somewhat hoarse voice. When parts of both cords are removed, more or less impairment of voice is inevitable. When the greater part of both cords has been removed, there may be so much subsequent stenosis that a permanent tracheotomy tube may be required.

Total Extirpation of the Larynx.—This operation should be practised in all cases of intrinsic disease when the growth is too extensive to be removed by thyrotomy, and also in many cases of extrinsic disease when the epiglottis or arytenoids or adjacent parts of the pharynx are affected, provided a reasonable prospect of removing the entire disease exists. A vertical incision is made down the median line of the neck from the hyoid bone to just above the sternum, and transverse incisions from sternomastoid to sternomastoid at each end of the vertical incision. The quadrilateral flaps thus marked out are turned outwards. The anterior triangles of the neck are exposed, and if there are any signs of

enlarged glands a thorough dissection of the neck should be carried out. The larynx and the upper rings of the trachea are freely exposed, the thyroid isthmus being divided, and the trachea is carefully isolated all round and completely separated from the oesophagus. The trachea is now cut right across transversely immediately below the larynx, and its end drawn forward into the lower transverse wound and fixed to the skin all round by a few sutures. This isolates the trachea from the wound, minimizes the risk of blood entering the lungs during the further stages of the operation, and allows the anæsthetic to be administered without interfering with the surgeon. The larynx is removed by careful dissection from below upwards, taking special pains not to button-hole the oesophagus. It is well to open the pharynx on the sound side first, so as to see the extent of the growth and ensure that as much of the surrounding healthy tissues as necessary is removed. A good deal of the pharynx may be cut away without impairing the success of the operation. The larynx being removed, there is a large gap left into the pharynx, and this must be closed very carefully by several layers of Lembert's sutures. The edges of the mucous membrane are carefully approximated by numerous close-set stitches of fine catgut. A second series of sutures is applied over this to unite the pharyngeal aponeurosis. All the divided muscles should then be sewn across so as to strengthen the new pharynx as much as possible. Finally, the skin wound should be closed by a few silk-worm-gut sutures, a drainage tube inserted, and ordinary dressings applied.

The results of the operation are fairly good, the immediate mortality being perhaps 12 to 15 per cent. By isolating the trachea and stitching it to the skin, and by closing the opening into the pharynx, the chief danger of the operation, septic pneumonia, has been greatly reduced. The patient is able to swallow from the first, and if the wound heals well there will be no need to feed him except by the mouth. Sometimes the wound gives way slightly about the fourth or fifth day, in which case tube feeding must be adopted for a few days. Often the entire wound heals by first intention. After recovery the patient is able to take food in the usual way, but can never dispense with the tracheotomy tube. Although unable to phonate, patients acquire a method of whispering which can be heard distinctly at several feet. The prognosis with regard to recurrence depends entirely upon the extent of the disease, being very favourable in intrinsic and unfavourable in extrinsic growths.

Extrinsic Growths.—In growths primarily extrinsic, removal can only be undertaken in the earliest stages. A small growth in the arytenoid region may sometimes be removed by a lateral pharyngotomy, and a growth in the epiglottic region by a sub-hyoid transverse pharyngotomy. Total extirpation of the larynx and removal of a portion of the pharynx may also be successfully carried out in a few cases. It must be borne in mind that the glands are always infected, and must be freely removed at the same time. These operations are attended with a high fatality, and recurrence is the rule, although the patients often remain free from disease for two years or so. It is possible that in the near future these growths may be more safely treated by diathermy; this avoids the chief dangers of the operation, whatever may be the ultimate results.

Where the patient's general condition, or the extent of the growth, or any other reason, forbids an attempt at complete cure, palliative measures must be adopted. These consist in relieving the pain and dysphagia by orthoform insufflations, morphia insufflations, or lozenges, and in most cases by giving opium internally in increasing doses (see also LARYNGEAL PHTHISIS). As soon as dyspnoea arises tracheotomy should be performed. The tube should be inserted as low down in the trachea as possible to diminish the likelihood of the tracheotomy wound becoming involved in the growth. In rare cases gastrostomy may be recommended.

H. Lambert Lusk.

LARYNX, TUBERCULOSIS OF (Laryngeal Phthisis).—In treating tuberculosis of the larynx it must be remembered that the disease is invariably secondary to tuberculosis in the lungs. At the same time, the disease in the larynx may give rise to the more severe symptoms; the loss of voice has a very depressing influence, and the pain and difficulty in swallowing may be such as to prevent sufficient nourishment or sleep. The laryngeal complication, therefore, greatly increases the gravity of the prognosis.

General treatment is of primary importance, and every case must be treated exactly as a case of phthisis, of which the laryngeal affection is merely an extension. This treatment is best carried out in a suitable sanatorium (see PHTHISIS). In addition, the patient with laryngeal complications should rest the voice; he may whisper, but even this should be reduced to a minimum. The cough, also, should be suppressed as far as possible. The patient must cough sufficiently to get rid of expectoration, but there is often a great deal of laryngeal irritation giving rise to useless cough. This irritation may be relieved by spraying the throat with simple cleansing alkaline lotions, such as a solution of borax, soda, and salt (5 gr. of each to the ounce of water), or by an oily spray containing menthol, camphor, oil of cloves, or similar oils, dissolved in liquid paraffin. Perhaps the best of all sprays to relieve cough is made from a solution of potassium iodide (8 gr. to the oz.) in a mixture of acetone 1, glycerin 2, and water 13 parts. If a drug is required, heroin or codeine in a sticky mixture is probably as safe and effective as anything.

The local treatment depends chiefly upon the site and extent of the local lesion and upon the patient's general condition.

1. If there is a tuberculous tumour in the larynx, either growing from a vocal cord or in the interarytenoid space, and the patient's general condition is good or his health improving, it will generally be wise to remove it. This can be done under local anaesthesia, with forceps or by curetting. After the growth has been removed, its base should be cauterized with a strong caustic, such as chromic acid or nitrate of silver fused on a probe, or with the galvano-cautery. The whole operation may be carried out with the cautery, the point being plunged deeply into the tuberculous tissue and three or four punctures made at each sitting. By this treatment a dangerous local lesion may be cleared away, with great improvement to the patient's general and mental condition.

2. In cases of superficial ulceration of the vocal cords, the surface of the ulcer may be curetted under cocaine, and then chromic acid or nitrate of silver freely applied. One to two sittings at intervals of three or four weeks often effect a cure if the patient's general condition is good. In some cases, when the ulcers have healed, the cords are left ragged, with small fibrous nodules. These nodules do little harm, except that they greatly impair the patient's voice. They may be removed either with forceps or with the cautery, usually with excellent results.

3. Where there is chronic thickening of the arytenoid region or of the aryepiglottic folds, with no tendency to ulceration—when the condition has become chronic, and the patient's general health is improving—the swelling may be reduced with the actual cautery. This is applied under cocaine, and the cautery point is thrust deeply into the oedematous mucous membrane. Two or three places only should be done at a sitting, and should be allowed to heal before other places are touched. If the punctures heal rapidly, and healing is followed by considerable reduction of the swelling, the treatment may be continued until all the swelling has disappeared. If this treatment is carried out in unsuitable cases, where the patient's general condition is bad, the cautery is apt to produce ulceration which tends to spread rather than to heal.

4. Localized ulcers associated with oedematous infiltration may be treated in a similar way, especially if not actively spreading.

5. If the epiglottis is ulcerated, or even infiltrated, especially if there is dysphagia, the epiglottis should be entirely removed. This operation can be carried out under local anæsthesia, the affected part being well painted with cocaine. A large punch forceps, such as that shown in *Fig. 53*, is then pressed down over the epiglottis so as to include the whole structure, which is removed with a single punch. This operation gives rise to very little bleeding or subsequent distress. The patients may immediately experience relief, and be able to take solid food with comfort. The operation should always be carried out when necessary, even if the patient's general condition is unfavourable, to relieve severe dysphagia. Large pieces of infiltrated mucous membrane in the arytenoid region have been similarly removed with punch forceps, and good results are reported, but I have no personal experience.

The above methods are indicated when the pulmonary disease is improving and the local condition is such that great improvement, or even cure, may reasonably be expected. When, in spite of general treatment, the chest condition is getting worse or the patient's strength is failing, the local treatment of the larynx consists merely in relieving the more distressing symptoms. These are *pain, dysphagia, and dyspnoea*.

Pain.—The pain may be relieved with lozenges of menthol and cocaine or

Fig. 53.—Punch forceps for the removal of the epiglottis.

Fig. 54.—Leduc's tube for insufflation by the patient.

orthoform. A very valuable remedy is the insufflation of orthoform in powder. This should be blown into the larynx about half an hour before the principal meal of the day, and may give relief to pain for twenty-four hours. The patient himself can be taught to suck up the orthoform into his larynx by means of a Leduc's tube (*Fig. 54*). The powder is harmless, and 5 to 10 gr. can be insufflated at each sitting. If these means fail to relieve the pain, heroin or morphine can be given internally or by hypodermic injection.

Dysphagia.—Where there is great pain or difficulty in swallowing, the food must be carefully prepared. As a rule, soft, semi-solid food of an un-irritating character can be taken better than liquids. No solid food should be given, and liquids should be thickened as far as possible by the addition of gelatine or starch. If, in spite of this, there is great difficulty in taking food, owing to the tendency for some of it to enter the larynx, Wolfenden's position should be tried. The patient lies prone, with his head hanging over the end of a couch, and sucks the nourishment up through a glass tube. The pain of swallowing may be relieved by a spray of cocaine before each meal, by a cocaine and menthol lozenge, or, better still, by insufflating orthoform as above described. When the dysphagia depends upon an infiltrated or ulcerated epiglottis, amputation of the epiglottis should be carried out, even in advanced cases of phthisis, if the patient is capable of standing it.

Dyspnoea.—In rare cases, where there is considerable infiltration and thickening in the region of the vocal cords, there may be dyspnoea; but, as a rule,

ulceration takes place before there is sufficient thickening to produce obstruction. If there is dyspnœa, relief may sometimes be given by simply puncturing the swollen tissues with a laryngeal curette under cocaine; but if this fails, or is not considered advisable, tracheotomy must be performed. Tracheotomy should never be carried out unless urgently required, because it almost invariably increases the patient's distress and his general symptoms. The cough becomes less effective, there is difficulty in expectoration, and the secretions accumulate in the lungs, leading to rapid spread of tubercle, together with signs of increased sepsis. The temperature rises, and the patients rapidly grow worse. Tracheotomy is therefore only a means of prolonging life by preventing asphyxia.

H. Lambert Lack.

LEAD PALSY.—(See PLUMBISM.)

LENS, DISLOCATION OF.

1. **Congenital.**—This condition is treated either with glasses, optical iridectomy, or needling, according to the degree of the dislocation and state of vision.

2. **Traumatic.**—(See EYE, INJURIES OF.)

W. Tindall Lister.

LEPROSY.—This intractable disease sometimes results in spontaneous cure, and in all cases the progress is subject to great variations. Periods occur during which the disease advances, retrogresses, or remains apparently stationary.

Attention to cleanliness, good food, and bodily comfort, in many cases is associated with marked improvement, and in a cold bracing climate similar marked improvement is common, and may be maintained for years.

Numerous drugs, local applications, sera, etc., have been advocated from time to time, but all, when fully tested, have proved unreliable. Some drugs, such as the iodides, are injurious. Of the others, sodium salicylate appears to be of some value during the febrile attacks. Mercury has been advocated for long periods and in many forms, and occasionally appears to be of value, especially in cases and in circumstances where there is a tendency to improvement. Intramuscular injections have the most effect.

Chaulmoogra oil, in gradually increasing doses (commencing with 3 min. three times a day in capsules gradually increased up to 30 min. three times a day), and gurgun oil, commencing with 10-min. doses, have many advocates. The same oils, diluted, are used as liniments.

X rays have given good effects on the local manifestations, but must be used with great care, as the leprotic tissues are of low vitality.

Injections of "Nastin," a fatty extract from a streptothrix (? of lepra) are said to produce markedly beneficial effects, but this method is still on trial. Nastin is a neutral fat, very similar to those obtained from the lepra and tubercle bacilli. It is mixed with benzoyl-chloride and dissolved in anhydrous olive oil; 1 c.c. is injected hypodermically, at first every week and then at shorter intervals. The treatment is harmless; there is slight local but no general reaction. The syringe and needle must be perfectly dry, as well as sterilized. "Cures" have been recorded, but, as with most of the different forms of treatment advocated, in the majority of cases there is little or no permanent good effect. Various forms of "vaccine" treatment have been tried since the streptothrix has been cultivated, but the results so far have been unsatisfactory.

The special manifestations may require surgical treatment. Amongst the minor of these, the painful perforating ulcers are readily relieved by free incision, dividing both the base and sides of the ulcer and subjacent tissues.

C. W. Daniels.

LEUCORRHŒA.—Leucorrhœa, pure and simple, is generally the result of morbid conditions of the cervix, and not of the endometrium. The natural secretion of the cervix is a glairy mucus, and this may be present in excess. In

many cases, especially in single women, this is the result of general ill-health, and not the cause of it, as is the popular idea. It is a pure hypersecretion, not due to any definite local lesion.

In married or parous women morbid changes may be discovered in the cervix which account for the discharge. In addition to changes in the cervical mucosa, the cervix may be bilaterally torn and the lips everted. If the discharge in these circumstances is immoderate, antiseptic or astringent douches, together with general tonic treatment, may be employed. In more severe cases solid nitrate of silver or pure carbolic acid may be applied to the cervix two or three times at intervals of a few days. Frequent applications of strong caustics to the cervical canal are dangerous, and if they fail to effect an improvement after the third application should not be repeated; such applications should be reserved for severe and long-standing cases. Trachelorrhaphy, or even the removal of the lips of the vaginal portion of the cervix if much hypertrophied and everted, may be required in very chronic cases of leucorrhœa which have not been benefited by the treatment above described.

W. J. Gow.

LEUKÆMIA.—In regard to treatment, it must be remembered that there are three main varieties of the disease: acute lymphatic leukæmia, chronic lymphatic leukemia, and chronic myeloid leukæmia, which is often called splenomedullary. The first of these runs a course of from a few days to a few weeks, and is invariably fatal. Very rarely, cases which commence acutely become less acute and pass into the chronic form. No treatment, beyond the symptomatic, is of any avail. The symptom which is apt to be most troublesome is hæmorrhage from some of the mucous surfaces. This is often the cause of death. The use of the x rays in this type has seemed rather to hasten the process than to retard it, apparently by a toxic action. Chronic lymphatic leukæmia, as regards its symptoms and physical signs, is not distinguishable from the myeloid form, except by examination of the blood. The only other distinction between the two is that in the lymphatic form the lymph-glands are more apt to be enlarged, and at an earlier period of the disease. These cases are very rare, and the treatment does not differ from that of the next form. Before the application of the x rays to the treatment of myelæmia, the remedy most used was arsenic, and very good results were sometimes obtained from its employment. What was aimed at was the diminution of the leucocytes in the circulating blood, and the diminution in the size of the spleen; and these ends were very often attained, especially in cases which had not lasted too long. The drug had often to be given in full doses, very much in the same way as is the rule in pernicious anæmia. It must not be forgotten in connection with any form of treatment in this disease that some cases show well-marked remissions, and the leucocytes may fall to normal without any treatment whatever. The condition is so insidious in its onset that cases probably rarely come under observation until the disease is well established.

Of late years a large number of cases have been treated with x rays, which have usually been applied over the spleen, and sometimes, in addition, over the long bones. The results have been very surprising. The spleen has diminished in size, sometimes falling back almost to normal, in a comparatively short time and with only a few exposures, and *pari passu* with that, the circulating leucocytes have greatly diminished in numbers and the general condition of the patient has improved. The earlier the case, the more certain is this result, and the more rapidly can it be brought about. Very old-standing cases, and especially those which have become anæmic and are in poor health, either do not respond so well or take a longer time to do so. There is no doubt whatever that this is a more certain method of producing a remission

than by arsenic, but it ought to be clearly understood that it is not capable of curing the disease. Cases which were supposed to be cured in the early days of the treatment are now reported as having died, and it has been found that second courses of x rays are not so uniformly successful as the first; still there is little doubt that the duration of life in many cases has been prolonged. It has not been clearly ascertained how the rays act. It is evident, however, that the leucocytes in the body are broken up, as there is a large initial increase in the amount of uric acid in the urine. This increase soon ceases, though the diminution of leucocytes goes on, and it seems probable, therefore, that the rays act by preventing the formation of leucocytes as well as by breaking them down. Some observers consider that this breaking down is due to the production in the blood of a substance toxic to leucocytes; others regard it as directly due to the action of the rays. The point has not yet been settled. Experiments in animals and some actual cases in human beings show that the treatment can be carried too far, and that it must be carefully controlled by blood examinations, for by prolonged action the power of the marrow to produce leucocytes can be completely abrogated. The cells which are mainly destroyed are those of the granular series. The basophils and eosinophils of polymorphonuclear type are the first to disappear; then the myelocyte forms; then the polymorphs and myelocytes of the neutrophil series; while the lymphocytes are entirely unaffected by the rays. In cases where these cells are present in large numbers, this may produce a condition of blood like a lymphatic leukemia. In other cases, apparently in the more advanced ones, the total number of cells may lessen, but the qualitative relations may not alter; that is to say, myelocytes are still present. The fact that the rays have no effect upon lymphocytes may explain their failure in cases of lymphatic leukemia. Great care must be taken in the actual application. Burning of the skin, of course, must be avoided. The applications should not be too prolonged, nor follow one another too quickly, as rises of temperature and other phenomena evidencing a toxic action may follow. Radiation twice, or at most thrice, a week is usually found most efficacious.

Recently benzol has been much used, given in capsules containing 5 min. with 5 min. of olive oil. The treatment is begun with one capsule t.i.d. after meals, and the dose increased steadily. Continental physicians have given large doses, and claim excellent results. I have never found patients able to take more than 20 min. of benzol t.i.d. without serious gastric disturbance, and sometimes considerable febrile reaction. In the course of the latter the leucocytes may drop to normal, as they are apt to do with any febrile complication, but they rise again to the previous level when the attack is over. Considerable symptomatic improvement is often obtained, but in only a few cases have I seen the leucocytes drop to anything near the normal, or the spleen materially diminish in size. When possible, this treatment should be combined with radiation, as better results may be got in this way than by either method alone.

I have had no good result with salvarsan.

The removal of the spleen has occasionally been attempted, but usually with fatal results. As the marrow is the primary seat of the disease, it is not to be expected that splenectomy would serve any useful purpose.

In cases where anæmia is prominent, iron or arsenic should be given, along with other measures, according as the colour index is low or high.

G. Lovell Gulland.

LICHEN PLANUS.—The method of development, and the symptoms which often accompany this disease, suggest some general cause, and we find that it is most readily attacked by internal remedies. Of these, the first place may be given to mercury, which, in the majority of cases, acts with great rapidity

in dispelling the eruption. The drug may be given in any convenient form, and the dose should be equivalent to $\frac{1}{12}$ gr. of the perchloride thrice daily. If mercury should fail, recourse may be had to the older remedy arsenic, which is often satisfactory. If that in turn does not dispel the eruption, antimony may be tried.

In acute cases, local applications are chiefly useful in allaying the itching, which is very severe, so severe sometimes as to threaten the patient's mental balance, and for this purpose lotions of tar or carbolic acid may be used. In the chronic patches in which the disease often lingers on the limbs, local applications are of more value. Unna's ointment—hydrarg. perchlor. 2 gr., carbolic acid 15 min., zinc ointment 1 oz.—may be tried; or salicylic ointment 5 per cent, or the tar ointment of the Pharmacopœia. In obstinate patches, the *x* rays may be resorted to with considerable confidence.

Norman Walker.

LIP, EPITHELIOMA OF.—(See MOUTH AND PHARYNX, MALIGNANT DISEASE OF.)

LITTLE'S DISEASE.—(See PALSIES, CEREBRAL.)

LIVER, CIRRHOSIS OF.—(See CIRRHOSIS OF LIVER.)

LIVER, HYDATID DISEASE OF.—This condition is to be treated in almost all cases by laparotomy; in a few cases it may be advisable to approach the disease through the thoracic wall. Aspiration and injection of the cysts should no longer be practised, for the method is rarely successful, and involves at least as much risk as the open operation.

The most satisfactory procedure is enucleation of the cyst and closure of the cavity in the liver without drainage; when this is not practicable, the cyst should be opened, its contents cleared out as far as possible, and free drainage established.

T. Crisp English.

LIVER, INJURIES OF.—In severe abdominal injuries the liver is more likely to be ruptured than any other viscus, and this accident is a particularly fatal one. In many cases the injuries are multiple and severe, and the patients die either at once or within a few hours. On the other hand, rupture of the liver may be caused by an apparently slight injury, and the serious nature of the case may easily be overlooked.

In all open wounds of the liver, immediate operation is necessary, for in these cases there is probably a large quantity of extravasated blood, foreign bodies may be present, other viscera usually are damaged, and the risks of septic infection are great. In cases of subcutaneous injury to the liver, the need for immediate operation depends entirely upon whether there is active or excessive hæmorrhage. Recovery from the slighter degrees of contusion and rupture may undoubtedly occur under palliative treatment.

TREATMENT.—The removal of the patient from the scene of the injury must be carefully superintended; in fact, in certain circumstances it is best to postpone removing him until some improvement in his condition has occurred. He is then put to bed, and kept absolutely still in the horizontal position; regular observations are made of the pulse, respiration, and temperature. Warmth in the form of blankets and hot bottles is applied according to the degree of shock; if there are symptoms of hæmorrhage, an ice-bag or Leiter's tubes may be placed over the right hypochondrium.

If the shock be severe, it must be actively treated by the usual methods;

if the shock is moderate, the patient may be allowed to recover from it without active assistance, for the measures which relieve shock tend to restart or to increase the hæmorrhage. No fluid or food should be given by the mouth, but nutrient enemata should be ordered if the patient survives the first few hours. Pain should be treated by giving acetyl-salicylic acid and phenacetin, 5 gr. of each, and repeating this every four hours if necessary. Repeated vomiting is usually an indication for operation; otherwise it may be controlled by 20-gr. doses of bismuth subnitrate; morphia and purgatives are to be avoided. As the shock passes off, careful watch must be kept for symptoms of increasing hæmorrhage; as stated above, all measures which tend to increase the blood-pressure must be avoided.

Operative Treatment.—This is indicated in all cases of open injuries to the liver, and in cases in which there are signs of severe or increasing hæmorrhage. If the initial shock be profound, operation must be delayed for two or three hours until the patient is in a condition to stand it. The abdomen is opened in the outer part of the right rectus muscle by a vertical incision; if more room is required, part of the rectus muscle is divided transversely. The simplest and most efficacious method of dealing with the wound in the liver is by packing it with dry sterilized gauze; this at once controls the hæmorrhage, and is more satisfactory than any attempt at suturing. The gauze is left *in situ* for about four days, and then is loosened and gradually withdrawn an inch or two at a time, preferably at first under light anæsthesia. The extravasated blood must be thoroughly mopped away, and it is usually advisable to flush the peritoneal cavity with saline solution. Drainage must be effected by the insertion of a tube and a gauze plug in the upper part of the wound. (See also WOUNDS OF THE ABDOMEN.)

LOCOMOTOR ATAXIA.—(See **TABES DORSALIS.**)

LUDWIG'S ANGINA.—(See **ANGINA LUDOVICI.**)

LUMBAGO.

General Treatment.—In a case of lumbago it is of paramount importance to ascertain, as exactly as possible, its true nature.

Gouty cases form perhaps the largest proportion; they are usually males of middle age and of the working classes. These demand the careful regulation of diet, etc., required by the uric acid diathesis (see **GOUT**); medicinally, a combination of colchicum and iodide of potassium sometimes acts like a charm.

R Potassii Iodidi	gr v	Magnesii Sulphatis	gr xxx
Spiritus Ammonia Aromat.	℥ xv	Aquæ Mentha Piperitæ	q.s. ad 3 ss
Vini Colchici (B.P.)	℥ xx		

Thrice daily in a half tumbler of water after meals.

True rheumatism may be the cause in a smaller group; in these, salicylates combined with alkalies will bring about rapid improvement.

R Potassii Citratis		Spiritus Ammonia Aromat.	
Sodii Salicylatis	āā gr xv	Tinctura Aurantii	āā ℥ xx
		Aquæ Chloroformi	q.s. ad 3 ss

Every four hours.

Salicylates thus prescribed should be left off gradually, and a dose taken, say, twice daily for at least ten days after the pain has disappeared. In obstinate rheumatic cases, quinine, with small doses of opium, should be given a trial.

R Quinina Sulphatis	gr v	Syrupi Aurantii	3j
Acidi Hydrobromici Diluti	℥ xv	Aquæ	q.s. ad 3 ss
Tinctura Opii	℥ vij		

Thrice daily.

Traumatism may be responsible for an attack of lumbago. Often a sudden muscular effort is the exciting factor in a gouty or rheumatic patient, and as such demands no special treatment. Occasionally, a sprain or "rick" of the back is followed by persistent lumbar stiffness, which may be classed as chronic lumbago. In such cases it may even be necessary to resort to an anæsthetic and various surgical manipulations to break down adhesions.

Local fibrositis is now known to be the pathological condition responsible for many cases of lumbago. The essential change is an inflammatory hyperplasia of the white fibrous tissue in the affected part: in lumbago the aponeurosis, insertions of muscles, fasciæ, and periosteum are the parts implicated. Definite indurations from an eighth of an inch to an inch in diameter may occur.

In acute cases a saline aperient should be given at the outset, and the patient confined to bed. Acetyl-salicylic acid in 10-gr. doses every four hours is useful for the relief of the pain; or the following combination:—

R Phenacetini	gr v	Antipyrinæ	gr vj
Acetanilidi	gr ij		

To be taken thrice daily.

In the less acute stages potassium iodide is the most valuable drug:—

R Potassii Iodidi	gr x	Tincturæ Nucis Vomiciæ	℥ xxv
Spiritus Ammoniac Aromatici	℥ xv	Decoctum Cinchonæ	ad 3 ss

To be taken thrice daily.

If the iodide produces severe symptoms of iodism, one of the organic iodine compounds such as iodipin in the form of tablets may be substituted.

In all cases of lumbago special attention must be given to securing a free action of the excretory organs. A brisk purge should be given at the onset, and a daily evacuation of the bowels secured by a suitable aperient if necessary. The patient should be encouraged to drink freely of water, or other bland fluids, to promote the action of the skin and kidneys. Morphia is seldom or never necessary. After the attack is over, a consideration of preventive measures is necessary, and these suggest themselves; the wearing of a "cholera" belt seems, at times, to aid in avoiding recurrence.

Local Treatment.—In every case some form of local treatment is called for, and, as a rule, is of more value than internal medication. At the onset, well-made linseed and mustard poultices applied across the loins will often give unspeakable relief. When available, a hot vapour bath or the electric light cabinet bath may be very useful. Counter-irritation in one form or another remains our sheet-anchor. Brisk friction with turpentine liniment, followed by the application of hot cotton-wool fixed with a flannel bandage, is an excellent remedy. One of the best external applications is a mixture of equal parts of chloral hydrate, camphor, and menthol. These three substances form a liquid when well rubbed together, and this should first be painted over the painful area, and then gently rubbed in with the fingers. Some patients find the cold sensation produced by the menthol objectionable; in such cases the menthol may be omitted, and equal parts of chloral hydrate and camphor employed, which also form a liquid when rubbed together. Another useful external application is to paint the painful area with weak tincture of iodine (B.P.), and then to apply a hot linseed poultice or a very hot fomentation. The heat converts the iodine into a vapour, which exercises an anodyne effect, and probably by absorption acts directly on the affected fibrous tissues. In the later stages, the aconite, belladonna, and chloroform liniment (see A.B.C. liniment) applied on lint is frequently most beneficial. Blistering is worth a trial in more obstinate cases. Acupuncture has sometimes succeeded when a lumbago proves more than usually intractable: ordinary surgical needles may be used, thrust deeply into the lumbar muscles at the seat of pain, and withdrawn after five to ten minutes.

The most effective local treatment in lumbago is the application of superheated air. It is advisable to concentrate the heat on the affected part by one of the various forms of apparatus that have been devised for the purpose. The application of the superheated air lasts for fifteen to twenty minutes, and must be repeated daily. Luff advises that this form of treatment be supplemented by immediate ionization (cataphoresis). In acute lumbago, ionization should be done with a 2 per cent solution of salicylate of sodium at the first two or three sittings in order to produce immediate mitigation of the severe pain. In more chronic cases, Luff directs the employment for ionization of a 2 per cent solution of iodide of lithium, and directs that the negative ion (the iodine) should be driven into the affected tissues. The ionization lasts for twenty minutes, and should be repeated daily if the skin will stand the treatment; otherwise it should be used on alternate days. Many patients improve rapidly from the first, but in severe cases a course of daily application for four weeks may be required. While this ionization treatment is being carried out, it is important that the administration of potassium iodide by the mouth should be continued.

Humphris has recorded good results from the static wave current, following the employment of local heat.

Massage is very useful in the later stages, but should only be employed when it causes no pain.

Not infrequently a case will be found to improve up to a certain point, and yet not entirely clear up: in such cases a course of spa treatment may be required to complete a cure.

Lewis Smith.

LUMBAR PUNCTURE is admissible as a therapeutic measure in all cases in which there are signs of increased intracranial pressure, e.g., meningitis, cerebral tumour, fracture of the skull, uræmic coma, eclampsia, and in some cases of tinnitus and vertigo. Headache, vomiting, and coma may thus be relieved, and the danger of optic neuritis supervening may be warded off for a time at least. The procedure may be repeated when symptoms return. Lumbar puncture is carried out as follows: Draw a horizontal line across the back at the level of the highest points of the iliac crests. This line crosses the vertebral column at the level of the tip of the fourth lumbar spine, and the puncture should be made just below this spine in the fourth interlaminar space. Puncture may be made with a platinum-iridium needle fitted to an all-glass sterilizable syringe, or with an ordinary antitoxin needle, or a small trocar and cannula. The needle should be about three inches in length. The patient should be lying on the left side with the knees drawn well up and the trunk bent forwards, or he may sit on a low seat, stooping forwards with the hands on the ground. The skin should be sterilized and anæsthetized by means of an ethyl chloride spray. The index finger of the operator should be placed on the tip of the fourth lumbar spine, and the needle inserted half an inch below and to the right of that spot, the point being directed horizontally forwards and a little inwards, till the arachnoid sac is reached. The syringe should then be detached and the fluid allowed to drop through the needle. Only a little fluid should be allowed to escape at a time: in most cases 5 c.c. will be enough.

Robert Hutchison.

LUNGS, OEDEMA OF.—(See CONGESTION, PULMONARY.)

LUPUS ERYTHEMATOSUS.—This is one of the most troublesome of skin diseases to treat, as the multiplicity of the remedies suggested shows.

One can recognize two distinct varieties, which may be described as the sebaceous or scaly, and the erythematous. For the scaly form, provided it is not widespread, Hebra's treatment, which consists of the vigorous application

of soap spirit on flannel, is often successful. For the erythematous form, dusting powders, and such applications as exercise a certain degree of pressure, e.g., collodion, are often valuable. It is of primary importance not to aggravate the disease, and it is a good plan to commence the treatment of almost any case with some soothing application such as boro-calamine lotion, on which many cases do surprisingly well.

R Aeidī Borici Calaminæ	3j	Zinci Oxidi Aquam	āā ʒiij ad ʒiv
Or,			
R Zinci Sulphatis Potassæ Sulphuratæ	āā ʒss-ij	Aquam	ad ʒiv

Ointments should, in the writer's opinion, be avoided, as they tend to irritate and spread the eruption. The following application will often be found useful :—

R Pyrogallol Oxidisatum 1 per cent in Acetone-collodion.

This was originally recommended by some German authority in 10 per cent strength, but that has not proved nearly so satisfactory as the weaker application. Quinine, in doses of 3 to 5 gr. thrice daily, strongly recommended by Payne and others, is occasionally useful in the erythematous type of case, but it more often fails than succeeds.

Like so many obstinate skin diseases, lupus erythematosus has run the gamut of all electric methods—Finsen, *x*-ray, and high-frequency. The Finsen method is reported to have been successful in several cases; the results of *x* rays have been successful in some, disastrous in others; and though the writer cannot speak of any marked benefit from general high-frequency applications, he has seen good results from sparking the lesions with a pointed electrode.

Recent experience suggests that these remedies must give place, in all except the acute cases, to the recently introduced treatment by the application of CO₂ snow. The good effects of this method in a disease so strikingly obstinate to treatment are most remarkable, and cases which have been under other treatment for years have been cured in a few months, sometimes in a few weeks, by the steady, discriminating use of this extreme cold. Those who are inexperienced in the use of this powerful remedy should begin with short applications, say of ten seconds, and should exercise only light pressure. But as they become familiar with the method the time may be lengthened and the pressure strengthened.

The curious relationship of this disease to chilblain indicates the desirability of promoting a vigorous circulation, and keeping the patient well over par; though it must be admitted that the disease often enough attacks persons in apparently robust health.

Norman Walker.

LUPUS VULGARIS.—It is necessary in the first instance to differentiate between cases as regards their variety and extent. The writer finds it convenient to describe the varieties as simple, catarrhal, fibroid, and warty or verrucose. The circumstances of the patient, and his general condition, are also of importance in deciding on the line of treatment to be followed. It is well to lay stress at the outset on the all-importance of early diagnosis, so that cases come under treatment at the early stage, and the more severe varieties of the disease do not develop. And it may further be laid down that, in spite of the great prominence given to novelty, it is perfectly possible to treat a large number of cases of lupus without the aid of electricity, and indeed, in many cases, the older simpler methods are to be preferred.

Since most cases, when they first come under observation, are catarrhal, this variety may first be dealt with. This catarrh is due to the complicating presence

of cocci, and is not a necessary accompaniment of the disease. The complication may be dealt with in various ways. It may be modified greatly by the internal administration of thyroid, to the extent of 10 or 15 gr. a day. It may be treated also by the application of mild antiseptic ointments, such as ammoniated mercury, 5 gr. to 1 oz. of vaseline, or by thorough scraping under anæsthesia. It is at this stage, and for this purpose, that the sharp spoon is most useful.

The fibroid form occurs most frequently on the limbs, and one may almost say of it that it has a natural tendency to recover. At all events, the prognosis is generally good. If the patch be very small it may be excised, care being taken that the incision goes both deep and wide of the disease. Generally it may be treated with success by the application of some counter-irritant, such as blistering fluid (B.P.) or liq. antimon. chlor. Occurring as it does on the limbs, it readily lends itself to treatment by Bier's congestion method. But, as has already been said, the tendency is towards recovery, and it is not wise to generalize as to the value of any particular treatment of lupus from its effects in fibroid lupus on the limbs.

The warty form may be looked upon as a mixture of two diseases, tuberculosis and verruca, and the complication may be got rid of, either by the spoon, knife, or the application of the *x* rays, which affect both conditions.

There remains for consideration the treatment of the simple variety of the disease, i.e., those cases where there is no apparent ulceration, but only, below the epidermis, those brownish (apple-jelly) nodules which are characteristic of tubercle of the skin. If the patch be small and the position favourable, it may be excised. The line of incision must go well clear of the disease, in every direction, and if the situation be such as to incline the surgeon to conservatism regarding the amount to be removed, the disease returns in the scar, and the last state is worse than the first. The next method for consideration is the caustic one. Many caustics have a selective action, i.e., their effect is more vigorous and rapid on the feeble tuberculous tissue than on the healthy surroundings. Arsenious acid has long been a favoured remedy. Hebra's prescription was as follows:—

R Acidi Arseniosi	gr x	Unguenti Rosæ	℥ss
Hydrargyri Sulphid. Rubri	℥ss		
Or,			
R Acidi Arseniosi	℥ss	Pulverem Carbonis Ligni	ad ℥j
Orthoformi	℥j		
	M. Fiat pulvis.		

Sig. To be made into a paste by the addition of spiritus vini and applied to the part.

One of these is applied to the part for at least forty-eight hours (being changed at intervals), and, provided the patient can endure it, should be continued for twenty-four hours more. The pain is however, very severe, and none of the suggested analgesic conditions have, in the writer's experience, proved of much value in ameliorating it; so that one has to fall back upon the internal administration of morphine. At the end of the period mentioned, the healthy surroundings are seen to be violently inflamed, and the diseased area is studded with a series of little black sloughs corresponding to the nodules. Under some application (and in the writer's opinion it is not desirable to aim at too rapid healing, and he therefore usually prefers a strong iodoform ointment), the part heals up, and if the application has been continued for a sufficiently long time, the disease may be permanently cured. The main objection to this method is that the resulting scars tend to be unsightly. Its place has therefore been largely taken by salicylic acid, which is best applied in the form of Unna's salicylic creosote plasters. These are applied night and morning. At first there is no inconvenience, but as the salicylic acid penetrates, and bores out the elements of the nodules, a more or less constant pain is experienced, and this

interferes very much with the use of the method in children. In a few days, the little white sloughs which represent the nodules separate, and the part may then be healed by zinc ichthyol salve muslin or some other soothing ointment. As before indicated, the writer prefers rather to delay healing, and always endeavours to persuade patients to persevere with the use of the plaster until complete healing has taken place. If that is not possible, he rubs in dry iodoform, or uses a strong iodoform ointment, or fills up the cavities with powdered uranium nitrate. If the disease is extensive, this method may still be used, different parts being attacked in succession. But when a very large area is affected and electric methods are not available, probably the best application is that known as Brooke's ointment, of which the following is the formula :—

R	Zinci Oxidi		Acidi Salicylicæ	gr xx
	Pulveris Amyli	āā 3ij	Ichthyolis	℥xx
	Vaselini Albi	3ss	Olei Lavandulæ	q.s.
	Oleati Hydrargyri (5%)	3j		
M. Fiat unguentum.				

The writer finds that Allan Jamieson's modification is much more easily remembered, and equally efficacious :—

R	Unguenti Hydrargyri Oleati (5%)	3j	Acidi Salicylicæ	gr xv
	Ichthyolis	℥xx		

To be rubbed in for half an hour every night, and twenty minutes every morning.

It is essential that the directions for prolonged rubbing-in be carried out ; simple application is of comparatively little value. Under the prolonged use of this method, the nodules are reduced in number, and may then be attacked by one of the methods already described. When the nodules are so far reduced as to be easily counted, probably the best, at any rate the simplest, method of treatment is their individual destruction. This may be brought about in various ways. The galvano-cautery is an excellent method. It permits of great accuracy of application, and it evokes a secondary reaction which is beneficial. The fine-pointed thermo-cautery is more generally available, and in skilled hands is probably almost as useful. The difficulty in its application is that it is not so easy accurately to pick out the nodules, since the cautery is hot, and the patient, at first at least, shirks the apparent ordeal by fire. Still more simple is the method recommended by Mr. Hutchinson, in which wooden matches are sharpened, and dipped in solution of mercuric nitrate, and then bored into each individual nodule. In this connection a caution must be given. The liq. hydrarg. nitrat. is prepared with nitric acid, and a fresh preparation is very much more active than that which has stood on a consulting-room table for months, and sometimes far exceeds the desires of the surgeon in its effects. These may, if desired, be intensified by cutting off the piece of wool which has penetrated the nodule, and leaving it *in situ*. Unna has recommended "gooseberry prickles" in preference to matches, but in the writer's experience they are inconvenient to handle, and no better than the matches. Carbolic acid may be used instead of the nitrate of mercury, and other caustics may also be chosen. In the case of children, who cannot be expected to submit patiently to the drawn-out pain of these methods, probably the best application is carbolic acid, for, although the pain is severe for a moment, the anæsthetic effects soon develop, and the pain is forgotten. The application of carbon dioxide snow, referred to under lupus erythematosus, is of value in some cases ; others fail to respond. Its application must be much more prolonged than in that disease, for here we aim at destruction.

The writer has already indicated his opinion of scraping, but there is no doubt that its temporary effects are good, and many patients have a preference for

scraping, since it usually gives them a period of relief. But it must be recognized that it is hardly possible to *cure* a case of lupus by simple scraping. If one aims at a cure, the scraping must be very vigorous, and the resulting scars are often almost as disfiguring as the lupus.

The cautery was, and still is with some, a popular method of treatment in extensive cases. Anæsthesia is, of course, required, and the instrument must be used freely, in order to destroy the tissues deep down. If applied to the surface only, it is simply a severe form of counter-irritation. Kaposi used a solid stick of silver nitrate, with which he ploughed furrows in all directions through the disease. This was followed by some improvement, as indeed is any method of counter-irritation, but the method is rarely employed now.

Before passing to the consideration of the electric methods, it may be well to refer to the fact that lupus of the skin is very generally associated with diseased oral or nasal mucous membrane, and it is often distressing to find cases long and carefully treated as to the skin, while the disease has been allowed to go on unchecked in the mouth or nose. In the mouth we have in lactic acid a remedy of wonderful efficacy. Some authors prefer to dilute it, but the writer uses it in its full strength. The mucous membrane should be dried with cotton-wool before the application, and the mouth washed out immediately afterwards. (See also NOSE, TUBERCULOSIS OF.)

Treatment by Electricity.—Of electric methods, the most generally useful is the *x*-ray; for the expense, both initial and working, of Finsen apparatus, places it beyond the reach of all but wealthy hospitals. Here one need lay down only a few general principles; those who intend to use these methods must go to fuller sources of information for their instruction. Here, too, the extent of the disease has to be carefully considered. If a patch is small it may be exposed—the surrounding parts being carefully protected by lead-foil—for a considerable period of time (twenty minutes to half an hour) to the *x* rays from a soft tube, with the deliberate intention of producing an *x*-ray burn. The ulcer produced takes a long time to heal, but it requires only simple dressing, which can be done by the patient himself at home. The results are often very satisfactory. In widespread cases it is more customary to proceed by means of a series of exposures, using the rays from a tube which is moderately hard, and beginners, at least, should endeavour to keep under the line of reaction. There is, however, no doubt that a moderate reaction is beneficial, and as experience increases this may be aimed at, by the use either of longer exposures or of softer tubes. Since the edge is usually the part where the disease is most active, it is often a good plan to produce greater reaction there. As it is obviously difficult to do this by means of the rays, other methods are adopted in addition. The simplest of these is the plan of painting the edge with pure carbolic acid. Under the steady and prolonged—often very prolonged—use of the rays, the lupus steadily improves. The nodules diminish in number, the hyperæmia disappears, and in favourable cases the condition of the skin is restored to an appearance not very far from the normal. The two drawbacks to this method are, the occasional production of severe burns, although these are much rarer than they used to be, and the occasional production of cancer, which is, unfortunately, commoner. It is not possible to say definitely which cases are likely to develop this, a complication to which all cases of lupus are liable, but in the writer's experience it has developed mostly in what might be called the "florid" cases of the disease, those associated with a good deal of hyperæmia and catarrh. It seems likely that this unfortunate complication is not to be attributed directly to the rays, but to the fact of their beneficial action compressing the ordinary years' duration of a case into a few months. It is the old cases of lupus which develop cancer, and by hastening the progress one seems sometimes to increase

this risk. Needless to say, when this complication develops it must be immediately treated by surgical means. All cases of lupus which have been treated by x rays should be inspected at frequent intervals, so that this terrible complication may be detected and promptly treated at the earliest possible moment. It must be remembered that x rays produce many other effects than those desired, and the parts which it is not intended to affect must be carefully protected by lead. The effect of the rays in bringing out the hair must be kept in mind, and if convenient the eyes should be protected. The writer, however, believes that the danger to these is exaggerated, and in the treatment of rodent ulcers, where it was not possible to protect the eye, he has not seen any ill effects. Where, therefore, lupus affects the eyelids, the rays may nevertheless be applied. A further advantage which the rays possess is that their effects are not confined to the skin, but the mucous membranes in the neighbourhood are also affected.

Though not strictly within the scope of this article, the writer feels compelled to repeat his many warnings as to the effect of the rays on the operator. The sterility which has been proved to result in animals is a matter which must be considered where the administrator is exposed for hours to the effects of the rays. But undoubtedly the principal risk is the development upon the hands of warty growths which develop into epitheliomata. These are generally to be found on the hands of young enthusiasts, or of those who were once young enthusiasts. It should be a fixed rule never to expose the hands to the rays, and the plan of testing a tube with the screen on the operator's hand is one which no sensible man should ever practise.

The Finsen method has been described so often and so fully that it is hardly necessary to say more than that it consists in focussing the light from a powerful arc lamp upon the area of skin to be treated. The part must be rendered anæmic by pressure of a crystal lens, and this is further used to cut off the heat by means of a stream of cold water which circulates through it. Each application must be of an hour's duration, and its efficacy depends entirely upon the skill and care of the nurse who applies it. If she does not understand the principles, does not get the light properly directed, and does not keep up constant pressure, the results are nil.

If all has been properly performed, a blister is evident on the following day; this is let out and dressed with any simple dressing, and a fresh part is attacked. The treatment of an extensive case requires a very long time, and it is the writer's opinion that the Finsen method should be reserved for comparatively small patches, which can be gone over in a reasonably short time.

Allied to these methods is the exposure to the rays of radium. Unfortunately the expense of this is so great, and the quantities procurable are so small, that only limited patches can be treated. The effects are very similar to those of the x rays. It is possible to produce burns just as with them. In the writer's opinion, the greatest value of radium is in lupus of the palate, which is not easily got at by the rays, and is inaccessible to the Finsen method.

In uranium (another radio-active substance), which is easily procured, we have a means of treating lupus which may possibly come into more general use. The application may be continuous, and the beneficial effects are often striking. It is, of course, particularly useful to those living in the country where electricity is not available. It is conveniently applied in the form of the powdered nitrate, and preferably to areas which have been "rawed" by the spoon or by salicylic acid plaster. It has a remarkable power of drying up discharge.

In conclusion, it may be said that the greatest remedy of all in the treatment of lupus is *perseverance*. The disease must be relentlessly pursued until the last trace of it has disappeared, and if the writer has seemed in any way to depreciate

the value of the Finsen method, he fully appreciates that it is to Finsen we owe the lesson of perseverance in the treatment of this formerly uninteresting disease.

The use of Tuberculin.—For some considerable time the majority of the cases under the writer's care have had, in addition to other treatment, regular doses of tuberculin. For out-patients the T.R. variety has been used, in doses of about 0.001 mgm once every three weeks. It is not altogether easy to be dogmatic about the result, for it has only in rare instances been used alone; but the impression conveyed to one whose experience in treating lupus is considerable is that the results of the other remedies are more rapid and striking when the patient is under tuberculin, and cases which have been under treatment for years have made more rapid strides when this addition to the treatment was regularly persevered with.

More recently a large series of cases has been treated in hospital with Koch's old tuberculin. The usual initial dose is 0.0005 c.c., but regard must be paid to the extent of the lupus, and of course to the presence of other tuberculous disease. In from eight to twenty hours the reaction, both local and general, develops. The temperature rises to 101–2–3°, and the part becomes red and hot and discharges freely. Uranium nitrate is often applied at this stage. The patients are usually three days in hospital, and return at intervals of a month for subsequent doses. These are graduated according to the reaction, and in the later stages considerable doses are sometimes required. But if the temperature rises to 101°, no increase is made. Nearly every case has benefited, some of them markedly, and hospital physicians will recognize the testimony that the patients rarely fail to turn up when their admission order arrives.

Tuberculin may also be used locally in the form of a 5 per cent ointment of O.T. In from twenty-four to thirty-six hours a marked local reaction is produced, which under the continued application of the ointment becomes more marked, without any rise of temperature indicating a general reaction. After three or four days the application is stopped, uranium nitrate or iodoform is applied, and the part heals up; and when the hyperæmia has passed away great improvement is often noted. This method is of special value in cases of lupus in the neighbourhood of joints when contraction has taken place. After three courses of this treatment a patient, whose left elbow was contracted almost to a right angle, went round his local golf links in 76.

Norman Walker.

LYMPHADENOMA. (See also TUBERCULOUS GLANDS.)—A large number of conditions are often confounded under this name, the principal being indolent tuberculous glands, lymphosarcoma, pseudo-leukæmia, and the true lymphadenoma. It is often exceedingly difficult in life to distinguish between these, and it is no uncommon thing to find that a case which had been supposed to be lymphadenoma turns out to be either tuberculous or sarcomatous. The really important point in diagnosis is to exclude tubercle. This may be done with fair certainty by the consideration of personal and family history; by the examination of other organs and of the sputum for bacilli; by the diagnostic injection of old tuberculin, or, still better, by the estimation of the opsonic index in conjunction with the injection of tuberculin T.R., according to Stewart and Ritchie's method (*Edin. Med. Jour.*, May, 1907). I have found this latter method exceedingly useful and reliable, but of late have used in preference von Pirquet, Moro, or one of the other skin reactions, which are at least as accurate, and much easier to carry out. Should all these fail, it is usually justifiable to excise a gland, examine half of it microscopically, and transplant the other half into a guinea-pig.

If the glands are found to be tuberculous, the question of surgical interference

must, of course, be considered. If, for any reason, this is inadvisable, good results can sometimes be obtained by arsenic and cod-liver oil given together, and by the judicious application of some ointment containing iodine. Iodine has sometimes been injected into the glands, and this is a well-recognized form of treatment in Italy, where it seems to have met with more success than in this country. Of course, the ordinary hygienic measures necessary for all cases of tuberculosis must be carried out in these cases, in addition. Very good results are sometimes obtained by the use of tuberculin T.R., either controlled by the opsonic index, or used in such doses and at such intervals as experience with that estimation has shown to be proper. It is not wise, for example, to use a greater initial dose than $\frac{1}{2000}$ mgram in adults, and in children a relatively much smaller dose, and as a general rule it is found that the positive phase, during which a second injection should be given, is at its maximum about a fortnight or three weeks after the first dose. Care should be taken never to embark upon this course until pus, if present, has been removed, either by incision or aspiration, nor should it ever be attempted when there is acute or sub-acute peri-adenitis.

Lymphosarcoma admits only of surgical treatment, and that, unless the disease begins in some accessible part of the body such as the tonsil or cervical glands, has little prospect of success. In cases where the condition commences in the mediastinal or abdominal glands, it is, of course, impossible to remove these, and where it commences in the glands about the pelvic brim, it is usually too far advanced before the patient seeks advice for anything to be done.

Of true lymphadenoma very much the same may be said. The only remedy which has much influence over it is arsenic, and the effect of that is, as a rule, only temporary. Excision should always be practised if the glands are accessible, and if complete examination has satisfied the observer that no other glands are involved than the superficial ones. Too often one finds, by the use of *x*-ray photographs and other methods, that the superficial glands are only the terminal links in a chain involving the mediastinal or abdominal glands. In such cases operation is futile. I have treated some cases with *x* rays, but with disappointing results. Salvarsan and neosalvarsan are definitely useful. After injection, especially intravenously, soft glands shrivel and harden, temperature drops, the patient's general condition improves. In the late stages of the disease the symptoms will recur after a longer or shorter interval, and subsequent injections have a diminishing effect, but in early cases the effect is much more prolonged, and in some cases I have succeeded in staving off recurrence by injection every two or three months. In some cases of lymphadenoma the patient is greatly distressed by evening rises of temperature, sometimes to a great height. I have known kryogenin of value in preventing this rise. It should be given in 5-gr. doses about an hour before the rise is anticipated, and, if necessary, repeated later in the day. For the weakness and prostration which attend the condition, cardiac tonics such as strophanthus and digitalis, rest in bed, and careful feeding with whatever the weakened digestion will stand, are essential. Fortunately, the course of the disease is often prolonged, and remissions of symptoms not infrequently occur.

G. Lovell Gulland.

MALARIA.—Quinine is the only drug that can be said to be a certain cure, but the method of administering the dose, and the compound used, vary in individual cases.

It is of the utmost importance that the diagnosis should be clearly proved by blood examination, as it may be necessary at any time to push the doses beyond the ordinary limits, and only when such certainty is attained are extreme doses justifiable. In all cases, during the pyrexial periods, rest in bed is essential.

The diet should be light, fluids (other than alcohol) administered abundantly, and the bowels freely opened. Changes of temperature, draughts, and chills must be carefully avoided.

Quinine is usually given as the hydrochloride, sulphate, or bisulphate. In some cases, where the taste is particularly objected to, the ethyl carbonate "euquinine," in equivalent doses, can be given. As this preparation is tasteless, it is particularly well suited to children.

Method of Administration.—Quinine can be given by the mouth or rectum, or by intramuscular or intravenous injection. If given by the mouth, the effects are most certain when the drug is in solution. Uncoated tabloids of the hydrochloride and bihydrochloride and bisulphate are fairly reliable. Sugar-coated tabloids, pills, etc., are almost worthless, and may be passed per rectum unchanged.

Rectal administration is useful in severe cases where frequent large doses are required, or where vomiting is persistent and intramuscular injections are objected to. The quinine should be dissolved with tartaric acid. If hydrochloric acid be taken as the solvent, the solution must be well diluted and the minimum amount of acid used. The injection is more likely to be retained if the medium be either normal saline solution or thin mucilage. In children, retention of the injection must be insured by pressing the buttocks against each other.

Superficial hypodermic injections cause much pain, and *intramuscular injections* should be substituted. Tetanus has resulted from such injections, and quinine appears to increase the probability of such an event if dirty needles be used. The careless preparation of the skin, instruments, and solutions, that are safe enough with morphia and other injections, are full of risk in the case of quinine. The syringe and solution should therefore be boiled immediately before use, and the skin rendered as aseptic as possible.

With these precautions, there is little risk of tetanus or of abscess, although there may be some pain and induration for a few days. The injection should be made into a large muscular mass such as the gluteus maximus; injection into the smaller muscles is more painful, and injection into the forearm has been followed by permanent paralysis of the median nerve. A daily dose of 9 gr. of the bihydrochloride dissolved in 20 min. of water will suffice for most of the intractable cases, but if there be any immediate danger to life, more frequent doses are absolutely necessary; or this method may be combined with rectal administration.

Intravenous injection is occasionally required as a last resource. It is not, as a rule, more effective than intramuscular or rectal injection, and is more dangerous.

Dosage.—This must vary according to the severity of the case and in different attacks. Minute doses, even the small amount of quinine contained in half a drachm of Easton's syrup, may control or reduce the fever in some cases, whilst in others, 60 gr. a day have had little effect, even when given intramuscularly. It is on account of the variation in the dose required that it is so important, in any grave case, that the diagnosis should be certain, as heroic doses may be necessary in order to save life.

In an ordinary case of benign tertian or quartan malaria, 5 gr. three times a day is an ample dose; smaller doses may be used, but with less certainty. In malignant malaria, similar doses may be successful, but the attendant must be prepared to increase them greatly if symptoms do not speedily subside, or if any grave signs supervene. A daily intramuscular injection of 9 gr. is sufficient in the great majority of cases.

If coma should supervene, there is little time to lose, and large and frequent doses should be given, e.g., 16 gr. or more intramuscularly, and hourly rectal

injections of 10 gr. till the symptoms subside. Under the free and frequent administration of quinine, even these grave cases usually recover rapidly. The risk of quinine poisoning must be run, for if the disease be not controlled, death will occur in a few hours.

Malarial convulsions in infants and children up to about five years of age belong to the same class of cases. Malaria in children shows comparatively few of the ordinary symptoms, and in the tropics its presence should be suspected in all cases of convulsions in children, particularly in those over six months old.

In such cases, rectal injections of quinine are of great value, and if ample doses are given, the convulsions speedily cease; but the doses to be effective must be large. Children stand quinine well, and a rectal injection of 5 gr. in a child a year old, followed by $2\frac{1}{2}$ gr. every hour till the convulsions cease, and then repeated at longer intervals, will, in the majority of cases, save the patient. With smaller doses there is a much greater mortality.

These doses are much above those authorized in the British Pharmacopœia, or approved by some authorities, but with small doses the condition of the patient is desperate, and even these heroic doses will occasionally be found to be insufficient. When the severe symptoms have passed, moderate doses will suffice to prevent recurrence, and these smaller doses may be continued, preferably in solution, by the mouth. Hot packs should be employed for adults and hot baths for children, and on any sign of cardiac failure, stimulants, preferably alcohol, should be freely administered.

Recurrences and relapses occur in the great majority of cases, and therefore, after convalescence from an attack of malaria, the administration of quinine should be continued for at least three months. It is well to reduce gradually the frequency of administration of the drug. For a full week after apparent convalescence, 5 gr. should be taken three times a day. For a further period of two weeks, 5 gr. once daily. Subsequently, 10 gr. two or three times a week, further reduced to once a week, should be taken.

Intolerance of Quinine.—Mere intolerance in the sense of dislike of the taste can be overcome in many ways, and especially by the substitution of euquinine in equal doses. The ordinary physiological effects are reduced by the use of bromides. The patient usually becomes less susceptible to these effects even when no bromides are given if he continues to take quinine.

In some persons, after frequent attacks of malaria, quinine may cause hæmoglobinuria. Such cases are not common, but do occur, especially in persons who have suffered from fever in Africa. In such cases, quinine must be administered cautiously, beginning with small doses, slowly increased till sufficient to control the fever is reached.

Various substitutes for quinine have been advocated from time to time. Of these, methylene blue is the most effective. It can be given in doses of 5 gr. in cachet with good effect, but is on the whole less certain in its action than quinine. Patients to whom this drug is given should be warned of the change that it will produce in the colour of urine and fæces.

Arsenic, in many forms, has been advocated. It does not destroy the parasites, and therefore is useless in the acute stages. During the convalescence, it is of high value in the treatment of the anæmia often present.

Adjuvants.—Phenacetin, phenazone, and other antipyretic drugs have been advocated. No reliance can be placed on these drugs as curative agents, but they relieve headache, promote diaphoresis, and render the patient more comfortable. In small doses, and in mild cases, their use is therefore occasionally permissible. There is no object in giving such drugs merely to reduce the temperature, and in no case are they a substitute for quinine.

Hot drinks, such as weak tea and various native decoctions (lemon grass tea, etc.), can be used freely to promote diaphoresis during the hot stage.

C. W. Daniels.

MALIGNANT DISEASE, INOPERABLE.—(See CANCER, GENERAL TREATMENT OF; MOUTH AND PHARYNX, MALIGNANT DISEASE OF.)

MALTA FEVER.—(See UNDULANT FEVER.)

MAMMARY ABSCESS.—Mammary abscesses appear to afford some difficulty in treatment, judging by the many cases in which secondary operations are necessary.

As soon as suppuration is evident, operation should be performed; the skin should be very carefully cleansed with the most rigid antiseptic precautions, for it is important to avoid introducing any fresh organisms. A general anæsthetic should be given, either A.C.E. mixture, or nitrous oxide gas followed by ether; gas by itself is inadvisable, for it often results in a hurried and imperfect operation. Puncture of the abscess without an anæsthetic, a plan often adopted, almost invariably leads to failure.

The nature of the incision depends on the position and size of the abscess. The essential points are that the incision should be free, that it should be made as low in the breast as possible, and that it should avoid the main milk-ducts. In most cases the best incision is a large one in the lowest part of the breast; a free opening here gives efficient drainage in the most dependent part, will not injure the main ducts, and will leave an inconspicuous scar. If the abscess is in the upper part of the breast, it should be opened from its lower and outer aspect. When there are multiple abscesses scattered through the breast, several incisions must be made, and be made freely, otherwise the whole breast may have to be sacrificed.

Mammary abscesses are often multilocular, and after incision it is essential to convert the loculi into one large cavity; this is done by inserting the finger and breaking down the intervening septa. A large drainage tube is then introduced, and it is well to secure this to the skin with a stitch; an antiseptic fomentation is applied, and the arm is placed in a sling. The cavity should never be scraped or irrigated. The fomentation should be changed about two hours after the operation, and then be repeated every four hours for the first two or three days; the tube should be gradually shortened, and then be replaced by a smaller one.

The patient should be kept to bed for a few days, but should be encouraged to sit up in bed as much as possible in order to facilitate drainage; the bowels should be kept well opened, and a liberal diet should be given; iron and quinine do much good in these cases.

Persistent Sinuses.—When a mammary abscess has burst spontaneously or has been inefficiently opened, multiple sinuses are apt to form and to persist. In fact, in many of these cases the breast is riddled with sinuses, and this continued suppuration seriously affects the patient's general health.

TREATMENT.—At the earliest opportunity the sinuses should be freely opened up, their walls scraped, and the cavities plugged with cyanide or iodoform gauze. Small pockets of pus must be thoroughly opened. The sinuses may be syringed with one of the following solutions: Merc. biniod. 1-1000; iodine 1 dr. to the pint; or hydrogen peroxide 2½ vols per cent. The arm must be kept at rest with a sling.

The most effective treatment, when it can be practised, is vaccine inoculation. Observations must be taken as to the micro-organism present; the corresponding vaccine is then prepared, and its use will often bring about a rapid cure.

The treatment of the general health is almost as important as the local measures. Sea air will usually cause rapid improvement, whilst iron, quinine, syrup. ferri phosph. co., (N.F.) and salines are valuable.

In obstinate and long-standing cases, *amputation* of the breast may be necessary, but should be avoided if possible. If this operation is performed, special precautions must be taken to avoid infection of the wound; the best method of rendering the opening of the sinuses aseptic is the use of the thermocautery.

Sub-mammary Abscesses.—These abscesses may be acute or chronic; they show themselves by œdema at the base of the breast, and by forward projection of the breast, which itself is not affected. The treatment consists in early and free incision at the lower and outer part of the breast, with free drainage. (See also ABSCESS.) *T. Crisp English.*

MAMMARY NEURALGIA.—(See BREAST, NEURALGIA OF.)

MARASMUS.—Before beginning the treatment of wasting in an infant it is important to exclude, if one can, the presence of any grave organic disease. Tuberculosis, congenital syphilis, diabetes, and latent empyema are those which are most likely to be present. Assuming that none of these is found, attention should be directed to the state of the stomach and bowels, and chronic vomiting or diarrhœa dealt with on the lines laid down in the articles on these subjects. If these also be absent and the case be one of wasting without apparent cause (i.e., one of true marasmus), the patient must be treated on general lines.

Attention to the hygienic surroundings is of the first importance. The child should spend much time in the open air (of course well protected from cold). Change to the seaside is often beneficial. The diet should be carefully considered. In the case of infants below four months of age a wet nurse should be procured if possible. Failing that, thoroughly peptonized cow's milk more or less diluted with water is the best substitute, or one may use Backhaus' Nutricia milk, or such a preparation as "Glaxo." In the case of an infant of about six months of age the effect of starchy food is always worth trying. It may be given in the form of baked flour or oat flour added to the bottles, or as Benger's or Savory & Moore's food. A child will often gain weight when fed in this way when he has failed to do so on any modification of milk alone.

In the case of children who are unable to digest *any* form of cow's milk, the diet may consist of whey and cream (1 oz. of cream to 8 or more of whey), of whey and raw white of egg, or of Mellin's or Savory & Moore's food made with whey, or of egg white (the white of one egg to 8 oz. of water sweetened with sugar. Yolk of egg may be added to the latter in small quantities, beginning with 5 min. of the yolk to the feed in quite young infants, the proportion being increased with age. In all cases raw beef-juice and cod-liver oil are useful adjuvants. Drugs are of little help except to meet special indications, but alcohol is sometimes useful.

Robert Hutchison.

MASSAGE.—There are certain broad principles in the administration of massage which involve the carrying out of the following special manœuvres.

Effleurage is a gentle stroking or rolling of the skin, gradually increased to moderately firm friction, and always directed centripetally. The palmar surfaces of the operator's fingers are employed when dealing with small areas, while over the larger surfaces the whole palm of the hand is applied to the patient's skin; occasionally the ulnar border of the hand is used in preference. Each stroke commences from the most distal point of the part under treatment; in the up-stroke somewhat firm pressure is applied, while in the down-stroke, which

should be absolutely continuous, less pressure is used. From the beginning to the end of the manoeuvre the hand of the operator does not leave the patient's skin, the rapidity of the stroke varying with the effect which one desires to produce. Rapid sharp strokes of 80 to 100 per minute are more stimulating, while slow firmer strokes of 60 to 70 per minute are rather more soothing in effect.

Pétrissage.—This is a kneading movement, and is one of the most difficult to perform correctly. The skin and muscles of the patient are grasped between the fingers of the operator's hand and kneaded seriatim from the peripheral parts to the centre of the trunk, the hold being alternately tightened and loosened.

It is of the utmost importance that neither the skin nor hairs should be dragged on, for this is both painful at the time and often productive of a crop of boils, which will put a stop to any massage for some time. In dealing with the larger groups of muscles, such as the quadriceps extensor, etc., it is well to use both hands at the same time. The muscles on both sides of the limb may be dealt with and rolled against the bone, constituting the special movement known as "fulling," from its similarity to what the linen bleacher does.

Tapôtéme consists in a series of blows struck in quick succession, either with the fingers, the edge of the hand, or the whole hand. The blow is *staccato* in character, coming from the wrist, rapidly delivered, and with a certain rhythm. To produce a superficial effect the fingers only are used, while if we wish to act on the muscles and deeper-lying structures, a series of chopping movements or strokes are given with the ulnar edge of the hand along the whole length of the muscle in its transverse axis. Bearing in mind that the object is to produce a slight mechanical impression, stimulating but not painful, care must be taken, when the whole hand is used, that what is intended as a sharp tap or stroke does not degenerate into a smack. No pain or bruising should be produced.

When the ulnar edge of the hand is used, the fingers should not touch the patient's skin, and the blow should come from the elbow. Considerable delicacy of touch is needed to carry out this movement successfully, and also considerable manual strength.

Friction Massage.—This consists in rubbing small circles from the peripheral parts centripetally, using the whole hand, the thenar eminences, or finger-tips, according to circumstances. It is of especial use when treating joints, or any part where kneading is impossible.

Vibration is in some respects a combination of the two preceding movements. A vibratory or shaking movement is added to them. It is the most difficult to learn of all the different massage movements, and is probably the only one which can be advantageously carried out by mechanical means.

There are several excellent electric vibrators on the market—the Barker, the Victory, and the "Sanitas" Pulsator. The use of one of these apparatus is an admirable adjuvant to ordinary massage, and it is one of the most important passive movements used in medical gymnastics. A machine-driven instrument, from the rapidity of the strokes and absolute regularity with which they are administered, can produce effects unattainable by the human hand. The effect may be made soothing or stimulating as chiefly desired, the circulation of any part is improved, and absorption hastened.

General Massage.—While it is immaterial whether we commence our manipulation with the upper or lower extremity, it is well as a matter of routine to follow a regular order, as, for instance, legs, arms, chest, abdomen, and back. The patient, except for the last-named region, lies in the supine position throughout, with only so much of his body exposed as is under treatment at the moment.

Massage of one extremity is very much like that of another, so that what is

said of the arm will in large measure apply equally to the treatment of the leg. In the case of patients who are hairy, however, it is often a good plan to crop the legs with a pair of scissors, or shave them, before trying to massage; much irritation, and even a crop of boils, may thus be prevented.

If the left extremity is to be manipulated, the masseur will stand at the patient's right hand. He begins by flexing and extending the toe two or three times, then the knee, ankle, hip-joint, etc. The patient's left foot is taken in the masseur's left hand, while with the right hand on the dorsal surface he strokes towards the ankle. Then the sole of the foot is kneaded with the fingers, and afterwards the skin around the malleoli and the tendo Achillis with the thumb and fingers.

When the left leg is being treated, the patient lies on his right side—the masseur may be seated. He supports the patient's heel on his knee or thigh while a few steady strokes are made upwards from the level of the ankle. The muscles of the calf are then thoroughly kneaded, as well as the muscles of the anterior surface of the leg. If the limb is large and fleshy, the more superficial layer of muscles is pressed and kneaded against the deeper layers (fulling); a little light effleurage then quickly concludes the treatment. After stretching the skin around the knee, and applying a little friction, the thigh is dealt with. Effleurage is at first applied to the whole thigh and hip. *Pétrissage* is then applied to the large group of muscles—*quadriceps cruris* and adductors,—both hands being used at the same time. The movements must pass from below upwards, and effleurage is used at the finish as usual.

The patient lying on his right side, effleurage is then carried out around the head of the hip joint, and the short muscles around the *trochanter major* are carefully kneaded with the operator's right hand.

In dealing with the upper extremity, the hand is manipulated much in the same way as in treating the foot; the *thenar* and *hypothenar* eminences are thoroughly kneaded and finished with effleurage, which is continued up the forearm. The wrist, elbow, and shoulder-joint are then freely flexed, extended, and circumrotated. Holding the patient's left hand in his right, the operator thoroughly kneads the forearm on its anterior and posterior aspects. Similar treatment is then carried out on the upper arm, finishing with the shoulder-joint.

The chest is treated to the extent of kneading the pectorals, with *tapôtement* to finish in some cases. Effleurage may be applied all over the chest, the posterior surface being dealt with when the back of the whole body is massaged.

To treat the back, the patient lies as comfortably as possible in the prone position, and friction and kneading is applied to the back of the neck. Effleurage follows along the whole back, somewhat vigorous and rapid in character.

Thumb and finger movements are applied to the *erector spinæ* and the deep muscles of the back, and following this the muscles of the hips and buttocks are thoroughly kneaded. Rapid effleurage of the whole surface of the back is now performed, and very quick stroking over the spine.

Massage of the Stomach and Abdomen.—The object of the treatment of the stomach with massage is twofold: (1) To increase its motility or contractile power when in an atonic condition; and (2) To improve the quality and quantity of the secretion.

Massage properly carried out will always increase the acidity of the gastric juice except when malignant disease is present. In *hyperchlorhydria*, the tenderness over the epigastrium will often prevent the carrying out of massage, and seeing that massage would aggravate the condition, this is just as well.

In cases of diminished acidity, however, massage may be very helpful. To reach the comparatively limited area of the stomach wall that is accessible to

touch, the patient must in the first place be thoroughly relaxed and deep manipulations used; if there be any rigidity of the abdominal muscles these manipulations will be impossible.

If relaxation cannot be obtained when the patient is in the supine posture, with his legs drawn up and head raised, he should turn on his right side and the masseur work from behind him.

Deep kneading and shaking, occasionally followed by hand-vibration and slapping, are the movements most commonly employed. The treatment should be given about an hour after food, and should last from ten to fifteen minutes.

In applying massage to the abdomen, it should be seen to that the patient has emptied the bladder before beginning, and if possible had an action of the bowels. In order to get the muscles completely relaxed, the patient's head and shoulders are elevated, his knees flexed, and he is asked to breathe deeply and regularly. Some difficulty is experienced in getting the proper degree of relaxation in women—and nervous subjects generally. The patient's attention should, if possible, be distracted by conversation, etc.

To begin with, the masseur puts both hands underneath the patient's body until they meet under the lumbar region; the hands are then drawn forwards, compressing the patient's flanks and at the same time lifting somewhat until the hands again meet in the middle line of the abdomen. Deep kneading is begun in the right iliac space with both hands, and the entire abdomen kneaded thoroughly several times from the right to the left side. The left iliac space is treated in the same way, and the colon is followed through its entire course and treated with digital kneading.

The concluding movement is light pressure of the abdomen with the whole of the operator's hand, to which he then imparts a vibratory movement.

A practical point in conclusion is: Should we administer massage with a vehicle, such as powder or oil, or with the hand alone? A good deal of pétrissage and massage to the abdomen can be easily done with comfort to the patient through a light garment; but as a general rule it is well to use some powder or unguent. I have found a preparation, known as cimolite, quite ideal as a powder; and if oil seem preferable, Dee oil, a refined liquid paraffin, is best.

The following are some special affections advantageously treated by massage:—

Atonic Dyspepsia.—This is much helped by massage of stomach—chiefly effleurage directed from left to right, and hand vibration; tapotement is also used. The same treatment applies to cases where the atony has gone on to actual gastric dilatation.

Constipation.—Kneading is applied along the course of the colon, the treatment being finished with rather rapidly applied effleurage, right and left hand alternately. Specially good results are seen in children.

Headache.—If of digestive origin, general massage often helps; but carefully applied local massage is also useful and, along with pressure on nerves as they emerge from the different foramina, sometimes affords great relief.

Infantile Palsy.—General massage and electric massage of the affected parts are of much service—combined with movements, active or passive—the muscles and groups of muscles being trained to carry out co-ordinated movements. Contractures must be stretched, and may require some surgical intervention at the commencement.

Insomnia is frequently much benefited by general massage, which is best applied at bedtime; but it is useless or even harmful in some subjects whom massage fidgets.

Lumbago and Myalgia.—Massage is best applied after some form of local heat, such as an electric light bath, and should consist of effleurage, pétrissage, and some vibration. Here the use of the electric or mechanical vibrator is sometimes followed by magical results, though the pain may return later.

Neuralgia.—Massage must be gentle in character, and is best associated with some warm application.

Neurasthenia.—Massage plays an important part in the "Weir Mitchell treatment" of this affection. The patient is usually started with half an hour twice daily, and this is increased to an hour, electricity being sometimes combined with it.

Neuritis.—Massage is too painful to be borne in the acute stage as a rule, though sometimes light effleurage and kneading may be applied with benefit. Later on, as the condition improves, massage may be applied freely along with exercises.

Disseminated Sclerosis.—Electricity in any form increases the irritability of the nerve, and worries the patient; but plain massage and exercises are distinctly beneficial.

Progressive Muscular Atrophy.—The condition of the muscles is improved, and, along with it, the patient's general health. These patients are easily fatigued, so the massage must not be prolonged and must be gentle in character.

Paralysis Agitans.—Passive followed by active movements serve to strengthen the weak muscles and lessen the amount of contraction. The patient should practise assuming correct attitudes, and, walking in front of a mirror, endeavour to control the tremor by force of will.

Sciatica.—Massage is here of great benefit, kneading and vibration being applied over the nerve along with "dry stretching"—or full flexion of the extended limb on the abdomen.

Writers' Cramp, etc.—The arm, shoulder, and upper part of the spine on the affected side should be massaged daily. The contracted muscles should be stretched and the muscles opposing them exercised actively.

Sprains.—Massage is of the greatest service, and may start from the day of the injury. It should be very light at first, lasting about ten minutes; increasing in a day or two to twenty minutes. At first it should be applied rather above the affected joint sprained, especially if there is much inflammatory effusion.

T. D. Luke.

MASTITIS.—This condition may be conveniently described under three divisions: (1) Acute; (2) Chronic lobar; (3) Chronic interstitial.

1. Acute Mastitis.—This is usually associated with cracked nipples during lactation; it also occurs during pregnancy, shortly after birth, and at puberty, and as the result of injuries and the specific fevers.

TREATMENT.—Prophylactic treatment has been referred to under **NIPPLES**; any cracks or fissures of the nipple must be attended to; suckling must of course be stopped, and the milk should be drawn off gently with a breast pump. Hot fomentations are then applied with moderately firm pressure, and are repeated every three or four hours; the arm is placed in a sling. In order to diminish the secretion of milk, a light diet is given, with restriction of liquids, and the bowels are freely opened with saline purgatives. With this treatment most cases of acute mastitis will recover.

The difficult cases are those in which it is doubtful whether suppuration is occurring or not. The temperature is an unreliable sign, as simple mastitis may cause a considerable rise in nervous women. Suppuration may be suspected under the following conditions: (1) Failure of the swelling to subside under the treatment recommended above; (2) Any fixation of the skin over the indurated area; (3) Continued temperature; (4) Insomnia.

When in doubt an exploratory puncture may be made with a small scalpel or tenotome into the centre of the swelling, division of the main milk-ducts being avoided. An incision should not be made unless there is good reason to suspect pus, for if no pus is found the wound is very liable to suppurate, and a troublesome sinus may form. (See **MAMMARY ABSCESS**.)

2. Chronic Lobar Mastitis.—In this variety of chronic mastitis a portion only of the breast is affected, usually as the result of injury, or as a sequel of lactation; continued irritation, such as that of badly fitting corsets, is commonly a cause.

TREATMENT.—All forms of irritation should be removed. The arm should be put in a sling and a breast bandage firmly applied. The best local application is the ointment (B.P.) or the glycerin of belladonna. If the condition persists, the breast should be firmly strapped, or mercurial ointment be firmly applied on lint. Repeated blistering will often cause rapid resolution of the indurated area. Iron, arsenic, quinine, and sea air are valuable.

If there is any doubt about the condition, or if it persists or increases in spite of treatment, the troublesome area should be excised.

Chronic Interstitial Mastitis.—This may occur at any age, but is met with most commonly between the ages of thirty-five and fifty; there is usually no obvious cause for it; both breasts are generally affected, but one may suffer more severely than the other.

TREATMENT.—The treatment of this condition forms a very difficult problem: no hard and fast rules can be laid down; each case must be considered individually, treatment varying with the extent and distribution of the mastitis, and with the age and general condition of the patient. The following points may be emphasized:—

1. In many cases, the condition is mild and non-progressive, and does not give the patient any serious trouble. She may come under observation complaining of a swelling in the breast which she fears may be cancerous; reassurance, if it can be honestly given, is the main treatment required. Belladonna plaster or liniment may be applied.

2. If the disease be more advanced, more active treatment is called for; and this applies especially to those cases in which the condition is distributed evenly in the two breasts, and in which pain is a prominent feature. The trouble can usually be cured or considerably improved by the following measures: the application of mercurial ointment on lint, a circular hole being cut for the protrusion of the nipple; over this a firm bandage is applied; a mixture containing sod. iod. 3 gr., potass. iod. 3 gr., and tinct. nucis vom. 12 min., is taken internally three times daily after food, half a glass of water being taken with each dose. Improvement as a rule shows itself in seven to fourteen days.

3. The application of *x* rays in half-Sabouraud doses at 10-day intervals has been strongly advocated and, in my experience, certainly produces most marked improvement in some cases. Trial therefore should be given to this method before proceeding to more radical measures.

4. The question of *operative treatment* has to be considered. In France and the United States it is customary to regard this condition as pre-cancerous, that is to say, as being liable to develop into cancer, and so operation is recommended far more commonly than in this country. There is no doubt that cancer develops in a certain number of these cases, especially in patients over forty; but there is equally no doubt that the liability to the development of cancer varies greatly in different types of chronic mastitis. Each individual case therefore must be judged on its merits, for in some the disease is comparatively harmless, in others it is a source of danger.

If the trouble be persistent in spite of treatment, and be the cause of pain and worry to the patient, excision of the breast should be advised. If there be hard, irregular induration in the upper and outer quadrant of the breast, with enlargement of glands, excision is advisable. If the patient is over thirty-five years of age, and the mastitis is definite and resists treatment, then excision should be recommended. Under these conditions the disease may be considered as clinically pre-cancerous, and as such should be thoroughly removed. Removal of the breast for non-malignant conditions is an easy and simple operation; extensive incisions are not required, and the nipple may be spared if desired. (See also BREAST, TUMOURS OF.) *T. Crisp English.*

MASTOID.—(See EAR.)

MEASLES.—In this disease the chief danger is from complications of the respiratory organs; every endeavour, therefore, should be made to avert them. The air of the room should be kept fresh, and at the same time at a temperature of 60° to 65° F., and should be moistened by means of a bronchitis kettle, to

the water in which some aromatic, such as eucalyptus, creosote, or compound tincture of benzoin, may be added with advantage.

The very irritating early laryngitis is usually relieved by concentrating medicated steam round the patient—by means of a tent if he is in a ward or a large apartment—and by applying frequently-renewed hot fomentations over the larynx and trachea, care being taken not to blister the skin, in case tracheotomy should be needful. A mixture containing bicarbonate of soda, ipecacuanha wine, and compound tincture of camphor should also be given every four hours. Only in extreme cases of dyspnœa, however, should surgical interference be sought, for usually the laryngeal symptoms will subside as soon as the rash makes its appearance. But if the laryngeal obstruction requires surgical relief, intubation should be tried in the first place. Great care should be taken that the tube rests without pressure in the larynx, since in this form of laryngitis ulceration is easily caused. If the tube is constantly coughed out, tracheotomy should be performed, for in such cases persistence in intubation is almost certain to lead to ulceration.

The writer strongly recommends that in all cases of laryngitis in measles occurring in localities where diphtheria is at all prevalent, a subcutaneous injection of 4000 units of antitoxin be given. Laryngeal diphtheria, without any faucial affection, is a frequent complication of measles, and in most instances it is impossible to be sure, without waiting for two or three days, whether the laryngeal symptoms are due to diphtheria or not. Laryngeal symptoms arising after the appearance of the rash are especially likely to be due to diphtheria.

The photophobia consequent upon the conjunctival injection or inflammation necessitates that light should not be allowed to fall directly upon the patient's face. But the room should not be darkened except when the patient is asleep at night. In these cases the eyes should frequently be bathed with a saturated solution of boracic acid, and occasionally with epinephrin, 1-1000, and cocaine, 1-2 per cent solution. These remedies will usually prevent more serious complications.

Special attention should be paid to the cleanliness of the mouth ; few cases of measles are without stomatitis in some degree.

A high temperature and delirium are best treated with cold sponging or cold-water packs. For robust children iced water may be used. If pneumonia be the cause of these symptoms, an ice poultice should be applied to the affected lung. At the same time 2 gr. sulphate of quinine should be given every four hours, with an alcoholic stimulant (brandy or champagne).

In other respects the lung complications should be treated on ordinary principles (see PNEUMONIA, BRONCHITIS, etc.). The most common is lobular pneumonia, and for this 4 or 5 min. of tincture of belladonna every four hours is very useful. Stomatitis is not infrequent. The mouth, therefore, must be frequently washed or swabbed out with the solutions mentioned in the article FEVERS, ACUTE INFECTIOUS.

Vomiting is best met by peptonizing the milk and giving a bismuth mixture.

The treatment of diarrhœa depends upon its cause. If it be due to undigested food, give less food for a time and peptonize it, or give whey ; clear out the bowels with a dose of castor oil. If the diarrhœa still persists, prescribe some astringent, and if this fails to act, add small doses of paregoric or laudanum. The writer has found the following mixture from the Guy's Hospital Pharmacopœia very useful :—

R Bismuthi Carbonatis	gr ij	Glycerini Acidi Tannici	℥v
Pulveris Cretæ Aromatici c. Opio		Mucilaginis Acaciæ	℥xv
(B.P.)	gr j	Aquæ	q.s. ad ʒj

If there is colitis, the lower bowel should be washed out twice a day with warm water. In very intractable cases, raw beef-juice should be tried, instead of milk or other nourishment. If the motions are very offensive, some intestinal antiseptic is indicated, as recommended in the article on TYPHOID FEVER. Severe cases of diarrhœa will require some stimulant : brandy is the best.

Other complications do not call for any special notice.

There is often much wasting after an attack of measles, especially when there has been diarrhœa of any severity ; so that during convalescence close attention must be paid to the child's diet. Cream, cod-liver oil with iron, are often indicated in addition to the ordinary food.

Uncomplicated cases of measles may be allowed out of bed a week after the temperature has become normal, and out of doors in another week or two if the weather is fine. Such cases are free from infection at the end of three weeks from the appearance of the rash. Probably even complicated cases are free from infection at the end of four weeks. But it is advisable to keep pulmonary cases isolated till the lungs are clear.

Quarantine period : three weeks.

MEDITERRANEAN FEVER.—(See UNDULANT FEVER.)

MEGRIM.—(See HEADACHE ; MIGRAINE.)

MEMBRANA TYMPANI.—(See EAR.)

MÉNIÈRE'S DISEASE.—(See EAR, AFFECTIONS OF ; VERTIGO ; SETON, TREATMENT BY.)

MENINGITIS.—For therapeutic purposes it is convenient to divide cases of meningitis into four main groups :—(1) *Acute Infective Meningitis* ; (2) *Epidemic Cerebrospinal Meningitis* ; (3) *Syphilitic and Tuberculous Meningitis* ; (4) *Posterior Basic Meningitis*.

1. **Acute Infective or Purulent Meningitis.**—Most of these cases are secondary to some septic process in the bones of the cranium, whence the organisms penetrate the dura mater and spread through the pia arachnoid. The majority of cases, as a matter of fact, follow suppuration, acute or chronic, of the middle ear.

The treatment of meningitis secondary to gross suppurative conditions of the cranial bones must first of all be directed to the original source of infection, and is therefore primarily surgical. The diseased area of bone must be freely exposed, and any pus must have free exit.

In addition, certain general measures, applicable to all cases of meningitis, should be adopted. These comprise the following : The patient must be kept in bed, in a quiet, darkened room, his head shaved, and an ice-bag or a Leiter's coil of cold tubing applied to the scalp. In cases due to ear disease, leeches should be applied behind the affected ear. A mercurial purge, such as calomel or blue pill, followed by a saline aperient, is administered, and the bowels thereafter kept regular. If the temperature become alarmingly high, use sponging. Convulsions should be controlled by a mixture containing potassium bromide 20 gr., chloral hydrate 10 gr., syrup. aurantii $\frac{1}{2}$ dr., and aqua chloroformi to 1 oz. repeated every four hours if necessary. Withdrawal of cerebrospinal fluid is of great value, not only for purposes of diagnosis, but as a therapeutic measure. It diminishes the excessive intracranial pressure, thereby tends to relieve the headache, and sometimes even restores a comatose patient for a time, at least, to consciousness. The amount of fluid to be withdrawn depends largely on the degree to which the intrathecal pressure is increased.

Normally, in health, the cerebrospinal fluid issues from the needle drop by drop, but in cases of meningitis one often gets quite a jet or fountain of fluid. Allow this to flow until the pressure is reduced to normal. Negative pressure, by suction with a syringe, should never be employed.

Purves Stewart.

2. Epidemic Cerebrospinal Meningitis.—The patient should be kept quiet in a darkened room. Great care must be exercised in order to avoid bedsores, which are particularly prone to form rapidly. A certain amount of restraint is necessary in delirious cases. It should be applied by methods recommended in the article **FEVERS, ACUTE INFECTIOUS**. The joints should be wrapped in cotton-wool lightly bandaged on. In most cases nerve-sedatives are called for, and of these the most efficacious are morphia and opium. Large doses of these drugs can be tolerated in this disease; 25 min. of laudanum every hour; or $7\frac{1}{2}$ gr. of opium at the beginning, and 1 gr. every half hour; or morphia hypodermically in doses of $\frac{1}{4}$ to $\frac{1}{2}$ gr. at intervals of a few hours. Opium or morphia appears to be most beneficial when administered very early in the illness. As the patient becomes drowsy, the dose must be diminished, or the administration stopped. In cases where there may be any objection to opium, potassium bromide or chloral hydrate may be used. The following mixture will be found useful:—

R Potassii Bromidi		Extracti Cannabis Indicæ	
Chlorali Hydratis	āā gr cxx	Hyoscyaminæ	āā gr j
		Elixir Simplicis	q.s. ad ʒj

Of this mixture, a child of three is given 10 to 15 min. every twenty minutes until profoundly under its influence, and the dose must be repeated as soon as there is either moaning or restless movement of the limbs. The dose for an adult is half a teaspoonful, administered in the same manner.*

Most authorities agree that counter-irritation to the spine and back of the head is a valuable measure; so that blistering, or rubbing the spine with stimulating liniments such as camphor liniment, or mustard poultices, may be employed. It is not desirable to blister deeply; frequent flying blisters are preferable. Cold should be applied to the head, either by means of crushed ice in a flannel or cotton cap made in two layers, or by iced water running through an aluminium coil. In severe cases hot-packs or baths (water at 104° F.) for fifteen or twenty minutes, two or three times a day, are extremely useful for the relief of pain, hyperæsthesia, insomnia, and delirium. The bowels should be kept freely open by castor oil or calomel. Stimulants are to be employed when the state of the heart requires them. In severe and prolonged convulsions chloroform should be given. The diet is that of the febrile condition: small quantities of easily digested nourishment given frequently.

Removal of some of the cerebrospinal fluid by *lumbar puncture* is a method of treatment that has been recognized for a considerable time. This operation must frequently be performed in order to obtain fluid for the purpose of diagnosis; it can, therefore, be made use of at the same time as a therapeutic measure.

According to Sophian, who has had a large experience, a general anæsthetic during lumbar puncture is dangerous, and should be used only for violent patients. He makes use of what he terms "water anæsthesia." The patient is allowed to suck water up through a straw, and during the operation will sometimes drink as much as nine or ten glasses full. This measure acts especially well with children; but some delirious adults will quickly become quiet.

The skin at the site of puncture should be thoroughly cleansed and painted with iodine. An ordinary exploring syringe will suffice for making the puncture and drawing off the fluid. The needle should be strong and have a fairly wide bore. The whole apparatus should be sterilized. The patient should lie on one

* In the opinion of the American Editor this mixture should be used with extreme caution.

side with the spine flexed as much as possible, the head and shoulders being bent downwards and the thighs flexed sharply on the trunk. The puncture should be made between the third and fourth or fourth and fifth lumbar vertebrae. If there is any difficulty in defining these spaces, a line should be drawn from the highest point of one iliac crest to the highest point of the other, and the puncture made where this line crosses the spine. In children the puncture should be made in the middle line, but in adults it should be made slightly outside it. The needle should be inserted steadily, slowly, and slightly upwards, to the depth of $1\frac{1}{2}$ in. in children, and about 3 in. in adults. The fluid must be allowed to flow out of its own accord. If it is very thick the needle may have to be cleaned now and then with a sterilized stilette or piece of wire. When it cannot flow because of its thickness, slight suction may be applied by the syringe. In such cases, too, the lower part of the spinal canal should be washed out gently with warm normal saline solution before injecting *curative serum*. For though lumbar puncture alone is a valuable measure in certain cases, it should be only a preliminary to the injection of serum whenever this can be obtained.

The best method of injecting serum is that of Sophian. The amount of cerebrospinal fluid withdrawn, and of serum injected, is regulated by the blood-pressure. The withdrawal should be stopped when the pressure has fallen 10 mm. in an adult and 5 mm. in a child. When there is no change in the pressure during withdrawal, or when the pressure rises, fluid should be allowed to escape till it runs out through the needle at the rate of 1 drop every three to five seconds.

To inject the serum, the barrel of an ordinary antitoxin syringe (such as Roux's) should be attached by three or four inches of indiarubber tubing to the needle or cannula which has been inserted into the spinal canal. The serum, previously warmed in a water-bath to the normal temperature of the body, should be poured into the barrel and allowed to flow into the spinal canal by its own weight. If pressure by the piston be necessary, it should be applied slowly. Usually, as the fluid enters the canal, the blood-pressure drops steadily. After a total drop of 20 mm. in an adult with average blood-pressure of 110 to 120 mm., the injection should be stopped. Occasionally there is a temporary rise of pressure on injection.

According to this method, the average dose of serum has been 20 to 25 c.c. in adults, and somewhat less in children. Occasionally it may be 30 to 40 c.c.

Should any of the following symptoms occur during the injection—stupor; shallow, irregular, slow, stertorous respiration; dilatation of the pupils; incontinence of urine and faeces: the injection should be stopped and fluid allow to flow from the canal by lowering the barrel through which the serum is being introduced. Epinephrin in large doses should be injected intramuscularly. If the lumbar puncture has failed to withdraw fluid from the spinal canal ("dry puncture"), serum may still be injected, but the injection must be done very slowly, and if possible by gravity.

After the injection the lower part of the patient's body should be raised so that the fluid may gravitate towards the brain.

The injection of serum should be repeated daily till there is some improvement in the patient's condition, which will usually take place within four days. It should be repeated also if any symptom of a relapse occurs.

The serum which so far has given the best results is that made by Flexner and Jobling, of the Rockefeller Institute of Medical Research, New York.* But those prepared by Burroughs & Wellcome, Kolle, and Dopfer, can also be recommended.

It is advisable to perform lumbar puncture and to allow the cerebrospinal fluid to escape, even when no curative serum is immediately available. For

* This serum is now made by the New York City Department of Health.—AMERICAN EDITOR.

undoubtedly certain cases, especially those in which there are marked symptoms of intracranial pressure, receive benefit from this treatment. In purulent cases (again when the curative serum is not at hand), a 6 per cent solution of lysol should be injected into the spinal canal to the amount of the cerebrospinal fluid withdrawn. Good results have also been obtained by the administration of hexamethylenamine by mouth in 10-gr. doses every four hours.

In cases in which injection of serum by lumbar puncture has failed to give relief, and symptoms indicative of intracranial pressure still persist, it is very likely that the serum is prevented by accumulation of exudate from reaching the cerebral meninges and ventricles. In such cases it is justifiable to inject serum straight into the lateral ventricles. In order to reach a ventricle of an infant, the needle is made to enter at the corresponding angle of the anterior fontanelle. The needle, which should be about 8 cm. ($3\frac{1}{4}$ in.) in length, is introduced downwards and towards the median line at an angle of about twenty degrees, to the depth of about 4.5 cm. ($1\frac{3}{4}$ in.). Fifteen to twenty c.c. of fluid should be allowed to flow out, the ventricles should be irrigated with normal saline solution at a temperature of about 105° F., the excess of this fluid should be allowed to run off through the needle, and finally 15 to 20 c.c. of serum should be slowly injected. When the fontanelle is closed, the bone should be exposed over the second frontal convolution 3.5 cm. ($1\frac{1}{8}$ in.) from the middle line, and should be penetrated by a Doyen perforator, followed by a burr, which leaves a cup-shaped fossa and exposes the dura mater sufficiently for the operator to see whether any large vessel is present at the spot. The ventricle can be reached by inserting perpendicularly into the second frontal convolution, for a depth of 4 to 5 cm. ($1\frac{1}{2}$ to 2 in.), a hollow exploring needle with a blunt point and openings at the side.

Injection of serum into the ventricle should be repeated every day or two until improvement is observed.

A vaccine (prepared by isolating the meningococcus from the patient's own cerebrospinal fluid and killing it by heat) has been employed in a few cases. But this treatment appears to be suitable for chronic and relapsing rather than for acute cases. There is experimental evidence to show that a vaccine would be very useful as a prophylactic in epidemic times. (See also SPECIFIC THERAPY.)

The patient may be allowed out as soon as he is well enough.

Quarantine period: one week.

E. W. Goodall.

3. Syphilitic and Tuberculous Meningitis and Meningo-encephalitis.—

The treatment of the *tuberculous* variety of meningitis offers but little prospect of success. One should, however, employ the general measures already described. In addition, mercurial inunction of blue ointment to the abdomen, or administration of mercury by the mouth, is advisable. Repeated lumbar puncture relieves the intracranial pressure, if the communicating channels between the cranial and spinal ponds be not already closed by adhesive meningeal inflammation.

In *syphilitic* cases the prospect of recovery is much brighter. Both mercury and iodide of potassium should be pushed energetically, together with salvarsan or neo-salvarsan. Iodide of potassium may be given in doses of from 10 to 20 gr., three times a day. Mercury may be given by the mouth in full doses, say 1 dr. of the liquor hydrargyri perchloridi (1-900) three times a day, or by inunction of a drachm of blue ointment daily, or by intramuscular injections of a soluble mercurial salt. For this purpose it is convenient to give 1 c.c. of a 1 per cent aqueous solution of benzoate of mercury twice or three times a day, according to the severity of the case.

With regard, however, to treatment by salvarsan or neo-salvarsan, we must

be careful, as in all cases of cerebrospinal syphilis, to avoid maximal doses. It is prudent to give doses not exceeding half the maximal amount, i.e., 0.3 gram of salvarsan (instead of 0.6 gram), 0.45 gram of neo-salvarsan (instead of 0.9 gram) intravenously, repeating the dose at intervals of about a week for five or six successive weeks, until the cerebrospinal fluid loses its lymphocytosis and its globulin, and until its Wassermann reaction becomes negative.

The efficacy of intravenous salvarsan or neo-salvarsan treatment may sometimes be enhanced by the intrathecal administration of the patient's own serum, according to the following method: An hour after the intravenous administration of salvarsan or neo-salvarsan, when the patient's blood is presumably abounding in syphilitic antibodies, a sufficient amount of blood (about 40 c.c.) is withdrawn by venipuncture to yield 12 or 14 c.c. of blood-serum. The blood is centrifuged, to get rid of the corpuscles (which, if injected into the cerebrospinal fluid, would undergo hæmolytic), and is diluted to a 40 per cent mixture with freshly-made, sterile, normal saline solution. This dilute serum is kept for half an hour or longer at a temperature of 56° C., and is then ready for injection. On the day following the salvarsan injection, 30 to 35 c.c. of this dilute serum are injected intrathecally—previously withdrawing a certain amount of cerebrospinal fluid, partly to lower the intrathecal pressure and make room for the serum, and partly for control observations upon the cerebrospinal fluid with regard to its cytology, the presence of globulin, and the Wassermann reaction. This combined salvarsan and serum treatment may be repeated once a week for a number of weeks, the duration of treatment being guided not only by the clinical signs and symptoms, but also by the systematic examination of the cerebrospinal fluid.

Purves Stewart.

4. Posterior Basic (Simple Basal) Meningitis.—This form of meningitis, almost exclusively met with in young infants, is to be regarded as a sporadic form of epidemic cerebrospinal meningitis, and is produced, like it, by the meningococcus.

If the disease be diagnosed within the first week, lumbar puncture should be performed and antimeningococcus serum injected (see above). After this period the serum is of no avail, but a vaccine should be prepared, if possible from the cerebrospinal fluid, and vaccine treatment begun as soon as possible, an injection being given every third day. (See SPECIFIC THERAPY.)

In addition to this, which is the specific treatment of the disease, repeated lumbar puncture (q.v.) is of use in relieving intracranial tension and lessening head retraction and vomiting. It may be repeated with advantage every three or four days. The fluid should be allowed to flow until it begins to come only in drops.

Treatment by drugs is of no use except to meet special symptoms; bromides, for example, may be required for restlessness or convulsions, and opium for pain. Mercurial aperients are useful. The nose and nasopharynx should be kept clean by washing out with an alkaline lotion (e.g., borax, 2 gr. to the ounce), and if the ear-drums are bulging, they should be perforated and a boric lotion used twice daily for irrigation.

Careful nursing is of great importance, and it may be necessary to feed by the nose tube for long periods.

Robert Hutchison.

MENOPAUSE.—For the nervous and vasomotor disturbances of the menopause (headache, flushings, perspirations, etc.) bromides are the most efficient remedy, e.g. :—

E Potassii Bromidi	℥j-iss	Tincturæ Lupuli (20%)	℥iij
Tincturæ Sumbulidis (B.P.) (10%)	℥iij	Aquam Camphoræ	ad ℥vj

One tablespoonful after each meal.

The following is also a useful prescription :—

R Ammonii Bromidi	gr. x-xv	Tincturæ Nucis Vomice	℥ x
Spiritus Ammonię Aromatici	℥ xx	Infusum Gentianę Co. (N.F.)	ad ̄ss

Before each meal.

Ichthyol in 3-gr. doses in capsule is also serviceable. Ovarian preparations have proved disappointing.

Robert Hutchison.

MENORRHAGIA and METRORRHAGIA.—These may be considered together for the purpose of this article. It must be remembered that menorrhagia and metrorrhagia are symptoms and not diseases, and that a diagnosis of the cause of the bleeding must be made before any rational treatment can be adopted. One should never treat unusual bleeding without an examination, except in young unmarried girls in whom the history precludes the possibility of pregnancy. In menorrhagia or metrorrhagia occurring in older women, whether married or single, it is impossible to over-emphasize the importance of making a vaginal examination, and, if necessary, a bimanual examination. Carcinoma of the cervix or of the body of the uterus may be present without causing any symptom besides bleeding—there may be a complete absence of pain, wasting, or any foul-smelling discharge—and neglect to make a local examination may deprive the patient of her only chance of cure.

An increased amount of bleeding is common in young girls at, or soon after, the time of puberty. The patients are usually anæmic, and often undeveloped. Improvement of the general health by the administration of iron and by the removal of the causes of the anæmia, e.g., long hours of employment indoors, constipation, and dyspepsia, usually brings about a cure. In some cases rest in bed is necessary, and is usually efficacious. One of the most useful drugs is cannabis indica, which may be given in doses of $\frac{1}{4}$ gr. of the extract three times a day. Ergot is generally of little use in such cases. "Styptol" (cotarnine phthalate) in doses of $\frac{2}{3}$ to 1 gr., three or four times a day, is much more likely to prove successful. Lactate of calcium, 30 gr., every other day in water, is useful in anæmia of young girls with excessive bleeding.

In older girls frequent causes of menorrhagia with no abnormal physical signs are found in mental strain, worry, assumption of responsibility for the first time, etc., and in occupations involving long hours of standing. In these cases, rest, calcium lactate, ergot, and iron are to be advised.

In cases where early pregnancy is diagnosed or suspected, the possibility that extra-uterine pregnancy is the cause of the bleeding must never be forgotten.

After miscarriage or labour, if the uterus, though enlarged, does not seem to contain any retained portion of the ovum, ergot, rest, and hot douches will be sufficient treatment. If, on the other hand, the uterus is not only bulky but seems likely to contain some portion of the ovum, the cervix should be dilated and the uterine cavity explored with the gloved finger. If no definite piece of placenta can be found, the endometrium should be curetted.

Increased frequency of the monthly periods does not necessarily call for treatment. If the flow, though occurring more frequently than normally, is not too free and has no deleterious effect on the general health, no special treatment is required.

"Erosions" of the cervix may cause a blood-stained discharge. After making certain that the "erosion" is not an early carcinoma, by testing its friability, etc., and, if necessary, by microscopical examination of an excised portion of tissue, the treatment will consist in rubbing it with silver-nitrate stick, or swabbing it with pure carbolic acid or iodized phenol. If the erosion bleeds readily, bimanual examination may reveal the fact that the patient is pregnant.

Mucous polypi of the cervix should be twisted off with a pair of blunt forceps, such as ovum forceps. An anæsthetic is not necessary except in the case of a very nervous patient. When a middle-aged or elderly woman who complains of unusual bleeding is found to have a mucous polypus of the cervix, the attendant should not be content with removing this, but should keep her under observation, and, if the bleeding persists or recurs, should dilate the cervix and explore the interior of the uterus.

The fact that a patient with uterine fibroids has arrived nearly at the time when the menopause may be expected does not necessarily contra-indicate an operation. Atrophy of large fibroids after the menopause is rare, and degeneration is common. Unusual bleeding at the time of the menopause must never be diagnosed as being due to the menopause until every other possible cause has been excluded. Carcinoma of the uterus is particularly common at this time of life. Recurrence of bleeding after a more or less prolonged period of amenorrhœa in a patient who is known to have uterine fibroids should always arouse the suspicion that there may be malignant disease of the endometrium. Any irregularity, ulceration, or new growth of the cervix, must be investigated by the aid of sight and touch, assisted, if necessary, by microscopical examination. If there is any suspicion that there may be malignant disease of the body of the uterus, the condition of the endometrium must be investigated, after dilatation of the cervix. The treatment of carcinoma of the uterus, involving major operations, is outside the scope of this book.

It is well to remember that a hydatidiform mole may occur at about the time when the menopause is expected, and that the history in such cases is often misleading, so that pregnancy may not be suspected until an examination is made.

Excessive bleeding at the time of the menopause, when no local cause can be found, may be treated by rest, ergot, bromides, and hot douches. Ergotin in pills is sometimes not so efficacious as is the liquid extract of ergot in an acid mixture, such as :—

R	Liquoris Strychninæ Hydrochloridi		Extracti Ergotæ Fluidi	℥ xxx
	(1 per cent)	℥ iij	Syrupi Zingiberis	℥ xxx
	Acidi Hydrochloridi Diluti	℥ x	Aquam	ad ʒ j

Two tablespoonfuls to be given three times a day.

One need not be afraid to employ iron during the occurrence of unusual bleeding from the uterus. It is often the most useful drug that can be given. (*Vide* also articles on HÆMORRHAGE, UTERINE ; and FIBROIDS OF UTERUS.)

H. Russell Andrews.

MENSES, RETENTION OF.—(See AMENORRHŒA.)

MENTAL DEFICIENCY IN CHILDREN.—With regard to the treatment of these cases, two general statements may be made :—

1. In the vast majority the condition is, strictly speaking, incurable, in the sense that children who are mentally weak to begin with will remain so to the end, whatever is done.

2. There are few mentally deficient children, however, who are not capable of great improvement under suitable treatment.

These two statements are equally true, but the latter is much the more important as a basis of action.

It is a great mistake to suppose that the imbecile, because he cannot be cured “tuto, cito, et jucunde,” is therefore outside the sphere of the medical practitioner. Indeed, he is one of the very few members of the community who should rank as a patient from his birth to his death. If his mother gets no help in her management of him from her medical man, she is not likely to get it from

anyone else. It is obviously the doctor's duty to lessen as much as he can the suffering caused by the presence of an imbecile in a family. With this end in view, he has to treat both the child who is causing the suffering, and the parents who are feeling it.

When a baby is mentally defective and his parents do not know it, the first question that arises is : Are we to tell them ? If they ask plainly, they must, of course, be told the truth. If, however, as often happens, they ask no direct questions (either from ignorance or because they are afraid of the answer), it is usually far better to tell them nothing. There are two reasons for this : (1) A very large proportion of imbecile babies die early. When this happens, it is clearly well for all concerned when the child's defect has remained a secret known only to the doctor. (2) The parents often know nothing about the subject of mental defect. When this is so, a sudden intimation that it is present in their child, if made before their own observation has prepared them to receive it, is apt to produce unsatisfactory results. They either refuse to accept it, or, if they do so, it causes such discouragement as to paralyze their efforts for his improvement.

Whether the parents realize the significance of their child's backwardness or not, the main thing is that they should turn their attention actively to what can be done to improve him. It is by trying to make him do things better, that they will come to see the true state of the case. They should, however, be told plainly that the expectation of sudden unworked-for recovery at seven, or fourteen, or any other age, is an utter delusion.

The extent to which mentally defective children benefit from treatment, and the best treatment to employ, vary, of course, greatly, according to the degree of the defect and the nature of the case. In many forms of the condition, the improvement under bodily and mental culture is remarkable. In the lowest type of idiocy, no treatment, beyond general mothering, may be possible. And there are cases, e.g., of epileptic and syphilitic dementia, in which any attempt to train the mind will only aggravate the child's condition.

The object of our treatment, so far as the child is concerned, is to make him as happy and as good as possible. As his happiness will largely depend on how many things he can and does do and notice, and on how he commends himself to others by his behaviour, our chief aim must be to make him more capable and likeable. We must also try to give him some sense of duty, proportionate to his intellect, and to show him that his duty lies in doing things that he is quite able to do.

What follows refers chiefly to young children (under five or six years). It is mainly at first that the mothers require assistance ; and the treatment cannot be begun too early.

The main indications for treatment may be stated as follows :—

1. *Attend to the General Health.*—This includes the giving of good plain food suited to the child's powers of mastication, attention to the bowels, much open-air exercise, frequent baths, and especially warm clothing, for the child will always be duller if he is feeling cold.

If epilepsy or cretinism be present, their treatment is, of course, to be seen to. It is also important to treat such conditions as rickets, anæmia, tubercle, and dyspepsia, which may greatly interfere with the child's mental, as well as with his bodily, vigour.

Local defects, such as refractive errors, adenoids, and contracted tendons, are often well worth attending to in these children ; and massage and electricity are sometimes useful.

Craniectomy has proved of no value, and whether surgical operations for chronic hydrocephalus are ever of benefit to the intellect is not yet settled.

2. *Awaken the Child's Faculties, (a) Bodily, and (b) Mental.*

a. *He must be encouraged in the voluntary use of all his muscles* regularly and carefully. Such exercises are not only good for improving his strength and co-ordination, but are also helpful in stopping the purposeless automatic movements which so many of these children have. Musical drill, dumb-bells, ball games, bean-bags, walking between the steps of a ladder, nail-boards, threading beads, and all sorts of kindergarten occupations, are useful for the older and more intelligent of the children, as well as singing and reciting. For young children and those who are less capable, various very simple actions, such as clapping hands, or playing with a rattle, may to some extent answer the same purpose. It is important to teach the child chewing if possible; and if he dribbles, his lips may be strengthened by exercises, such as holding a pencil transversely between them for a given time, and by blowing whistles, trumpets, etc.

b. *Teach him to notice things* and to compare their characters—roughness and smoothness; hardness and softness; heaviness and lightness; heat and cold; colours; shapes (circles, squares, triangles, spheres, cubes, cylinders, etc.); distances; sounds (musical and other); tastes and smells. Take him out, or to the window, and let him see the people, horses, dogs, cars, etc. If objects do not attract him, perhaps bright light and colours will. Find out what arouses his attention, and let him have it. Encourage him to look at, listen to, and handle anything that he is taken up with. Any sort of interest will help to brighten him.

3. *Encourage him to use his Awakened Faculties in giving himself Pleasure.*—Remember that he needs to be taught to do many things which normal children do of their own accord without teaching. Incite him to try to do things; and, at first, plan easy successes for him. If he deliberately wants a thing, tries to get it, and succeeds, this is a most valuable and a very pleasant lesson for him. In the case of a baby, if he likes a noise, give him a key and a pot-lid and let him make it for himself. Never let the mother or nurse go on doing for the child anything that he can be made to do for himself. For most mentally defective children mere memory knowledge is of little use, but the more things they can do, the better for them.

4. *Promote Self-control.*—This is of immense importance, and very difficult. It includes a number of things. There is, firstly, keeping himself clean and letting his mother know when he requires to be attended to. Some mentally defective children cannot be taught cleanly habits at all. A great many, however, who seem to have complete incontinence in early childhood, may, with persevering training, become quite normal in this respect in time. General personal cleanliness, and tidiness in person and dress, are also constantly to be insisted on. Another point of great importance is that bad habits of all kinds, to which these children are particularly prone, must be watched for and checked at their earliest beginning. This applies not only to such things as masturbation, thumb-sucking, and dirt-eating, but equally to little tricks of manner and expression (grimacing, unpleasant noises), which do the children much harm by drawing attention to their defect and making them objectionable to others. The acquisition of good manners, including good temper, is of far more consequence to the child in most cases than that of reading or writing, and the ability to speak nicely and to use a knife and fork like other people is for him an invaluable accomplishment. Thoroughness in everything, so far as it is practicable, is of inestimable importance. The mother must never acquiesce in the child's doing less than his best because he is weakly.

5. *Cultivate the Moral Character.*—Prompt obedience is as all-important in the education of character in mentally defective as it is in ordinary children. Ideas of justice, honesty, truthfulness, affection, unselfishness, and gentleness

to younger children and to animals can and should be inculcated. If we exclude some rare cases of so-called "moral imbeciles," we may say that there are few mentally defective children who have not some sense of right and wrong to develop.

Institution Treatment.—If the home is comfortable and well-conducted, it is generally far the best place for the mentally defective child, during the first five or six years of life at least. After that, if he is educable, there are usually great advantages in sending him to an institution. If he is being well brought up, he will, indeed, in most cases, do no harm whatever to his normal brothers and sisters. It is, however, very discouraging for him, as he grows older, to be associated in his work and play with normal children. Not only are they apt to tease him, but the fact that they always do everything so much better than he does is very demoralizing. If, again, he is kept apart from other children, he loses the immense advantage and pleasure of society and healthy rivalry. These he will have among children of about his own level. Certainly, for most of these children, institution treatment is much happier as well as more instructive, because more stimulating, than treatment at home.

John Thomson.

MENTAL DISEASES.—General Considerations.—Any medical man may be called on at any time to treat a case of mental disease without a specialist's assistance, and without the aid of a mental hospital. What is here to be said on the subject will refer to home treatment and management rather than to the more organized treatment which is possible in a mental hospital. This task is often one of great difficulty and responsibility. There are considerations in carrying it out which do not occur in the treatment of any other disease. From the purely medical point of view mental disease may rightly be called brain disease; but inasmuch as the mental faculties, power of regulating self-action, and personal liberty, are specially involved, questions other than medical necessarily arise in most cases. The right treatment of mental disease can seldom be restricted to the giving of medicines. The patient's life has to be regulated, his whole environment provided for, and frequently his liberty restricted. There are often questions of extreme urgency which have to be faced. Is the patient's life in danger through his own actions? Are the lives and safety of those about him in any danger? Is his business or reputation or his social position at stake? Is his brain forming a pathological habit which may become permanent, and issue in mental death? The symptoms of his disease may largely consist in changed ideas, perverted affections, lessened will-power, immorality, or crime. Still, the doctor must never forget that at the back of all those mental, moral, and legal disturbances there is disease of the brain cortex as their real cause. He must ever keep in mind that the brain cortex is so related to every function and organ of the body that bodily symptoms in abundance will usually be found, if they are looked for, as an essential part of every case of mental disease. Examination of the body and its functions, therefore, before treatment is decided on, must be as thorough as, and commonly far wider in scope than, is required for most cases of bodily disease.

PREMONITORY AND EARLY SYMPTOMS AND THEIR TREATMENT.

Some cases arise suddenly and with few premonitory symptoms, but the majority have such prodromata, which it is of the first importance for the family practitioner to recognize and treat. It is here that the general practitioner's knowledge and skill come in rather than those of the specialist, who is commonly not called till the disease has established itself. Those premonitory symptoms are often bodily as well as mental in character. It is certain that if the right treatment be adopted in this early stage, many cases need not become technically

"insane" at all. The insomnia, nervous exhaustion, explosions, and toxæmia on which mental disease is so often founded might, in such cases, be put right, and the disease go no further. The brain has a solidarity of action whereby a disturbance in one area tends to spread into others if not checked at its source. Those early symptoms and prodromata of mental disease consist chiefly in different cases of the following symptoms :

Sensory symptoms such as headaches and all kinds of perverted sensations in head and body, sleeplessness, loss of flesh, digestive troubles, constipation, altered secretions, dry skin, circulatory disturbances, blood changes, neurasthenia, hysterical attacks, changes of facial expression, twitchings and muscular restlessness, and many other such bodily disturbances. All such changes may mean either that the brain is becoming deranged and causing such disorders, or that disorders have arisen elsewhere than in the brain and are causing auto-intoxication, reflex excitability, or nerve-cell starvation. The more usual of the early and prodromal mental symptoms are loss of energy and power of doing work, irritability, hyperæsthetic or anæsthetic emotional states, morbid anxieties, accentuations of natural temperament, undue "nervousness," inability to fix the attention, morbid antipathies and suspiciousness, mental automatism, and mental actions independent of the patient's volition. The mental attack is not a simple and localized phenomenon in most cases. The sensory, motor, and nutritional functions often break down before the mental apparatus is reached.

The treatment of such preliminary and early symptoms of mental disease is necessarily different in different cases, but it mostly comes under the following headings :—

1. Remove the cause as far as possible.
2. Restore the functions of any bodily organ that may be disturbed in its normal working.
3. Try and change the patient's environment for the time being, so as to give him the stimuli or sedatives of different air, new surroundings, change of food, a change of occupation and of social life.
4. Try and effect a better general nourishment of the body, this usually implying specially digestive and tempting foods, aids to digestion and alimentation, bitter tonics, sometimes dietetic alcoholic stimulants, hydrotherapeutics, and life as much as possible in the open air. Food medicines, such as cod-liver oil, extract of malt, and plasmon, are often most useful. Such patients should be regularly weighed, and every pound of body weight gained will often be found to indicate the further removal of the patient from the threatened mental attack.
5. Antagonize and get rid of toxins, endogenous or exogenous, by purgatives, intestinal antiseptics, serums, or vaccines, as may be indicated by the symptoms present.
6. The use of direct and stimulating nerve tonics and blood-forming medicines, such as strychnine, the mineral acids, and iron.
7. The judicious use of hypnotics and nerve sedatives, where insomnia and muscular instability exist. Paraldehyde in small doses given experimentally, hot water at bed-time, warm baths, hot applications to abdomen at bed-time, hot whisky-and-water or London porter, trional, sulphonal, veronal, and the bromides, all in small experimental doses, not continued too long, may be indicated as suitable in different cases.
8. The removal of all possible sources of mental worry and anxiety is clearly indicated. As a rule it is worry, not work, that causes a mental attack.
9. Rest in bed, either alone or combined with massage, is in many such cases an effectual therapeutic measure ; but my experience is that in cases with mental symptoms, early bed treatment, with the isolation that is usually prescribed along with it, is a measure not unattended with danger. I have seen scores of melancholics become daily worse, and the mental malady aggravated, by this

means. The patients got more self-centred through having no distractions from their morbid fancies.

10. There are other cases where life in the open air, vigorous exercise, out-door games, fishing, golf, tennis, etc., will suit the patient best. It is often well to try rest first, and if it fails, to try exercise. Many cases will do well with rest for a week or a fortnight, and then exercise following on it.

11. If the case is syphilitic in origin, salvarsan should be employed with other anti-syphilitic remedies, but experience up to this time has not shown many good effects from that agent in chronic syphilitic diseases.

Risks and Warnings.—Quick and exciting travel is nearly always to be avoided, as being both exhausting and irritating. Sea voyages, long or short, are always attended with danger of easy suicide: are, indeed, often suggestive of such a catastrophe. Many are the persons whom I have seen sent to sea and who never returned. Such a sea trip is too often a recommendation of despair. It should never be undertaken without the most careful consideration of the risks involved. In giving sedatives, hypnotics, and alcohol in any form, remember that in some constitutions a drug habit is very easily set up. Watch, therefore, whether the patient is beginning to like his drug too well. Some cases can be, and are, over-fed through the zeal of the doctor and the anxiety for speedy cure by anxious relatives. I often used to fall into this error. Watch the tongue, the liver, and the bowels, as well as the kidneys, if over-feeding is carried out. Some tonics are unduly stimulating in some cases, and should, therefore, not be pushed. Strychnine is the chief of these. Remember that in many cases change of employment is the best rest. Use recreations with circumspection. In certain cases, if they do not cheer, they bore and irritate. Always consider the reactive capacity and peculiarities of the brain you are treating. You often get the exact contrary reaction to the one you are aiming at, when the brain is in an abnormal or exhausted condition. It is well to assume in many cases that human brain constitutions are various, that mental working is infinitely subtle, and that our knowledge is limited: therefore our treatment is, more or less, of an experiment which may turn out to be wrong in any case. Do not, therefore, hesitate to alter it if your plan is not working well: but naturally a wise man does not accentuate this view to the patient or his relations. Dogmatism always comes in well in medical treatment, but never more so than when the mind is affected and has to be cured.

ESTABLISHED MENTAL DISEASE AND ITS TREATMENT.

If the preventive treatment of early symptoms has failed, and mental disturbance of a more decided kind has shown itself, then the medical man is at once faced by many responsible questions. One of the first of these is the following:—

Is the treatment to be conducted at home, in rooms, or in a mental hospital? The patient's relations, he himself, if sufficiently sensible, and the family doctor, all naturally desire home treatment if this is possible. As a matter of fact, it has been the experience of all who have had most to do with mental cases, that home is on the whole the worst place for treatment, but there are *exceptions*. A man's, and especially a woman's, home, is so naturally the place for the treatment and care of sickness and weakness, that it must not be left without sufficient reasons. Some persons, too, are such home birds, that being turned out of it is an especial hardship and irritation. In all I am about to say I assume that the home is good, and that there are means to provide good nursing and all other requirements. There are many cases of short toxic delirium, of mania transitoria, of epileptic excitement, of puerperal insanity, of very slight melancholia, and above all, of insanity of the aged, where home treatment can be effectually carried out if good nursing, companionship, and

attendance can be secured. Especially is this the case if the home happens to be in the country or in the open suburbs of a city.

If it is decided that home is not the best place for care and cure, then, if the patient has sufficient means, or if he has kind relatives in the country who want to do him a service, a suburban house, or rooms in such a house, or a country residence, form the next alternative in certain cases. The private house of a doctor, a clergyman, or any other person of intelligence, is often a suitable temporary hospital in a mental case. In Scotland we have the enormous advantage of being able legally to treat an early case of mental disease away from his home, "for profit" and without certification, for six months. Though the profession in England strongly desires such a measure for that country, the Lord Chancellor and the Attorney-General have three times failed to get it passed by Parliament. The house we are to use should, if possible, have an enclosed garden. Rooms on the ground floor should nearly always be selected for use if the case is an acute or suicidal one. All door-keys should be taken away and kept by the nurse. Inside bolts to the w.c.'s and bathrooms should be taken off. The windows should be temporarily stopped so that the lower sash cannot be raised more than five inches. These precautions do not, however, apply to all cases. A sunny and cheerful outlook is a distinct adjunct to treatment. The medical visits should be frequent and thorough. They make the patient feel he is under treatment and not merely in isolation. Every precaution against suicide and accident should be carefully taken and stringently enforced. The patient should never have his medicines or administer them himself. In many cases the day should be systematically divided up as a therapeutic measure. Though the nearest relative is legally responsible, yet the doctor and nurse must be invested with plenary powers. I have superintended the treatment of almost every kind of mental disease, from acute mania down to the mildest melancholia, in such circumstances, with reasonable success in many cases. It is largely a question of the doctor, the house, and the nurse. The expense is necessarily great, and risks cannot be entirely eliminated. The forms of insanity that are on the whole most suitable to treat in this way are melancholia where the suicidal impulse is not very intense, adolescent insanity of the milder types, recent puerperal insanity, hysterical insanity, mental disease associated with neurasthenia, mild and fairly manageable cases of mania, lactational insanity, that of pregnancy, senile insanity, and some cases of alcoholism. Poverty or limited means seldom admit of home or private treatment, but it is surprising how often it is possible to get even poor people with mild mental symptoms sent off for a change to some country relation, with admirable curative effects.

If the case is unsuitable and the means are inadequate, or if treatment at home or in rooms has failed, then comes the question of a good mental hospital. The chief considerations which determine such a decision are a continuation of acute symptoms, a marked aggravation of the disease, intense persistence in and subtly schemed suicidal attempts, great violence, homicidal impulses, very dirty habits, much noise, offensiveness to decency, quarrelling with a succession of nurses, and manifest failure of other methods of treatment. These undoubtedly point to institution treatment, where there is abundant nursing, a medical régime of orderly living, discipline, suitable rooms, and instant medical attendance. Many patients will obey the rules of an institution quietly who will not submit to personal orders. Good institutions, too, have suitable occupations, amusements, and means of passing the time which cannot be got in private treatment. They have villas, means of classification, hospital wards, and seaside houses. I am of opinion that scarcely any case that seems curable should ever be allowed to drift into incurability without such a hospital being

tried. The mental and therapeutic effect of hospital treatment is sometimes immediate and indubitable.

Speaking of hospital treatment, I am strongly of opinion that in all our large general hospitals there should now be instituted wards suitably administered and specially adapted for the treatment of our poor suffering from early and transient mental symptoms. Especially since the treatment of so many recent cases of insanity by rest in bed plus medical treatment has been found efficient, the provision of such wards in our general hospitals is called for.

If a hospital is decided on, certain legal forms and medical certificates are required, but the particulars of these, and the forms themselves, can always be got from the physician in charge of the institution. A very difficult question often occurs after everything has been arranged. How is the patient to be got to hospital? My advice is, leave that to the physician or take his advice. Avoid deceiving the patient. Say he is going to be under a doctor's care. The principle holds good that a man whose mind is affected has a moral right to truthful statements. But I admit there are many exceptions to this axiom, where truth may clearly aggravate the symptoms of the patient's disease. Then it comes to be a medical question whether euphemisms and a certain modification of brutal candour may not be reckoned among the medicines the patient has to swallow for his good.

Nursing.—The securing of a good and experienced nurse, male or female, is one of the most important early considerations. Nowadays experienced and certificated nurses of both sexes, trained under the Medico-Psychological Association rules, can be got from most nursing homes. A "mental nurse" has many advantages over one with no such special experience. The orders to the nurse must be specific, and in detail. She should keep a regular record of the food taken, the exercise, and the patient's condition and symptoms, mental and bodily. Provision must be made also for her going off duty, as no kind of nursing is more exhausting than the nursing of a bad mental case. If means allow, the nursing strength ought to be over what would be necessary in a case of ordinary bodily disease.

Feeding.—The next thing that has to be provided for is the feeding of the patient. A good cook is often of as much importance as a good doctor. Food should always be tempting, nourishing, well cooked, and well served. For most acute cases some of the food at least should be fluid or nearly so. Nothing is so good, so handy, or so easily got as milk or liquid custard, made of a pint of milk just under the boiling point, into which one or two eggs, after being beaten, are stirred, with sugar. Such a custard is dietetically a meal. Several such custards a day constitute a nutritive diet that is easily digested. The doctor should always be provided, in case it is required, with a long rubber tube, No. 12 or 14 catheter size, with a funnel attached, which can be passed through one nostril, and in this way the patient may be fed if food is entirely refused; this can now be got from all surgical instrument makers. If the feeding has to be long continued, the custards can be supplemented by strong soups, mutton ground in a mortar, vegetable juices, jellies, fruit juices, wines, and sugar in solution. The condition of the stomach and of the digestion must, of course, be the test of how much food is to be given. In my judgement, under-feeding is more risky to recovery than over-feeding, in most acute cases. Nourish your patient well, and make him gain in weight, are rules to which there are few exceptions in mental medicine. Frequent feeding and night feeding are often required. To many cases a tumbler of hot milk at bedtime, with sometimes 1 or 2 oz. of whisky added, will be found to be the best soporific the patient can have.

Bed Treatment versus Exercise in the Fresh Air.—Of late years, in this

and all other countries, many early and acute mental cases are being treated in bed, for the first few weeks at least, and often for longer periods. The theory of this mode of treatment is that the symptoms present in most such cases are either the result of bodily weakness or exhaustion, or tend towards those conditions. It is to conserve the strength of the patient that this is recommended. Undoubtedly, when patients die in the acute stages of mental disease, the brain cells often show marked signs of having undergone the process of chromatolysis, which indicates that the katabolic process, that of using up material, is in excess of the anabolic process, or building up material, in the substance of the cells. Rest treatment in bed for mental cases was the natural outcome of the success of the Weir-Mitchell treatment in neurasthenia. It is most applicable to very acute and exhausting cases, to those who are thin and ill-nourished, to those who are easily excited by outside impressions, to puerperal cases, to many toxic cases, to cases where the temperature is high, and to those with concurrent bodily disease. It should never be forgotten, however, that moderate and suitable exercise or sitting in the fresh air is one of the sheet anchors of the treatment at some period of nearly every mental case, and during its whole course in many such patients. Active or long-continued exercise must not be pushed to excess. It must be prescribed and watched as a powerful medicine is watched. It can soothe and stimulate, can cure insomnia, can help digestion, can stimulate appetite, can promote the action of the excretory organs and of the bowels, and can stimulate normal metabolism in every tissue and organ. If there is muscular restlessness or nervous "fidgetiness," it often affords the best outlet for such superfluous energizing. Massage is a substitute for it in some cases, but an uncommonly poor substitute. The fact is, rest and exercise should not be looked on as antagonistic systems, but complementary to each other, each being the right thing at different stages of the same case or in different cases. There is no doubt, however, that the bed treatment in many cases solves certain difficulties of the treatment at home and in rooms, and is a great boon, therefore, to the doctor as well as to the patient.

Occupations and Amusements.—In most cases of mental disease, provision must be made for the patient's mind being withdrawn from his own morbid ideas and feelings. He must be taken out of his morbid self. Selfishness and self-centredness are the characteristics of most forms of insanity; therefore we must try to get the patient to do simple kinds of work, such as gardening, knitting, or sewing. We must also amuse him by suitable games, such as golf or fishing, or anything else that he takes an interest in. The social instincts are often morbidly lessened, and we must try and provide suitable company and pleasant social intercourse. In fact, for the treatment and cure of this disease the patient's whole life must be conditioned. This is never a simple matter, and implies constant thought on the part of the doctor and the nurse. New problems and new conditions may arise every week, and must be met. Mental disease is as various as the human countenance. The human brain is not a simple mechanism; human nature is complex; and mental disease is a disorder of both in their highest functions and deepest recesses.

The use of Tonics and Nerve Stimulants.—There are very few cases for which tonics of some sort are not beneficial at some stage. I unhesitatingly put quinine and nitrohydrochloric acid as amongst the most generally useful, and applicable to most cases. There are some cases where the temperature is high, such as acute puerperal mania, where I am in the habit of giving 10-gr. doses of quinine three times a day, with markedly good effect; but in most instances 1 to 5 gr. three times a day, combined with 3 min. of dilute nitrohydrochloric acid, will be found sufficient. Strychnine is only applicable in the early stages in simple melancholia, and in the later stages of all insanities when the acute

and excited symptoms have passed away. Iron is applicable where anæmic conditions exist. I often use a pill composed as follows:—

R. Pil. Aloes et Ferri (B.P.)	gr. iiij	Extracti Nucis Vomicae	gr. ½
Quininae	gr. j		

This is, of course, laxative as well as tonic. The compound syrups such as Easton's, Fellows', etc., should not be given indiscriminately. They often cause excitement, and frequently aggravate insomnia. They are not suitable in most acute cases, nor in excitable melancholia, nor in super-sensitive neurasthenic cases, nor in hysterical patients, nor where convulsive symptoms exist.

Laxatives, Hepatic Stimulants, and Intestinal Disinfectants.—The most ancient treatment of insanity we know was the Hippocratic practice of using a strong purgative in the shape of hellebore. It is certain such a practice has remarkably good and curative effects in many cases. Few things are more evident in most acute cases and many chronic forms of mental disease than derangements of digestion, of the action of the bowels, and of the hepatic functions. The tongue will very often be found coated and furred. It tends frequently to be dry, this morbid condition being shared by the mucous membrane of the mouth and throat. It will be found that in most cases of melancholia the bowels are inactive and are often obstinately constipated. Frequently the stools are devoid of bile, while the colour of the skin and of the conjunctivæ is muddy and yellowish. Of late years the opinion has become strong and widespread that the contents of the bowels may become very septic, and that catarrhal conditions of the stomach and bowels frequently result from this cause. Dr. Ford Robertson, of the Scottish Asylums Pathological Laboratory, has lately astonished those of us who have seen most symptoms and treatment of insanity, by drawing attention to the enormous multiplication of micro-organisms over the surface of the mucous membrane of the stomach, duodenum, and small intestine, in general paralysis. As the result of those clinical and pathological facts, it may be said that purgatives have lately "come in again." Calomel, so long disused in psychiatric practice, has come into use in a marked degree, either in alterative and disinfectant doses of $\frac{1}{8}$ gr. to 1 gr. twice a day, or in larger purgative doses of from 1 to 5 gr. at night. Its good effect in some cases cannot be questioned. Castor oil, cascara, aloes, podophyllin, euonymin, iridin, and most of the common laxatives are largely used according to the fancy of the doctor or the constitution of the patient. Saline laxatives, including the ordinary mineral waters of the Continent, are used as early morning draughts with excellent effect. A melancholic or a maniacal patient with a foul tongue, bad breath, and constipated bowels, is in nine cases out of ten in a better state mentally after the bowels have been well moved. Purgative treatment must, however, not be pushed to an extreme, for it may weaken still further the patient, who cannot afford to lose any of his strength. There are a few cases, especially in epileptics, where croton oil will work wonders in quieting acute maniacal frenzy or in preventing the occurrence of this condition when the early symptoms begin to appear. A foul tongue and the use of purgatives need not, and should not, prevent feeding in large quantities in certain weakened or acutely excited patients. The old "rhubarb pill" is often an admirable tonic-laxative. The three intestinal disinfectants that are used most and seem to be most effectual are salol in doses up to 10 gr., β -naphthol 2 to 8 gr., and calomel in small doses. They should mostly be combined with laxatives. We have all been disappointed in their general usefulness, but in individual cases good results have been remarked by most practitioners who have used them. Some physicians begin treatment by washing out the stomach.

General and Cardiac Stimulants, Tonics, and Depressants.—The heart's action is often weakened in cases of mental disease, especially in patients suffering from excited melancholia, acute mania of long duration, and in the toxic and infective forms of mental disease. The blood-pressure should be taken in most cases; the presence of arteriosclerosis is thus discovered. There is often a seeming contradiction in the condition of the cardiac action and of the vascular pressure. We may have a very weakly-acting heart along with high vascular tension; very frequently indeed in the graver forms of melancholia, and in some cases of mania, the pulse-rate is high, up to 100 and even 150. This tends to continue during the whole of the acute period. I believe it indicates two morbid conditions: first, a toxic condition affecting the cardiac centres; second, a state of irritation in the brain cortex which acts secondarily on those centres. Alcoholic stimulants in the shape of wines, malt liquors, and spirits are often indicated in mental disease to combat weak cardiac action, impaired digestion, and collapse of the higher cortical centres. In acute puerperal mania, undoubtedly a toxic condition, I constantly give three and four glasses of whisky spread over the twenty-four hours, always, of course, along with some nourishment. I have even given far larger quantities than this, with the very best effect. Prolonged sleep often results from the use of alcohol in this way. Where the pulse is weak I use digitalis, strophanthus, and strychnine, along with tonics. In those quick-pulsed cases to which I have referred, iodide of potassium in 5-gr. doses is often very useful. I am in the habit of using the iodide for a time in nearly all the cases of alcoholic insanity. Thyroid extract, used in small doses of 5 gr. a day as an alterative, or in larger doses of 40 or 60 gr. a day, given for a week, as recommended by Dr. Lewis Bruce, is a most valuable remedy in certain cases. It affects the circulation, the general metabolism, and the nervous action, in a marked degree. When a case of mania has passed the acute stage, and there is threatened a condition of lethargy and the fear of dementia, to put such a patient to bed for three weeks, to give the thyroid extract for a week, beginning with 40 gr. for the first three days, and 50 or 60 gr. for the following four, the pulse being watched, the temperature taken, the diet regulated, and the patient carefully nourished on light, digestible diet, may be, I believe, the means of preventing such a patient sinking into incurable dementia. There is a loss of from five to twenty pounds in weight during the continuance of this "thyroid course," but after the medicine is stopped, the appetite, the digestion, and the assimilation of food become much stimulated, so that the patient will put on from 1 to 2 stones in weight within two months of the drug being discontinued. The patient should always be kept in bed for at least a week after the medicine is stopped. Thyroid extract in the smaller doses, from 5 to 10 gr., is, beyond doubt, a strong cortical stimulant. There are certain cases where, as pointed out by Dr. Lewis Bruce, the leucocytes are low in number. A hypodermic injection of 15 min. of turpentine in the flank is recommended by him to produce hyperleucocytosis, and so keep up the fight against injurious bacteria or toxins. If arteriosclerosis or high blood-pressure is present, no medicine is so generally useful as iodide of potassium in suitable doses and continued for a considerable time.

Baths and Hydrotherapeutics.—For a long time the ordinary hot bath has been used as a sedative for maniacal excitement, and as a hypnotic. There can be no doubt whatever of its powerful effect in certain cases, but unfortunately its use is attended with risk of cardiac failure and death. I have had this happen on two occasions, which naturally makes one very careful in the use of this powerful remedy. On the other hand, I have had cases where the sedative effect on an attack of mania was immediate and permanent. Considerable differences of opinion exist as to what the temperature of the water should

be. In some of the German psychiatric clinics, patients are kept in water at a temperature of about 97° for whole days and even for weeks. The results are reported to be good ; but this plan requires special arrangements. But to put a patient in a bath for half an hour in a temperature of 99° , with cold applications to the head, I have seen produce effects which were most striking. If this is followed by 10 gr. of veronal, with 50 gr. of bromide of potassium, given in a tumbler of hot milk, the patient will sometimes have a prolonged and most restorative sleep. This plan is always worth a trial in the early stages of excitement coming on quickly. It can be continued for weeks, safely and most beneficially, in some cases of mania.

Many cases of melancholia of the milder sort derive enormous and permanent benefit from a course of mineral waters with baths, at Harrogate, Bath, Buxton, Strathpeffer, at Schwalbach, Carlsbad, and the other German watering-places. Naturally the kind of water used, whether sulphur, iron, or saline, must be according to individual requirements. Gout, rheumatism, anæmia, and the effects of over-feeding with too little exercise, are frequently enough accompaniments and causes of mental attacks. In such cases those morbid conditions are naturally treated by the physician in the early and milder stages of the mental attack. Mild shower baths and spray baths are generally good stimulants in certain melancholic cases, and especially towards the end of acute attacks when lethargy and stupidity are threatened.

ON THE USE OF HYPNOTICS, SEDATIVES, AND MOTOR DEPRESSANTS.

Four cases out of five of recent mental disease have either sleeplessness, active brain excitement, or undue muscular activity as part of their symptoms. Such symptoms are so urgent that they seem to the patient's relations, to the nurse, and even to the doctor, to be the disease, and the only disease, he suffers from, and direct treatment of them seems therefore the most urgent of all the duties of the doctor in the case. To treat them thus directly means, in most cases, the use of hypnotics, sedatives, and motor-depressant drugs. The immediate effects seem so directly counteractive of the worst symptoms that it is not surprising they get more credit than they really deserve. Their use is sometimes undoubtedly curative : more frequently it is merely palliative, and in many cases it is really harmful at the time and afterwards, in spite of the apparent benefit it produces. Their use and selection, therefore, I consider a matter for the utmost care in each case. Their effects should be carefully watched, and in nine cases out of ten, treatment of the case, through them, should be looked on as only a part, and often a small though necessary part, of the real treatment of the case. We should always ask and observe whether those drugs are disordering other functions while mitigating the wakefulness and restlessness, and whether the natural tendency to recover in any case is interfered with by them. Is the patient gaining or losing weight during their use ? Is the hypnotic tending to restore the natural sleep habit ? Is a bad brain habit being formed ? Is the patient's inhibitory power—the highest mental function that he possesses—being increased or lessened ?

The effects aimed at through the use of those drugs are (1) To cut short the disease in acute cases ; (2) To re-establish the sleep habit of the brain ; (3) To tide over short attacks ; (4) To give needed sleep and rest to relatives and nurses ; (5) To combat temporarily dangerous symptoms ; (6) To take the edge off bad symptoms, so far as to let other measures have their effects, and to save the exhaustion of insomnia and motor excitement ; (7) To quiet screaming and noise ; (8) To give home or villa treatment a chance before a mental hospital is resorted to.

We must never forget, in the use of all hypnotic and sedative medicines

whatsoever, that given in large doses they are brain poisoners and arresters of function. Through experiment we have found out the doses that diminish the cerebral irritation. By the use of such small doses we lessen the morbid action that is going on in the brain cells, whose nutrition and katabolism we thus modify. I would lay it down as a principle that very few cases of mental disease should be treated by hypnotics and sedatives alone. To do so would imply a narrow view of the functions of the brain and their relation to the whole body. A physician's broad view of every case must be taken, not a mere specialist's brain view. To feed the patient, to restore the nervous and nutritive energy, to rest the brain, to restore to normal action every function that is abnormal, to exercise the muscles, to improve the controlling power, to restore the emotional faculties by providing natural pleasures, to remove attention from morbid to healthy objects, to make the environments healthy and healing—these must be the prime objects of treatment. We must always ask ourselves, when giving sedatives and hypnotics, whether any function is disordered thereby, whether the sleep and quiet produced is in some degree a natural or merely a drug sleep? As to sleep, our main object must be to restore this periodic brain habit. We must ask whether the patient is really refreshed in the morning? Is he really better in regard to his disease? Is he nearer recovery?

It is well, before we make up our minds which drug to use, to ask whether a pure hypnotic is needed, a general sedative and lessener of reflex irritability, a motor depressant, or a combination of these. Many cases need different drugs with different effects, at different phases of the malady. I would put paraldehyde, chloral, methyl-sulphonal, and veronal as types of pure hypnotics; sulphonal and opium as hypnotic-sedatives; the bromides and their combination with cannabis indica and hyoscyamus as types of the diminishers of reflex irritability, mental, cerebral, and spinal, with some sedative effects; and hyoscine as the type of motor-depressants.

Paraldehyde.—This drug I have used very extensively for many years. It is unquestionably the quickest and the best hypnotic we yet know. It is safe, acts very quickly, the sleep it produces is more apt, I believe, than that of any other drug, to pass gradually into normal sleep—"tired nature's sweet restorer." No doubt, in a few cases, it causes headache and disagreeable feelings. I have even seen, though very rarely, diarrhœa and sickness produced by it. It is of no use, and should not be given, as a sedative during the day. It seems to act on the very highest cortical cells and not on the motor areas. In mild cases of melancholia and mania, drachm doses will be sufficient. Mixed with tincture of orange, and slightly sweetened, its disagreeable taste may be somewhat modified. It may be given by the mouth, as an enema, or in capsules. If drachm doses are found insufficient, the quantity may be gradually increased to 4 dr. I have even given 6 dr. I have known $1\frac{1}{2}$ oz. given by mistake, with the result that the patient had a twelve-hours' stertorous sleep, with no bad after-effects. It should be given after the patient is undressed, with the room darkened, and the head should be laid on the pillow the moment it is taken. It never depresses the heart's action, but, on the contrary, stimulates it. Its use may be continued in some cases for long periods without any bad effects. No doubt some patients acquire something of a paraldehyde craving, so that its use should always be periodically intermitted. In some cases I add $\frac{1}{2}$ dr. of bromide of potassium to the dose of this medicine to prolong the effect. I have seen many cases where insomnia has been completely overcome by it, with a speedy restoration to soundness of mental function.

Chloral.—Chloral was our great stand-by as a hypnotic thirty years ago, and many persons still believe in it as strongly as ever. If a hypnotic is only

needed for a few nights, chloral is admirable in 15- to 30-gr. doses; but unquestionably its prolonged use poisons and weakens the heart's action, and is not safe. I now attribute two sudden deaths after chloral in cases of mania in my early practice to its depressing cardiac action. It may be combined with the bromides with good effect.

Trional.—This is an admirable hypnotic in doses of from 10 to 20 gr. It should be given after the patient has gone to bed, and its effect is increased by a tumbler of hot milk. Its effects do not usually last into the next day. It seldom has unpleasant after-effects. It and sulphonal have lately been denounced by a German writer as destroyers of the cortical functions of the brain, but no sufficient proofs of this have been given. My experience has in no way confirmed this theory. On the contrary, I could quote cases where, after months of their continuous use, perfect recoveries have resulted—helped, as I believe, by those drugs.

Veronal.—Veronal is one of our later chemical hypnotics. It produces, given in 5- to 15-gr. doses, a sound, and in many cases almost natural, sleep, with few after-effects. It is safe and pleasant, but in most cases there is some confusion felt by the patient next day. I have seen a disagreeable skin eruption after its use.*

Sulphonal still has an enormous run as a hypnotic with subsequent sedative effects, which often last for twenty-four and even forty-eight hours. It takes from one to two hours to act after the dose is given. The sleep produced by it is in most cases refreshing, but it often leaves giddiness and unpleasant sensations in the morning. Not being soluble to any extent, it is best given in 10- to 40-gr.† doses stirred into hot milk. In Germany, the combination of sulphonal and methyl-sulphonal is highly praised. The cases in which sulphonal acts best are those of sleeplessness combined with restlessness, noisy excitement, and general troublesomeness to manage. In early cases I have over and over again seen it produce calm and comfort and an apparent arrestment of the attack. It is often combined with the bromides. My favourite prescription for the restless, irritable, excited, and troublesome senile cases is a mixture of 10 gr. sulphonal with 30 gr. bromide, given at night, or, if necessary, twice in the twenty-four hours. I am quite sure that by this means I have been able to keep many such cases at home, soothing gently their downward path, and rendering them manageable and a source of comfort to their relations. In melancholia, sulphonal often aggravates the depression. It seems to stupefy and bewilder such cases too much. I consider it certain that by its use I have been able to arrest the excited attacks in the periodic insanities, by giving it in the very early stages. In general paralysis, in the early stages with acute symptoms, I have seen it produce calm and manageableness, though I am bound to say that in such cases the patient seems to be pushed on too rapidly into the second stage of the disease. In some cases it aggravates the motor inco-ordination in this disease very markedly.

There is a danger in the use of sulphonal which must be kept in mind: its continued use may cause the condition of hæmatoporphyrinuria. This is a very serious and indeed dangerous condition. The urine becomes bright red, the patient becomes excited, partially paralyzed, often vomits, the blood-corpuscles are found to be disintegrated, and the patient's life is sometimes lost, and is always in danger. Sulphonal should always be intermitted for a day or two once a week. The urine should be daily inspected while it is being used. A dose one night will often give two nights' sleep. It seldom excites

* Many serious results have been reported as following the use of veronal in doses larger than 5 grains.—ED.

† This dose would be considered excessive in this country.—AMERICAN EDITOR.

any craving for its continuance. I do not now use sulphonal so frequently as I used to do.

The Bromides.—As a result of a prolonged experience of their use, I combine bromides in most cases with the other sedatives, hypnotics, and motor-depressants, so as to accentuate, but especially to prolong, their effects. For this purpose they do what no other drug will do. I prefer the bromide of potassium in most cases, but often use the bromide of sodium where I desire a less effect. By their use we obtain the effect we aim at with less doses of sedatives, and we are able to get several hours' longer sleep or brain rest. From 20 to 60 gr. of this drug, added to 5 gr. of veronal, will very often double its hypnotic effect. But one has to keep this fact in mind, that if prolonged in melancholic conditions they may increase the mental depression. In epileptic brain excitement they are an absolutely essential means of treatment, and in large doses. Their continuous use in most cases of epilepsy will commonly prevent the occurrence of acute attacks of epileptic mania altogether. By this means, out of seventy epileptics under my care, I deprived myself of the means of demonstrating epileptic mania to my students for many years.

Opium.—There is a greater diversity of opinion in regard to the good or bad effects of opium than in regard to any other such drug. In Germany, and largely in America, the majority of cases of melancholia are treated by opium in doses of 1 gr. twice a day. Kraft-Ebing says that opium is one of the most important of the sedative remedies. He, and the German school generally, contend that it diminishes mental hyperæsthesia, improves the appetite, stimulates the vasomotor nerves, and has a good trophic effect on the central nervous system, so that its nutrition is improved. Its advocates maintain that in many cases its use is specific as a remedy in early melancholia. I used it largely and experimentally at one time, but it seems to me that its effects are by no means those believed in by the German school. I performed a series of experiments with it on many melancholics and maniacal patients, the result of which was that I almost entirely lost my faith in opium as a remedy in mental disease. Almost all my patients lost weight during its use, the secretions were often dried and the bowels constipated; while of all agents, next perhaps to cocaine, it was apt to set up a craving in the sensible melancholics for continued use and larger doses. Still, I admit that there are individual cases where opium does good and should be used. (See also ELECTROTHERAPEUTICS.)

MERALGIA PARÆSTHETICA (Bernhardt's Disease).—(See NERVES, PERIPHERAL, AFFECTIONS OF.)

METEORISM.—(See FLATULENCE.)

METRRORRHAGIA.—(See MENORRHAGIA.)

MIGRAINE.—A term often applied to any severe attack of headache occurring periodically. In its more limited use, however, it is applied to a group of symptoms characterized by headache, general or local, peculiar visual phenomena, generally with the loss of central vision and scintillations round the periphery, and vomiting. Vomiting may relieve the headache, but the patient often remains in a prostrate condition for several hours. The visual phenomena may be present without other symptoms. The symptoms occur usually in persons of a nervous temperament, whose occupation is sedentary and requires concentrated visual and other attention. It is not infrequently hereditary.

TREATMENT.—This may be dealt with under two heads: (1) *The Acute Attack*; (2) *Between the Attacks*.

1. Treatment of the Acute Attack.—The patient will often awake in the morning knowing that he is about to have an attack of migraine; in such circumstances, a brisk effervescing saline purgative will sometimes inhibit it.

During the attack the patient should be kept in bed in a slightly darkened room, 1 or 2 grains of calomel, or blue pill, should be administered, and the patient given hot water to drink. For the relief of headache, local remedies may be tried by the application of heat or cold to the head, a mustard plaster, or leeches. The feet should be kept warm by hot-water bottles. As a rule habitual sufferers prefer to be left in absolute quiet and not to be disturbed by any local application.

A large number of drugs are accredited with specific powers in giving relief; among the most important are phenacetin, acetanilid, caffeine, and bromides; and these in various combinations are often used with success, both during and before an attack.

2. Treatment between the Attacks.—The occurrence of an attack depends so much on general health, that attention to this, to any anæmia, constipation, or gouty condition, is of the first importance.

The eyes, too, should be carefully examined, and errors of refraction attended to, not only the more marked errors, but even the slighter degrees of hypermetropia and astigmatism.

The teeth, nose, ears, all require careful inspection, and attention should any abnormality be found. Disorders of the digestive and urino-genital systems must be borne in mind. But even when all these possible factors have been eliminated, there yet remain a certain number of cases in which the migraine returns periodically without any very definite cause.

Diet.—Regulation of diet is of the first importance. The patient should be instructed to have meals regularly, long intervals between food should be avoided, and a short rest be insisted on before the meal is begun. Many patients are benefited by being placed on a diet in which animal food is eliminated or greatly diminished. In some cases, however, this form of diet is not only not beneficial, but the frequency of the attack is actually increased. In such cases a simple meat diet may be advised. (See also HEADACHE.) Patients are, as a rule, better without alcohol in any form, but wine and whisky may be allowed when it seems to improve the general condition. An alkaline water such as lithia, Vichy, or Contrexéville may be taken with advantage with meals, and a small dose of sodium iodide (gr. iiss) added to this often proves beneficial.

Mode of Life.—The patient should be instructed to avoid as far as possible all mental and ocular fatigue, should lead a quiet, regular life with moderate outdoor exercise, and should avoid hot, crowded, and smoky rooms.

Drugs.—The remedy which, when taken during the interval, tends more than any other to delay the return of the attack, is nitroglycerin. This may be given in $\frac{1}{2}$ - to 1-min. doses of the liquor trinitrini, twice a day, the dose being gradually diminished to the smallest amount that suffices to ward off the attacks or to diminish their severity or frequency. The drug may be given in the following mixture :—

R Spirit. Glycerylis Nitratis	℥vj	Acidi Phosphorici Diluti	℥iij
Tincturæ Nucis Vomicae	℥iiss	Aquæ Chloroformi	q.s. ad ℥vj

Ft. mist. One tablespoonful to be taken at 9 a.m. and 9 p.m.

Or nitroglycerin can be conveniently administered in tablet form, one tablet, containing $\frac{1}{200}$ to $\frac{1}{100}$ gr., being taken twice a day.

At the same time it is well to recommend the patient to take half a pint of hot or cold water every morning directly after rising. This form of treatment

is very simple ; it can be carried out without inconvenience over long periods, and has in my experience been attended by very good results. The treatment of some cases of migraine by the administration of thyroid has been attended by success. In other cases, such drugs as the bromides, gelsemium, cannabis indica, arsenic, and strychnine do good.

Counter-irritation.—Blisters or other forms of counter-irritation may be used, and the insertion of a "seton" has been advocated in intractable cases, and is said to have prevented the attacks so long as the seton was in position. (See also HEADACHE, and SETON, TREATMENT BY.)

F. E. Batten.

MITRAL DISEASE.—(See HEART, VALVULAR DISEASES OF.)

MOLLUSCUM CONTAGIOSUM.—Treatment of this condition depends on the number and size of the lesions. If they are of some size and still moderate in number, they are best removed by the flat curved scissors. If they are very tiny, they may be squeezed out, and a drop of pure carbolic acid applied to their cavities. When the lesions are close-set, very numerous, and of considerable size, the writer can testify to the benefit following exposure to x rays, under which crops of sixty or more will disappear in two or three weeks.

Norman Walker.

MORPHIA HABIT.—(See DRUG HABIT.)

MOSQUITO BITES.—Prevention by use of mosquito nets and suitable clothing is most reliable. Kerosene and many of the essential oils will keep mosquitoes off. Oil of lavender and pennyroyal are the most effective, but to many people these remedies are more objectionable than the mosquito bite. A mixture of such oils, as advised by Colonel Alcock, I.M.S., will be more successful than any single one, e.g. :—

R Olei Bergamotæ		Olei Terebinthinæ	℥ij
Olei Caryophylli		Quininæ Sulphatis	gr. xx
Olei Lavandulæ	āā ℥ss	Alcoholis	℥viij
		Aquam	ad Oj

This is much used in India. The irritation from mosquito bites is relieved by aqua ammoniæ, but all friction must be avoided.

C. W. Daniels.

MOUTH AND PHARYNX, MALIGNANT DISEASE OF.—Certain general considerations apply to the treatment of malignant disease of all parts of the mouth and pharynx, and it will be convenient to refer to these before giving the special procedures which may be necessary according to the anatomical situation of the growth.

VARIETIES OF MALIGNANT DISEASE.

Squamous Epithelioma.—This is by far the commonest tumour met with throughout the tract, from the lips to the œsophagus. It is indeed practically the only one occurring in any part except the tonsillar region.* It is a tumour of extreme inveteracy if left untreated or dealt with only at a late stage. It has a marked tendency to affect the neighbouring lymph glands, so much so that as soon as the diagnosis of the primary tumour can be made, lymphatic infection must be assumed to be present. For a variable time the growth is limited strictly to the region where it begins. It then forms a hard, well-defined nodule or plaque in the superficial tissues, and projecting more or less beyond them. As time passes, a stage is reached at which the local resistance to the tumour seems rather suddenly to yield. The rate of growth increases, the tumour becomes ill-defined, and usually softer. This change—the onset of submucous invasion—

* The nasopharynx is not dealt with in this article.

is of great gravity as regards the curability of the disease. It occurs ultimately in all cases, and the variability in its time of onset is the chief reason why the prognosis of, for example, cancer of the tongue has in the past been so baffling. The well-known nodular variety of cancer of the tongue, in which the disease from the start presents a mass growing into the tongue substance from the deep surface of the mucous membrane, with little external projection or ulceration, is a typical instance of precocious submucous invasion, and has a correspondingly sinister reputation for malignancy. Growths with a large amount of external fungation or cauliflower-like projection usually have but little submucous invasion, and are therefore often relatively easy to cure in spite of their alarming appearance.

Great stress is here laid upon the presence or absence of submucous invasion, because it is the most important fact in designing the treatment of a given case. If invasion has not begun, and the growth is hard, well-defined, and relatively prominent, while the glands, if palpable, are also hard and distinct, the disease can *almost certainly* be arrested by an operation of quite moderate severity. If invasion has occurred, although the growth may yet be comparatively small and the glands not palpable, a severe operation is necessary, and the outlook even then much less certain.

Generally speaking, a growth in the superficial stage may be cured by a local removal which includes a margin of healthy tissue of at least half an inch everywhere beyond the extreme limit of palpable induration. The part removed must have the growth at its centre, and must not be determined by the anatomical structure of the region. The older type of operation, which was designed in accordance with the anatomical features (excision of the tongue or half the tongue, laryngectomy, etc.) must therefore be replaced by a pathological type of operation in which the determining factors derive from the pathological peculiarities and requirements of the disease in the given case.

When definite submucous invasion is present, the half-inch margin is quite useless, and must be at least doubled in all directions, while in certain directions in which the disease is known by preference to spread, it must be further extended.

In every case, whether early or late, superficial or diffuse, a gland operation must be done. It should be bilateral, and should include all the fat, glands, and connective tissue of the region, dissected in one mass. When the glands are not palpable, the limits of the dissection are the level of the cricoid below, the posterior border of the sternomastoid behind, and the attachment of the mylohyoid above. The base of the parotid should be cut across at the level of the angle of the jaw. When the glands are palpable, the dissection must begin below at the clavicle, and should include the whole of the sternomastoid and the internal jugular vein. It is not usually safe to remove both internal jugular veins. The one on the side less affected should be spared.

As long as operation is feasible, it is the only treatment which should be considered in cases of epithelioma. When the condition is so far advanced that the tumour cannot be removed with any reasonable prospect of a satisfactory result, treatment by radium implantation is sometimes desirable. The selection of suitable cases and the technique of the treatment are matters which should be left to those having special experience. The actual procedure of inserting radium into an epithelioma of the mouth or pharynx should never be regarded as a trivial matter, for very small defects in technique may result in the patient's condition being made very much worse by the treatment. In general, it may be said that surface applications are quite useless, and that implantations should be done through an external wound, the maintenance of asepsis in which is of absolutely vital importance.

Sarcoma.—Malignant connective-tissue tumours may be regarded for practical purposes as occurring only in the tonsillar region, either in the tonsil itself or in the pharyngeal wall close to it. Three groups of such tumours may be distinguished: (1) The round- and mixed-cell sarcoma; (2) The lymphosarcoma; and (3) The endothelioma.

1. *Round- and Mixed-cell Sarcoma.*—The first group occurs chiefly in the tonsil; the tumour grows rapidly, is often surrounded by much œdema and duskiness of the mucous membrane, and ulcerates readily. Gland involvement is not constant, and is sometimes absent even at a late stage.

This group, in cases without extensive gland involvement, is the only one which can readily be dealt with by operation with a fair chance of cure.

2. *Lymphosarcoma.*—The second group affects the tonsil or the lymphoid tissue at the base of the tongue, and sometimes both. Ulceration does not occur early, but gland involvement is early and marked.

Lymphosarcoma, if at all advanced and showing the extensive bilateral gland affection which is almost always present, is rarely accessible to operation. Fortunately, most of the non-epithelial tumours of the tonsillar region are very susceptible to radium treatment, and yield rapidly to implantation or even to surface application. The position of radium in regard to the treatment of these tumours is entirely different from that it occupies towards the treatment of epithelioma. In the former case it must be taken into consideration as a primary method of treatment. The final decision, and the technique used, must, however, remain essentially matters for the expert.

3. *Endothelioma.*—The third group is peculiar in that the tumour is apt to be associated with inflammatory signs, or even suppuration, at an early stage. Gland involvement is practically constant, except in the earliest stages.

If removed early, before the capsule of the tonsil is penetrated and before gland enlargement has occurred, endothelioma is very favourable, but on the other hand it is very difficult to recognize. At a later stage it seems almost impossible to eradicate by even the most extensive operations.

GENERAL PRINCIPLES OF OPERATIVE TREATMENT.

A proposed operation for cancer of the mouth or pharynx has necessarily to be considered by the patient and the practitioner with especial regard to the *prospect* of cure it affords, the *danger* it involves, and the amount of *permanent mutilation and disability* it produces. The first and third of these features are obviously the most important. It has already been pointed out that fairly definite prognosis is often possible if careful attention is paid to the type of growth and its stage of advancement; and it may be repeated here that a tumour of the superficial localized type should be regarded as normally curable, and that the presence of enlarged glands, if they are of the same type, cannot be regarded as affecting the prognosis at all gravely—provided, of course, that an operation of the modern type is done. It may be added that the tendency to replace the older operations of excision of some given organ by operations designed completely to remove some given tumour, has already diminished the necessity for therapeutic mutilation which has given to cancer of the tongue or throat a large part of its terrible reputation. If an operation gives a reasonable chance of cure, without serious permanent disability, it is clear that the amount of risk to life it involves is comparatively a secondary consideration when the disease for which it is advised is necessarily fatal if left untreated. As a matter of fact, the actual danger of operations undertaken in cases where there is even a moderate chance of eradicating the disease is quite small; and unless there is some special complication present, the question of risk should not be the predominating factor in a decision which in former times it of necessity was.

There can be no doubt that even at the present time, the resources of surgery in the treatment of cancer of the mouth and pharynx, especially of the latter, are underestimated, and that a certain number of cases are watched until the disease is inoperable, in the full belief that cure is from the earliest period impossible.

Dangers of the Operation.—Operations about the mouth and pharynx, when properly conducted, appear to cause less *shock* than similarly extensive procedures elsewhere. It is quite rare for any serious anxiety to arise on this account, even after very severe operations. Similarly, *primary hæmorrhage* is very rarely serious or even troublesome. The formal preliminary ligature of vessels is, in the writer's opinion, unnecessary, but measures must always be taken to preserve the air-passages from the entry of blood.

The one serious danger is *sepsis*. It may take the form of acute septicæmia due to infection through the fresh wound-surface ; of pneumonia with gangrene of the lungs ; or of local infection of the wound, with cellulitis of the neck which may spread to the mediastinum. The first two conditions are almost necessarily fatal, and are usually manifest within forty-eight hours of the operation. Infection of the neck and mediastinum are extremely serious in themselves, and always accompanied by a special risk of secondary hæmorrhage.

Pulmonary Infection.—This is unquestionably due to aspiration of infective material into the lungs during the operation. Anything, therefore, which interferes with the airway, and consequently increases the force of suction at the upper laryngeal opening, is a source of danger. The more septic the mouth and growth, the more the growth is disturbed, the more the airway is restricted, and the longer the operation, the greater is the danger of pneumonia. The most efficient precaution against this complication is a preliminary laryngotomy or tracheotomy, with efficient plugging of the pharynx. This procedure is easy, quickly performed, and, in itself, quite free from risk.

Local Infection.—All fresh wounds exposed to contact with oral or pharyngeal mucus necessarily become infected. The infection runs a specific course : superficial sloughing always occurs, suppuration sets in about the fifth or sixth day, while by the tenth the sloughs have separated more or less completely and the wound is granulating. The granulating surface is immune to further infection. The severity of the process is dependent on the degree of sepsis in the mouth and growth, and the extent and complexity of the wound. If the mouth is septic the infection readily becomes uncontrollable, especially if there is the least chance of imperfect drainage in the wound.

The danger of local infection is directly proportional to the distance of the seat of operation from the lips. Operations on the lips and cheek are practically free from such risk ; operations on the free part of the tongue have a slight, but almost negligible, liability to serious infection ; while operations on the posterior third of the tongue, the tonsillar region, and the rest of the pharynx, bring with them very grave dangers from this source.

Disinfection of the Mouth.—It will be seen that the two great dangers of treatment, pulmonary and wound infections, are traceable to sepsis in the mouth and in the ulcerating surface of the growth. The latter, however, is to a large extent dependent on the former, for the cleaner the mouth, the less is the tendency for the growth to develop the well-known foul ulceration. Sepsis is therefore essentially a consequence of the condition of the mouth. Experience of the larger operations, and especially those on the pharynx, shows that the difference in prognosis noticeable in patients who have teeth and in those who are edentulous is so great as scarcely to be capable of exaggeration. The condition of the teeth is much less important than their presence. As long as any teeth are present, even if there be no evident infection of the gums, any of the

larger operations may be followed by serious sepsis; whereas edentulous patients scarcely ever give rise to any anxiety in this respect. It is remarkable that the effect of the loss of all the teeth does not become manifest for some considerable time (several weeks at least) after their removal; so that, for example, if a patient who has had septic teeth removed is operated on as soon as the gums have healed, he will be found still to be liable to severe wound infection.

The ordinarily-prescribed preparation for operation, as by scaling the teeth, removal of stumps, cleansing by brushing and dental silk, is shown by experience to be of very little value as a preventive of sepsis after any of the larger operations.

In persons over fifty, such teeth as are present can only be an increasing source of trouble, and there is little doubt that a complete clearance of the mouth at about this age has a great deal to be said for it on general grounds. It is certain that if an edentulous mouth were normal at the age at which the incidence of cancer in the upper alimentary tract reaches its height, the mortality of operations for this condition would be enormously reduced.

Supposing the patient not to be edentulous, the first care of the practitioner, as soon as he suspects the existence of cancer, should be the condition of the mouth. In the majority of such patients the teeth and gums will show ample reason for energetic treatment, and as a rule but little persuasion is needed to get the patient to assent to radical measures. The urgency of the matter lies in the fact that the longer the interval between the loss of the teeth and any operation that may be necessary, the less the danger of such operation will be.

If the growth is small, and on the anterior part of the tongue, extraction of all teeth may perhaps be dispensed with, and the ordinary measures used; but if the growth is large, situated far back in the tongue or in the pharynx, this indulgence cannot be allowed.

Essentials of the Operation.—Every operation undertaken for malignant disease of the mouth or pharynx may be regarded as divisible into certain definite stages, each distinct from the others and having a well-defined share in the attainment of a successful result. In all the larger operations, the most important phases are as follows:—

1. Safeguarding the airway, if necessary by laryngotomy or tracheotomy and plugging the pharynx or larynx.

2. Digital examination of the growth, to determine as far as possible its exact situation and extent, and to decide upon what route shall be followed in exposing it.

3. The exposure of the growth. It should be kept very clearly in the surgeon's mind that this must be a distinct step in the operation, to be completed before any attempt to remove the tumour is begun. All methods which involve an attack on the tumour before its mucous surface is freely exposed, tend to lead to confused and inadequate operating.

4. The removal of the tumour with an adequate margin of healthy tissue according to the nature of the case.

5. The restoration of the parts to the normal, as far as may be, by the use of such plastic procedures as are possible. If the gap left by the removal of the tumour cannot be completely closed, raw surfaces liable to contact with oral or pharyngeal mucus must be reduced as far as possible, and the wound left in a condition favourable for the handling of infective complications.

Certain general precautions must be maintained throughout the operation. Every effort should be made to avoid unnecessary handling of the growth, or any manipulation which exposes it to squeezing or laceration. Raw surfaces, especially such as are to be closed, must be rigorously protected from contact

with mucus or other septic matter, and from the risks of implantation of cancer cells from the tumour. As soon as the tumour is exposed, its surface should be destroyed with the actual cautery or freely swabbed with pure carbolic.

TREATMENT OF INOPERABLE MALIGNANT DISEASE.

The decision that a given case of cancer is inoperable involves a very grave responsibility, and should never be made without careful consideration of all the features of the case. The difficulty of coming to a just conclusion is added to by the natural shrinking of both patient and surgeon from the infliction of an operation which, if wrongly decided upon, is certain to add to rather than diminish the sufferings entailed by the disease.

Supposing, however, a decision against operation has been come to, treatment by radium may next be considered. In cases of epithelioma, such treatment has not often much to offer, and should never be entered upon lightly (see RADIUM THERAPY).

If purely palliative treatment alone is available, the control of sepsis is by far the most important line to be followed. Of measures designed for this, the reduction of dental sepsis is the most efficient, and it is often desirable to deal with this source of infection once and for all by clearing the mouth if there are but few teeth. The extraction of a large number of teeth is, of course, quite a serious procedure in enfeebled persons, and should not be advised without due consideration. When the ulcer is accessible, local treatment of it may do much to relieve pain and fœtor. The surface may be gently mopped, and then thickly powdered with orthoform. Occasional swabbing over with pure carbolic is sometimes of great value. If a large cavity is present, it may be filled with powdered boracic acid every few days. This has a powerful antiseptic action, but the sodden powder is sometimes difficult to clear away.

When pain is severe, morphia must be used. It may be combined with small doses of atropine when salivation is marked. A great deal can be done by the judicious use of these two drugs, often in surprisingly small doses. When the growth is in the tongue or floor of the mouth, persistent neuralgic pain in the inferior maxillary branch of the trigeminal nerve usually comes on sooner or later. For this, the nerve should be injected with alcohol at the foramen ovale, a comparatively simple procedure which may give complete relief, and is greatly to be preferred to the intra-buccal division of the lingual which used formerly to be advised.

When the growth is in the pharynx, tracheotomy is necessary sooner or later. It can always be done under local anæsthesia, and should invariably be preferred to laryngotomy. But little can be done by way of local treatment of the growth; the control of sepsis in the mouth, however, undoubtedly influences the rapidity and foulness of the ulceration. Salivation and difficulty in swallowing mucus, with resultant distressing cough, are common, and are best controlled by small doses of morphia and atropine subcutaneously. It is important to remember that irritative cough can often be controlled by a dose of morphia (gr. $\frac{1}{12}$) so small as to produce none of the narcotic and after-effects of the drug. In the late stages of the disease, abscesses frequently form in the neck. They can usually be drained through a simple puncture, which, if made with a narrow, sharp knife over thinned skin, is practically painless.

Applications of radium, in doses not calculated to produce any considerable effect on the growth, are sometimes of value for the relief of pain.

Palliative operations are of very little value in cancer of the mouth or throat, and should rarely be undertaken. It occasionally happens, however, that a small growth in the mouth gives rise at an early period to inoperable gland disease.

In such a case the primary growth may sometimes be removed, when this is possible without an extensive operation.

In conclusion, a word of caution may be added as to the difficulty of estimating the probable duration of cases of inoperable carcinoma. The disease, although in the long run always progressive, varies greatly in its course in different patients and at different times. Occasionally it seems even to retrogress for a time. Attempts at exact prognosis are therefore of very little value. (See also CANCER, GENERAL TREATMENT OF.)

OPERATIVE TREATMENT OF SPECIAL REGIONS.

Epithelioma of the Lip.—When the disease is of slow growth and superficial, or when it is definitely papillomatous, a comparatively small operation is adequate. The tumour is excised with a margin of a third to half an inch on all sides, and the parts brought together. In order to do this it is generally necessary to make incisions outwards into the lip from the lower angles of the gap left by the incision. The resultant triradiate incision is closely stitched on its mucous and cutaneous aspects. No dressing is necessary. A gland dissection is always necessary, the submaxillary as well as the submental regions being dealt with. The submaxillary salivary glands are of course removed, and it is as well to carry the dissection as far back as the internal jugular vein.

When the growth is diffuse and of rapid course, a much more extensive resection of the lip is necessary, including all the structures superficial to the bone as far down as the base of the jaw. This operation may be combined with the gland dissection. The lip is reconstituted by sliding up flaps from the neck.

Epithelioma of the Tongue and Mouth.—The three common places where epithelioma starts in the mouth are the lateral border of the tongue, the sublingual fold, and the gum about the molar teeth. Any chronic, progressive, localized lesion in either of these situations beginning in a middle-aged or elderly man is more likely to be epithelioma than anything else. Elsewhere in the tongue the disease may start on the dorsum (when it is usually preceded by chronic syphilitic lesions), close to the anterior faucial pillar, or on the posterior third. In the second case, it may be regarded as belonging to the tonsillar group, and in the third case the tumour is essentially pharyngeal.

Dealing here with growths of the dorsum or lateral margin of the oral part of the tongue, treatment is to be designed according to the nature of the disease. If it is of the superficial localized type, excision with a full half-inch margin is adequate. To carry this out properly it is usually necessary to divide the cheek, a procedure which leaves a scarcely perceptible scar if the wound is properly sutured. The wound in the tongue should always be closed with mattress sutures of catgut. Unless the wound surfaces are brought together, hæmorrhage and sloughing may occur. Mere suture of the mucous membrane edge to edge is quite useless. In these cases it is usually best to do the (bilateral) gland dissection first, and to deal with the primary growth at an interval of ten days.

When the growth shows distinct submucous invasion, or involves the floor of the mouth, or has begun on the sublingual fold, the jaw must be divided to give adequate access, and the growth, with an inch margin, must be removed, including the underlying muscles down to the great cornu itself. The mouth wound can usually be closed by turning the anterior part of the tongue back on itself. When the growth comes near to the jaw, the inner table of the bone must be sawn off and removed with the tumour. Some infection of the divided ends of the jaw frequently occurs, but the advantages of free exposure quite compensate for this.

In these cases, also, the gland operation should be done first, though there is

a certain risk of pneumonia arising as a result of aspiration of septic material during the long and difficult neck operation.

After the operation on the primary growth, the patient should be sat up in bed, fed by a rubber catheter passed into the œsophagus when necessary, and the mouth should be syringed out from time to time with dilute peroxide of hydrogen. All trouble from hæmorrhage is prevented by proper suture of the tongue wound. A laryngotomy should usually be done as a preliminary, but the tube is removed at the end of the operation.

Epithelioma of the Tonsil and Tonsillar Region.—This group includes growths of the anterior pillar, of the tongue close to the pillar, and of the posterior third of the tongue. The best access is obtained by dividing the jaw at the anterior border of the masseter. This enables the growth to be fully exposed on its mucous aspect, and its downward extension defined and dealt with. The bone is exposed by a flap outlined by an incision carried through the middle of the lower lip and then outwards just below the base of the jaw. The wound left by excision of the tumour can usually be completely closed, and often union is obtained without any leakage from the pharynx. Growths of the posterior third of the tongue are also to be reached by this method. They are, however, very difficult to eradicate, as they tend from the first to be of the deep-seated, diffuse type. The order of primary operation and gland operation is often difficult to decide upon. If the glands are not at all or but little enlarged, they may be dealt with (on both sides of the neck) first. The risk of aspiration is, of course, considerable; and it is sometimes advisable, when the primary growth is very foul, to remove it first, or to do tracheotomy as a preliminary to the gland operation. If there is doubt as to the operability of glands or primary growth, the more doubtful should, of course, be dealt with first. In some cases, however, the size of the glands may be such that they prevent access to the primary growth, and then they must be removed first.

Epithelioma of the Laryngeal Opening.—This is a form which tends to produce symptoms early, and is therefore very favourable in the results it yields to operative treatment.

Access is obtained by lateral transthyroid pharyngotomy, the ala of the thyroid and the great cornu of the hyoid on the diseased side being removed before the pharynx is opened. Necessarily, therefore, the gland operation must be done first, or combined with the primary operation, a procedure which is quite feasible if only the unilateral gland dissection be done, the other side of the neck being reserved for a second stage. The growth, which occupies the epiglottis or aryteno-epiglottic fold, can, if operable with any reasonable chance of cure, practically always be removed without a total laryngectomy, so that speech can be preserved—a matter of the very greatest moment.

After free exposure and removal of the growth, the wound left is firmly closed by mattress sutures, and then the wound of access in the pharyngeal wall is stitched. As a rule, it is necessary for the tracheotomy tube to be kept in for about a week. If the pharyngeal wall is properly closed, leakage does not occur. Very rapid healing is then attained.

Epithelioma of the Laryngeal part of the Pharynx.—There are two very distinct types of disease found in this region—viz., growths of the pyriform sinus, and growths of the tubular part of the pharynx behind the cricoid cartilage.

The *pyriform sinus type of growth* is a common disease of middle-aged and elderly men, and owing to the frequency with which it is overlooked in the early stages, it is one of the gravest forms of malignant pharyngeal tumour. It is desirable, therefore, that some reference be made to diagnosis. The tumour begins in the deep recess of the pharynx which lies between the ala of the thyroid externally and the lateral wall of the larynx internally. It therefore invades the

thyroid cartilage at an early stage, penetrating it and forming a swelling externally, which is either overlooked, mistaken for a gland, or regarded as being due to syphilitic perichondritis. Internally, its growth causes a smooth, rounded swelling of the lateral wall of the larynx, surmounted by an oedematous aryteno-epiglottic fold, and often mistaken for a gumma. No ulceration is visible on the laryngeal aspect; such ulceration as is present in the early stages is, of course, entirely pharyngeal, and deeply buried in the pyriform sinus, so that it is usually quite invisible to laryngoscopic examination.

In the early stages of the disease adequate removal is possible without total laryngectomy. The ala of the thyroid must be excised, and the lateral wall of the larynx on the diseased side. The cricoid ring can usually be left intact.

In a late stage a diffuse subperichondral infiltration occurs, and a total laryngectomy must be done.

Later still, the lateral and posterior pharyngeal walls are affected, and removal is possible only by a large laryngo-pharyngectomy, followed by a plastic reconstitution of the pharynx. It is doubtful, however, whether such operations are to be advised, seeing that the chance of cure is so small as scarcely to be appreciable.

Growths of the tubular part of the pharynx (post-cricoid or hypo-pharyngeal tumours) are also common, and remarkably prone to occur in women, and at a relatively early age. Here also the results of operation are bad because diagnosis is not made so early as it should be. Any complaint of pharyngeal symptoms of a persistent kind should always lead to rigorous examination by an expert in the use of the modern direct methods.

The operative treatment of these cases at an early stage of the disease, although difficult and complex, is not merely feasible but remarkably encouraging. No details of the procedures need be given here; but it may be remarked that they should always include free exposure of the tumour, and provision for reconstituting the pharynx by a skin flap. Unless the surgeon is prepared to proceed at once to a plastic operation of this type, he is apt to be disinclined to excise the tumour freely enough to give a satisfactory result.

Wilfred Trotter.

MOVABLE KIDNEY.—(See KIDNEY, MOVABLE.)

MUCOUS DISEASE.—(See DYSPEPSIA IN CHILDHOOD.)

MUMPS.—The painful swelling of the parotid glands will be relieved by the application of hot fomentations with a few drops of laudanum sprinkled upon them, or of glycerin and belladonna.

Pain may also be allayed and sleep afforded by Dover's powder or laudanum, the dose being according to age. When there is orchitis, the testis must be supported and hot fomentations applied. In severe cases, the application of ice will answer better. If these measures fail to give relief the testis should be incised. The organ should be brought out through a 2 in. vertical incision in the tunica vaginalis, and the tunica albuginea slit in a dozen places; the incisions should not be over $\frac{1}{4}$ in. in length, should only just go through the tunica, and should be parallel to the long axis of the testis. If necessary, the epididymis should be similarly treated. A drainage tube should be left in the tunica vaginalis, and the wound closed round it. The scrotum should be firmly bandaged. So far as I know, this operation has been performed in two cases only; but in neither did the testis atrophy.

In some epidemics cases have occurred in which there have been symptoms indicative of acute inflammation of the pancreas, viz., sudden and intense pain in the epigastrium and left hypochondrium, vomiting, and collapse, and

occasionally jaundice. Tincture of opium in 2-min. doses, in $\frac{1}{2}$ dr. of glycerin and water, should be given every hour, or more frequently if the pain is very severe.

Hydrotherapy will be found useful in those not common cases where the temperature is high and symptoms of excitation of the nerve centres are present; with it may be combined a sedative mixture (see FEVERS, ACUTE INFECTIOUS).

The patient should be kept in bed at least eight days, even in the mildest cases; in severe cases, longer. He may be considered free from infection three weeks from the onset of the parotitis.

Quarantine period: twenty-five days.

E. W. Goodall.

MUSCLE SPRAINS.—(See SPRAINS.)

MUSCULAR RHEUMATISM.—(See RHEUMATISM, CHRONIC.)

MYALGIA.—(See RHEUMATISM, CHRONIC.)

MYASTHENIA GRAVIS.—This rare disease is characterized by muscular weakness, and by the facility and rapidity with which the muscles become exhausted as the result of both voluntary effort and faradic stimulation. Our knowledge as to its etiology and pathology is at present uncertain, and no treatment is known which will arrest or cure it; a good deal, however, can be done by palliative measures.

All unnecessary muscular effort should be prohibited, and especially is this the case as regards the muscles chiefly affected. If the symptoms are severe the patient must be confined to bed. Mental excitement of every kind is to be avoided. The patient should be warmly clad, as cold undoubtedly tends to aggravate the symptoms.

The feeding in these cases requires careful attention. When there is weakness of the muscles of mastication and deglutition, the larger portion of the food should be taken early in the day, for the weakness becomes more pronounced towards evening. The food should be of high nutritive value and be taken slowly. Solid food should be minced in order to spare the muscles of mastication. It is possible that the lives of some fatal cases might have been saved had this precaution been attended to, for asphyxia consequent upon the impaction of an unchewed bolus in the throat has in several cases caused death. Where dysphagia is pronounced, rectal feeding is preferable to the stomach tube, the passage of which is apt to produce great exhaustion.

Faradism is on no account to be used, since it increases the "myasthenic state." Very weak galvanic currents applied to the affected muscles have been said to do good in some cases, and may be employed. Massage appears to be of no service.

Drug treatment is unsatisfactory. There is no agreement as to the beneficial effects of any one remedy. Various drugs—among which potassium iodide, hypodermic injections of strychnine, and thyroid extract may be mentioned—have, it is affirmed, done good in individual instances; but the relapses and intermissions which are so common, in the absence of any detectable exciting cause, render therapeutic deductions difficult. The writer has seen a large number of drugs employed, but has not been able to convince himself in any case that improvement was the direct consequence of the "remedy." Arsenic and strychnine may be given as a general tonic.

Strümpell points out that attacks of dyspnœa, which when they occur have such serious prognostic significance, are sometimes relieved by pulling forward the tongue. In a severe attack where there is great weakness of the respiratory muscles, artificial respiration may have to be used.

Edwin Bramwell.

MYCOSIS FUNGOIDES.—Arsenic was formerly the only treatment which had any influence, and that only a retarding one, on the fell progress of this disease. Since, however, in 1902 Allan Jamieson first demonstrated the wonderful effects of x rays, that treatment has practically taken the place of all others. Under suitable exposures the ulcerated surfaces heal up and tumours melt away as if by magic. Every fresh outbreak must be treated, and these are frequent; but watchfulness and steady perseverance in the occasional use of the rays are successful in restoring the victim to, and keeping him often for many years in, a state of comparative health and capacity.

Norman Walker.

MYELOMATA.—(See BONE, TUMOURS OF; JAWS, TUMOURS OF.)

MYOCARDIAL FAILURE.

REST.—In the great majority of cases of cardiac muscle failure, bodily rest is an essential part of the treatment, and *alone* its influence, by no means very rarely, determines a profuse diuresis. The diminution of work on the part of the heart implied by such rest is sufficient to enable the organ to recover its vigour and again to perform its functions efficiently, so that venous stasis ceases. Of late years much has been heard of the treatment of heart disease by means of baths and graduated exercises. It is in certain cases of slight cardiac muscle failure that this treatment is most likely to prove useful—in cases of a heart muscle that has become “flabby” and lost its tone. In many such cases, no doubt, the disturbance of the circulation is not all central, i.e., cardiac, in origin, and blood conditions, probably in the direction of plethora, may play a part. As far as the “exercise” part of the treatment is concerned, it is worth noting that the treatment is not recent, and as long ago as 1854 Dr. Stokes, in his book, “The Diseases of the Heart and of the Aorta,” refers to a patient whom he advised “to pursue a system of graduated muscular exercises,” and remarks that “the symptoms of debility of the heart are often removable by a regulated course of gymnastics, or by pedestrian exercise even in mountainous countries;” but Dr. Stokes’s use of the expression, “debility of the heart,” clearly designates the type of case that was in his mind’s eye. By sedentary occupation and abstinence in the matter of exercise, combined with a vigorous digestion and good appetite, it is easy for certain individuals to pass into a condition that may be regarded as the most remote from the desirable one which is known as “fitness” or “training” among the athletic. No one expects “good wind” in a stout person, and his “bad wind” is to be attributed largely to the condition of his heart, which, however, cannot be regarded as “diseased,” but only as temporarily “debilitated.” Moreover, there are factors other than cardiac that have to be reckoned with in the circulation; for instance, the quantity and quality of the blood, and the state of the tissues of the body, including the capillary walls. Upon these, graduated exercise, diet, and general regimen may be expected to exert special influence.

When, however, the heart muscle is failing intrinsically, it is surely irrational to impose upon it a heavier burden. If a patient has severe dyspnoea on exertion, and, still more, if he has dropsy and a congested liver, there can be no question as to the absolute necessity of rest. But he may have neglected early warnings and have struggled on till his dyspnoea has become *orthopnoea*, and he is no longer able to lie down. In a hospital ward, into which heart cases of this kind are quite commonly admitted, it is a very rare thing to find a patient really unable to remain in bed with his shoulders well raised and supported on a “bed rest” or pile of pillows. In the paroxysm of dyspnoea that occurs in certain cases of Cheyne-Stokes respiration, the patient will sometimes spring out of bed as the dyspnoeal period reaches its maximum. In the

circumstances, the hypodermic injection of morphine and atropine will usually be effectual in allaying the distressing condition, and enabling the patient to remain in bed. When a patient is incapable of passing the night otherwise than sitting on a chair, leaning forwards, supported on the back of another chair, his greatly œdematous legs swelling till the tense skin cracks and exudes serum, his plight is very terrible, and treatment very difficult. Care must be taken that he does not bury his face in a pillow or in his sleeve while his neck is sharply bent, and so become asphyxiated. The presence of much secretion in the bronchial tubes renders morphine dangerous; moreover, there will usually be serous effusions that directly or indirectly interfere with the action of the heart and lungs. Such effusions may be mechanically removed, while the presence of secretion in the bronchi need not absolutely forbid the use of morphine, though it necessitates an infinitesimal dose being given, and that well guarded by atropine or strychnine as a respiratory stimulant. Moreover, dry cupping over the lungs is often useful in the circumstances. By these means it may be possible to get the patient once more to remain in bed. But in truth, the condition described may often be anticipated by treatment, and its full development is most often seen in patients who have struggled on without, or in spite of, medical advice. Digitalis, strophanthus, and allied drugs are much more likely to bring about a diuresis when the patient is recumbent, or at any rate in bed with shoulders raised.

In the promotion of rest it is often useful to have two small beds, which can be brought up side by side, the patient being changed from one to the other night and morning. Although the changing entails movement, and even slight exertion, it may be that, on the part of the patient, such movement and exertion are no greater than are involved in the ordinary "making of the bed," while to neglect this last is often to produce "soreness" of compressed parts, and ultimately bedsores.

Hospital patients appreciate the use of a crossbar, suspended by a rope from the roof or bracket on the wall, by which, especially in the case of heavy patients, movements of the body are greatly facilitated. No doubt the exertion entailed by the use of the crossbar is injurious, but compromise has to be made, and such exertion is to be weighed against the manœuvres requisite in lifting a heavy patient about, even when several skilled attendants are available, which is seldom the case in a private house. In the latter, the writer has occasionally had constructed by a joiner an apparatus resting on the floor, affording the patient the advantage of the hospital suspended crossbar. Though it may seem paradoxical to say so, the contrivance really tends to the promotion of rest. When some of the beds in a ward have the crossbar referred to and others are without it, patients with grave heart disease, and their nurses too, prefer the beds so provided. Another mechanical aid to the cardiac sufferer is supplied by affording him a resisting object against which he may press his feet, and so raise himself up in the bed, or at least prevent himself from slipping down.

DIET.—In the treatment of cases of cardiac muscle failure, there is perhaps no part more important than the diet of the patient; and yet how often is this neglected, while, as the saying is, "no stone is left unturned" in the matter of drugs. Yet the common experience of humanity—and especially of athletic humanity—teaches that the influence of diet on the heart muscle is immense.

That the heart is chiefly influenced in the process of training is rendered almost certain by the extraordinary improvement in "wind" that is brought about. First in occurrence and first in importance throughout, in cardiac disease, is the symptom *failure of "wind."* While the heart muscle, which we know to possess many special and remarkable attributes of its own, is chiefly influenced by the process of training, of which dietetics form so important

a part, muscles of the ordinary voluntary type no doubt share in the influence exerted, and especially, it is allowable to believe, the *respiratory* muscles. In one respect the old system of training may be open to criticism, in that the drinking of water was discouraged. The writer would mention in defence two considerations: that large draughts of water *with meals* are probably injurious, and that, as a matter of actual experience, a largely nitrogenous diet is *not conducive to thirst*—rather, he thinks, the opposite, *salt* meats of course being excluded.

One of the three cardinal symptoms of cardiac disease is engorgement of the liver—"venous stasis"—revealed by its swelling and tenderness. This condition of the liver no doubt interferes with the functions of its cells. These functions concern both carbohydrate and albuminous feeding; but it may be presumed, perhaps, that they concern the former rather more than the latter; at all events it will give relief to have one set of functions reduced to a minimum, while the other set is exaggerated. If the writer be wrong in attributing the major influence of the liver to be upon the carbohydrate constituents of the food, the reduction of these constituents will in any case leave the liver cells more energy to bring to bear upon the albuminous constituents.

In heart cases, again, as regards the digestion of the two great classes of food referred to, a strong argument in favour of a chiefly albuminous diet is the much greater tendency of the carbohydrate elements of food to produce flatulence, and every clinician knows the amount of distress this occasions to cardiac sufferers. For this distressing condition, the writer knows no treatment so effectual as the withdrawal of carbohydrates from the dietary.

It must not be supposed that a diet of "beef and water" is advocated. Two considerations must be allowed predominance; one concerns metabolism chiefly, and has been already discussed, the other concerns primary digestion. Is the "mixed meal" of modern life not based upon the fact that the average healthy individual has an excess of digestive power? Surely it will give relief to weakened digestive organs (and who can doubt that these are weakened in heart disease?) if, instead of the "mixed meal," the albuminous and carbohydrate constituents of the food are given as far as is possible separately? The fatty constituents of the food will be considered later. If a beef-steak and a rice pudding are taken together, will not the latter interfere with the digestion of the former in the stomach, where the saliva must soon cease to act? No doubt in disease the digestion of albuminous food is often accomplished essentially in the intestine, and in an alkaline medium, as for instance in severe fevers; but in heart disease it is a common marvel how long gastric digestive power is retained apart from attacks of gastric catarrh.

Only *simplification* in the feeding of the cardiac patient is pleaded for as regards primary digestion: that he should avoid the "mixed meal" of modern life. In primitive savage life, in all probability, man would eat his flesh food and his vegetable food separately, as he obtained them at different times and in different circumstances.

To carry out the principles referred to, the writer has for a good many years advocated for cardiac patients who are still able to take ordinary meals (and with temporary exceptions this state may continue almost to the end of the case), the following dietary:—

Breakfast: Chinese tea, or weak coffee and cream; toast—the bread cut in thin slices and toasted slowly—buttered cold. Fruit: bananas, etc.

Mid-day meal: any kind of flesh food, plainly cooked, with green vegetables (preferably passed through a sieve after thorough cooking and pounding); custard pudding or junket with cream, or cheese fondue, if a second course is required.

At 4 or 5 o'clock p.m. a cup of Chinese tea and cream. Nothing to be eaten. No sugar to be taken; if sweetening be required, saxin (saccharin) may be employed for the purpose. A very small piece of bread, thickly buttered (to check undue acidity) may sometimes be conceded.

Evening meal: similar to mid-day meal, the articles being changed.

No bread, no potato, and no farinaceous pudding on any account to be taken with the mid-day and evening meals.

Fruit, natural or cooked, without the addition of sugar, may sometimes be allowed after the mid-day and evening meals, as well as after breakfast. The writer believes that, whatever be the explanation, the carbohydrates of fruit, taken in moderate quantity, are less injurious than those of bread, potato, and farinaceous pudding.

There are certain circumstances that interfere with the adoption of such a dietary as has been outlined. Some individuals are intolerant of most fats, and on the other hand have great facility in the digestion of carbohydrates. Others, again, have an inveterate dislike to much flesh food, and two daily flesh meals are abhorrent to them. Compromise can generally be made without greatly departing from the principles of the dietary laid down. The cardiac sufferer may do well on a carefully regulated dietary comprehending only a minimum of flesh food, such articles as custard, junket, and fondues of cheese replacing it to a large extent.

There is a large class of patients whose habitual tendency is to take too large a quantity of both albuminous and carbohydrate food, and in addition to take too much fluid with meals. Usually the albuminous diet, detailed above, suits them, but if they insist on "mixed meals," these must be spare, and each should be *finished short of the feeling of satiety*. Another great class is composed of patients in whom cardiac muscle failure is associated with (one may say in most cases is secondary to) kidney disease. Although in chronic Bright's disease albuminous food is probably much better borne than theoretical considerations would lead one to anticipate, it seems hardly wise to throw an excessive burden on the function of damaged organs. *Small* "mixed meals" are usually best in the circumstances, and it is possible that casein and even egg albumin are less injurious than flesh, though the belief that white flesh is less injurious than red to patients with Bright's disease, has been too commonly and too rigidly held.

The good effects of an exclusive milk diet in the cardiac muscle failure of Bright's disease are generally admitted, but few patients will tolerate it for a lengthened period. The writer adds fruit to an otherwise exclusively milk diet in Bright's disease, and finds that it renders the diet very much more agreeable, and also serves to keep the bowels free—at least to obviate constipation.

In simple cases of cardiac muscle failure, attacks of gastric catarrh are common, as in cardiac cases generally, and for them "koumiss" or fermented milk is often useful, but the patient must not have any other kind of food at the same time. Some patients dislike the taste of koumiss, and will not take it. For them, peptonized milk may be used to the exclusion of all other food. If koumiss and peptonized milk alike are vomited, the best plan is to let the patient fast for from six to eight, or even twelve, hours, at the end of which time the sickness has usually ceased, though feeding must be resumed only gradually. Counter-irritation—as by a mustard and linseed poultice over the epigastrium—is often helpful, or seemingly so. The gastric catarrh of heart disease is, no doubt, often set up in the first instance by some indigestible article of food irritating the venously congested mucous membrane.

Unsatisfactory as is feeding by the rectum, it may be used when it seems necessary to give the stomach absolute rest for a considerable time. Four

ounces of milk with a teaspoonful of liquor pancreaticus (Benger) and a pinch of bicarbonate of sodium form a good enema. Even the throwing into the bowel of warmed normal saline solution renders a period of abstinence from food and drink more endurable. An acetone odour from the breath in gastric catarrh is probably associated with the starvation occasioned by the frequent vomiting.

DRUG TREATMENT.—Among the drugs useful in the treatment of cardiac muscle failure, digitalis is pre-eminent. The official preparations are all open to the objection that the crude drug from which they are made is more or less liable to vary in precise chemical constitution according to the soil in which the plant is grown, and many other pharmaceutical particulars. On the other hand, all are more or less and similarly active. So-called "physiologically standardized" preparations have been in vogue of late, but the writer has always doubted such preparations being permanent—that is, incapable of undergoing subtle chemical change after the assay, and in course of time. To attain, as far as is possible, to precision in the administration of the drug, the writer for many years has used largely the granules of "crystallized digitalin," of Nativelle, of Paris. The active principle they contain is unquestionably present in precise dose ($\frac{1}{40}$ gr. in each granule), but its action, of course, does not represent that of all the active principles contained in the crude drug, and it has one property—a so-called cumulative one—that is both useful and, in a measure, objectionable: useful, inasmuch as it is easy by the administration of the granules to bring the heart under its physiological effects; and objectionable, because the prolonged administration of even a small dose is apt to eventuate in a toxic effect upon the heart and also on the alimentary canal. Thus not only slowness and irregularity of the pulse may result, but be combined with abdominal pain and vomiting. The most desired effect of the drug in all its forms is an increased flow of urine—*diuresis*. But this may fail to appear before the manifestations of the objectionable effects referred to, and yet when, owing to the latter, the administration has been stopped for a day or more, profuse diuresis may set in and continue for a considerable time. It may be imagined that the drug has acted too energetically upon the arterioles in the first instance, so that in the kidney the requisite conditions for diuresis fail, and occur only later, when the effects of the drug have to some extent passed off. Whether this explanation be correct or otherwise, it accords well with the clinical facts. Another, fortunately rare, clinical observation with regard to the effects of digitalis is the abrupt supervention of a very profuse diuresis, which, however, is not maintained and cannot be re-established. In exceptionally severe and urgent cases, the writer prefers a freshly-made infusion of the crude drug, $1\frac{1}{2}$ or 2 drachms of which infusion he is careful to have given *every eight hours*: that is, three times in the day of twenty-four hours. On the other hand, he seldom gives more than two of Nativelle's granules in the twenty-four hours, one night and morning being usually the dose. Should he wish, however, to give a larger amount, he is careful to divide three granules equally over twenty-four hours, i.e., to give one granule every eight hours. In exceptional cases it may be desirable to "push" the action of the drug, and to give four doses in the twenty-four hours: a granule or $1\frac{1}{2}$ drachms of infusion every six hours. It seldom happens that as much can be taken for long without indication arising that the dose must be diminished, and during the administration very careful observation of the patient, *who must be in bed*, is necessary.

It is the custom of the writer to diminish the dose, after a varying time, during a course of the drug—for instance, to give a Nativelle's granule in twelve hours (twice daily) for a week, and then one in twenty-four hours for the following seven or ten days. Afterwards the treatment may be stopped, or a granule

be given once in forty-eight hours for some time longer. In this way the "cumulative" property of Nativelle's granules may actually be utilized. Recently a new granule of Nativelle's "crystallized digitalin," *red in colour*, and containing only $\frac{1}{600}$ gr. (0.1 mgm) of the active principle, has been prepared. Dr. Mackenzie estimates the strength of the old white granule to be that of 18 min. of the tincture.

In certain cases in which there is indication of too great contraction of the arterioles and of a pulse of considerable tension, it may be desirable to give, during the administration of the digitalis, a vasodilator—say a tabloid of erythrol tetranitrate ($\frac{1}{4}$, $\frac{1}{2}$, or 1 gr.), or a chocolate tabella of nitroglycerin, $\frac{1}{100}$ gr. or less, sufficiently often to keep up the physiological effect of the drug, and thus, as it were, to negative or diminish the influence of the digitalis upon the arterioles, which has probably been exaggerated. Moreover it is difficult or impossible to keep up a permanent vasodilator effect. While the administration of full doses of digitalis, under observation, for a short period, is usually quite safe, the prolonged administration of even small doses leads to toxic symptoms. Fortunately, abdominal pain, sickness, and vomiting are apt to supervene, and this last puts a stop to the further absorption of the drug, even if continued; but in certain cases in which quite small doses have been given for a long time, the patient being allowed to go about meanwhile, there is grave reason to believe that the drug has contributed, at least occasionally, to a sudden death, if it has not indeed been the cause of it. Much has been written about the use of the drug in aortic incompetence, simply from one—the theoretical—point of view; the writer has no fear of giving it in cases of this lesion, and has obtained excellent results from it. The fear has been expressed that the diastole being prolonged, more time would be afforded for the distention of the left ventricle by the regurgitated current of blood. In a case of slow pulse in this lesion, no digitalis having been given, the patient died suddenly. Had digitalis been given, it would have been impossible to eliminate the effects of the drug from the result.

The drug next to be considered in point of usefulness is undoubtedly strophanthus, the physiological action of which was long ago carefully worked out by Sir Thomas R. Fraser. If the action of strophanthus be exerted upon the heart essentially, and the musculature of the arterioles to a large extent escape, the drug should have a great field of usefulness in clinical practice, inasmuch as cases of relative heart-failure in the presence of arterial tension and peripheral resistance abound. It can hardly be said, however, that the indication has proved of practical value. For instance, some of the best results the writer has had from strophanthus were obtained in a case of rheumatic disease of the heart in a young subject with mitral incompetence but without mitral stenosis and aortic valve disease, and with very low pulse-tension. There could be no question of *post hoc* rather than *propter hoc* in this case, inasmuch as the same result was *repeatedly* obtained. On the other hand, strophanthus has often failed in cases in which arteriole contraction seemed to play a predominant part. Moreover, the introduction into our therapeutic armamentarium of vasodilators would seem still further to enhance the usefulness of digitalis and diminish the application of strophanthus. Admitting all this, and that the indications for the use of the drug are still to a large extent empirical, the right of strophanthus to the second place in treatment may be cordially admitted. Dr. Mackenzie questions the power of digitalis to raise the blood-pressure in the clinical subject, and the writer's experience would tend in the same direction. Certainly such result is unnecessary for the diuretic effect of the drug.

It seems to be practically impossible to give any drug, with justice, the third

place. The writer admits, however, that he at least has hardly given drugs such as *convallaria majalis* and *apocynum cannabinum* (of which the preparation "Cymarín" is a convenient form) a fair trial, inasmuch as he has reserved their use for the worst cases of heart disease, which have resisted both *digitalis* and *strophanthus*. Citrated caffeine, and still oftener diuretin (*theobrominum natrio-salicylicum*) and theocine, he has frequently found useful in setting up a diuresis in apparently most unfavourable circumstances. Generally he has regarded evidence of sound kidneys as an indication for the employment of the latter drugs, believing their action to be essentially exerted upon these organs. In at least one case of the heart-failure of chronic Bright's disease, however, he has seen a profuse diuresis result from their use. Whether the effect was dependent on the action of the drug upon the kidney or upon the heart, remained doubtful. Squill may be regarded as allied in action to *digitalis*, and is often an important constituent of cough mixtures used in the treatment of heart disease, as for instance Sir Robert Christison's :—

R Tinct. Opii Ammoniaci (B.P.)	aa ℥xx	Syrupi	℥xl
Spiritus Lavandulæ Compositæ	℥lxxx	Aquæ Menthæ Piperitæ	℥lxxx
Syrupi Scillæ			

Of the treatment of the complications of cardiac muscle failure this is hardly the place to speak; they are the complications for the most part of the venous stasis of heart disease in general. The writer deprecates the old custom of giving frequent purgatives in the treatment of heart disease, and especially with the object of removing serous effusion. There are cases, however, in which, notwithstanding the cardiac muscle failure, a considerable degree of vascular tension is maintained, and in which the cardiac failure may be said to be relative only. In such cases the occasional production of free purgation may have its use. Mercury is held by some to be of special value in diminishing peripheral resistance in such cases, calomel and pil. hydrargyri being the preparations usually employed. The antiseptic action of mercury in the intestine may also be of use. In place of a mercurial pill the following may be used as a purgative :—

R Euonymin	gr j	Extracti Hyoseyami	gr j
Iridin	gr ij		
	Fiat pilula.		

Pulv. jalapæ co. has a great reputation as a desirable purgative in heart disease. The dose has often, especially in hospital practice, to be large. More or less constant purgation entails exertions on the part of the patient which must be harmful in the end, while means of lowering arterial tension without exertion are nowadays available (vasodilators). For pulmonary œdema, dry cupping is often of use: the cups should be large and effectively applied. A few leeches may be usefully employed over a congested liver that is causing more than usual distress. Exceptionally phlebotomy may ward off the threatening danger of an over-distended and failing right auricle. Tapping may be required when hydrothorax or ascites is manifestly interfering with respiration and cardiac action, and dropsical legs may require the application of Southey's trochars or acupuncture, which should be used only with great antiseptic precautions. With regard to the use of the trochars, the writer has been much struck by the difference as regards the flow of serum in individual cases *apparently* alike.

Insomnia may threaten the patient's life, and prove most difficult of treatment; resort to morphine and atropine hypodermically will often be the best course to adopt, and generally so whenever an *element of dyspnœa* enters into the insomnia or is associated therewith. Under other circumstances

paraldehyde may prove useful. The treatment of pure insomnia in heart disease is often a matter that causes great anxiety to the physician: as in typhus and pneumonia, if the patient be allowed to go sleepless night after night, he will die, while the forcing of sleep may entail risk.

The question of the treatment of chronic dyspnœa practically resolves itself into the treatment of the heart, and aims at the restoration of its vigour, as far as that is possible, with the removal of subsidiary conditions interfering with the play of the lungs, such as hydrothorax and ascites.

The dyspnœa, coming on in paroxysms, and probably associated with a general tightening up of the arterioles, requires special reference. It is usually relieved, to a greater or less degree, by vasodilator medication, such as the inhalation of amyl nitrite, or the internal administration of erythrol tetranitrate, nitroglycerin, nitrite of sodium, etc. Alcohol, no doubt, acts largely like a nitrite, dilating the arterioles and so relieving the heart. When such remedies fail to relieve paroxysmal dyspnœa, with its violent "struggles for breath," the subcutaneous injection of morphine and atropine is the only reliable mode of treatment; but the dose should always be very small at first, and be slowly increased in subsequent attacks, until relief is obtained. Much blocking of the bronchi with secretion, and Bright's disease, especially the former, are contra-indications as regards the use of morphine: in both cases, if the treatment be employed, the first dose must be infinitesimally small, and the subsequent doses must be increased with the greatest caution, and according to results. The presence of albumin, even in large amount, must not of course be considered diagnostic of Bright's disease; in a heart case it may result from venous stasis of the kidneys simply.

Strychnine is a drug that has come greatly into fashion in the treatment of heart disease. Its action is probably an indirect one as far as the heart is concerned. Its essential action is that of a respiratory stimulant. The best results are obtained from its subcutaneous injection, but naturally such mode of administration is usually reserved for cases that have reached a critical stage.

Iodide of potassium is often recommended in those forms of heart disease that are associated with arterial disease. That the drug exerts a beneficial influence on the latter process in its earlier stages is doubtful, while in the later stages no evidence of improvement is usually forthcoming after its administration. It tends to lower arterial tension, however, and in this way its use may be to some extent beneficial, and it may be regarded as an expectorant, when much viscid secretion is present in the bronchial tubes. In a case of muscle-failure of the heart in a syphilized subject, the cause of which is not obvious, it might be prudent to employ the drug, with or without mercury, for a time, in view of the possible presence of a gumma in the myocardium. The removal of neoplasm is all that can be expected.

It is impossible to regard cardiac muscle failure as a definite clinical entity: its causes are too numerous and different, while it is they that determine the line of treatment. The chlorotic girl, and the middle-aged man with gout and granular kidneys, may equally be the subjects of cardiac muscle failure—the one curable, the other not, though susceptible to judicious therapeutics. In like fashion, the young rheumatic subject of myocarditis, and the old man whose progressive cardiac failure is wrought by his arteries alike increasing the burden of the heart and crippling its nutritive supply, furnish a striking contrast, though both are well-nigh equally hopeless. Between such extremes there is a vast number of cases of cardiac muscle failure that offer a fruitful field for therapeutic effort. Their treatment, however, must not be limited to drugs, but must include diet, rest, the regulation of exercise, and the freeing of the mind from worry as far as possible.

In chlorosis, rest in bed, iron, and a plentiful supply of red meat, usually speedily cure, without recourse to digitalis, strophanthus, or like drugs. In some cases, massage proves a valuable adjuvant. (See also SCHOTT-NAUHEIM *TREATMENT.*)

Graham Steel.

MYOCLONUS (in Childhood)—(*Paramyoclonus Multiplex, Myokymia*).—This condition may be met in children upwards of five years of age. It consists in simple, sudden spasms of individual muscles—not groups of muscles—and usually affects the same muscles on the two sides of the body. The movements resemble those produced by faradic stimulation of the nerves supplying the affected muscles. They do not occur rhythmically, and do not resemble any volitional movements. The face is rarely affected. Thus they may be distinguished from the exaggerated normal movements of muscle groups in Sydenham's chorea, and from the fantastic parody of normal movements which obtains in co-ordinated tic (habit spasm) and other functional derangements. The absence of sensory stigmata distinguishes myoclonus from hysteria.

The etiology of myoclonus is unknown. Probably it is due to congenital functional abnormality of the motor cortex and of the motor cells of the spinal cord. In many cases it is a familial affection. The prognosis is unfavourable as to cessation of the movements, though the disease is not as a rule dangerous to life. Spontaneous recovery may take place, but the complaint is wont to recur. Treatment is probably useless, though hydrotherapy, electricity, and arsenic have been credited with good results.

Leonard G. Guthrie.

MYXŒDEMA.—In carrying out the treatment of a case of myxœdema we have to make good the loss of function of the thyroid gland by supplying the secretion from another source. This can be readily obtained from the thyroid gland of an animal, such as the sheep. Normally the secretion is continually being carried into the blood-stream. We cannot exactly imitate this, but it is found in practice that, if the supply is given in a single daily dose, the results are quite satisfactory. The thyroid secretion may be administered by the mouth in several different forms. The actual gland itself may be given, and though, as a rule, this is not so convenient as one of the preparations of the gland, it may be useful when the patient lives in some remote place. The fresh gland can be readily obtained wherever sheep, oxen, or pigs are killed. If the raw gland is used, from one-eighth to one-quarter of the lobe of a sheep's gland is an average daily dose for an adult, one-fifth of a lobe being equivalent to 10 min. of liquor thyroidei (B.P. 1898). The raw gland may be lightly fried on the outside, or it may be minced and taken in some sweet vehicle, such as a syrup, to make it palatable. As a rule, it will be found more convenient to employ one of the two preparations, liquor thyroidei (B.P. 1898) and thyroideum siccum. The former is simply the original thyroid extract, which I first introduced twenty-three years ago, and the latter is a powder obtained by drying the minced glands at 90°–100° F. One grain of the powder should be equivalent to about 5 min. of the liquor, but in actual practice one grain of dried thyroid is only equal in efficiency to about 2 min. of the liquor. Of the two preparations the best results are obtained in the treatment of myxœdema by the use of the liquid extract, though the dry powder is more convenient, as it can be readily made up into compressed tablets.

In dealing with an advanced case of myxœdema, which is now rarely seen, the patient should be confined to bed during the first part of the treatment, so as to avoid any over-exertion. This is important, as these patients are apt to have some fatty or fibrous degeneration of the myocardium, and any increased exertion may induce an attack of syncope, which has proved fatal in several cases. Only

small doses of thyroid should be given at first, 2 to 3 min. of the liquor or 1 gr. of the dry thyroid, at bedtime. This dose may be gradually increased up to 5, 7, and finally 10 min., or to one 5-gr. tablet, during the course of two or three weeks, when the patient may be allowed to get up again. Exercise must be strictly regulated, and increased only by degrees, according to the condition of the pulse. Any increase of the pulse-rate beyond 80 or 90, when the patient is at rest, is an indication that the dose should be reduced.

In early cases in which no cardiovascular changes can be detected, this period of rest is not necessary, though patients should be warned against undertaking any unusual exertion during the first stage of the treatment. In these cases 5 min. of thyroid extract or one 2½-gr. tablet may be given each night, and the dose gradually increased up to 7, 10, or 15 min. according to the progress made. As soon as the first stage of the treatment is completed—that is to say, as soon as the symptoms of the disease have disappeared—a somewhat smaller quantity will probably suffice for the permanent dose. It is most important to make patients clearly understand the nature of the treatment, and the necessity for its steady continuance during the rest of life, in order to avoid a return of the symptoms of myxœdema. This is easily done in the case of educated people, who can readily understand the *rationale* of the treatment and the necessity for taking the thyroid extract regularly, as part of a daily diet. Some hospital out-patients, on the other hand, are inclined to neglect the treatment as soon as the symptoms have disappeared, and of course they sooner or later return as before. As a rule, 10 min. of the extract, or one 5-gr. tablet, each day is quite sufficient. Thus the first case of myxœdema in which I began the treatment, in 1891, took regularly 10 min. each week-night, that is, 1 dr. of thyroid extract each week. She remained well, and free from any symptoms of the malady, when last seen in 1913. In some cases a daily dose of 5 or 6 min. is sufficient; in a few, 15 or even 20 min. a day may be required. The liquid extract should be obtained fresh each fortnight.

During the first stage of the treatment, the solid œdema steadily diminishes, the skin gradually becomes less dry, and perspiration returns. The temperature rises to the normal level, so that the patient no longer complains of feeling cold. The normal mental and bodily activity is gradually regained, and the speech becomes natural. At a later stage, the hair grows again; in fact, the patient recovers, and remains free from the symptoms of the disease as long as a sufficient daily dose of the thyroid extract is regularly taken.

NÆVUS.—(See ANGEIOMATA.)

George R. Murray.

NAILS, DISEASES OF.

Eczema.—Treatment of this condition is always tedious, as it is difficult to get at the matrix. The ends of the fingers should be wrapped up in an ointment of salicylic acid, ½ dr. to the ounce, the ointment being pushed as far as possible under the nail fold. Oleate of tin, 1 dr. to the ounce, is also used in an ointment.

Ingrowing Toe-nail is treated of elsewhere (*vide* TOE-NAIL, INGROWING.)

Psoriasis.—Arsenic internally is indicated. The thickened nail must be scraped down by a piece of glass, and an ointment of salicylic acid, ½ to 1 dr. to the ounce, applied.

Chronic Hypertrophy (Onychauxis) is treated like psoriasis of the nail.

Onychogryphosis.—After thorough soaking in hot water to soften it, the superficial part of the nail is removed. In very neglected cases a fine saw may be required.

Onychia.—(See also WHITLOW.) Inflammation of the nail may be due to

coccal infection, to syphilis, and to tuberculosis. In the coccal form, fomentations with boric acid may be sufficient in mild cases, but where the affection is severe, and there is tension, the nail may have to be removed under anæsthesia, and fomentations and antiseptic ointments applied subsequently.

In the syphilitic forms, internal treatment is most important. Neo-salvarsan injections and mercury in the secondary, and the same remedies with the addition of iodides in the tertiary, forms will be required. As local applications, black wash and the yellow oxide of mercury ointment are useful. The diseased nail may require removal. In the tuberculous form, removal of the infected part, and possibly of the terminal phalanx, may be required.

Ringworm.—Both the endo- and ectothrix varieties of the trichophytons may affect the nails, the former being the more common parasite. The nail should be well scraped and the following solutions, suggested by Harrison (of Bristol), used. For fifteen minutes the nail is soaked in a lotion consisting of equal parts of liq. potassæ and water with $\frac{1}{2}$ dr. of potassium iodide to the ounce. The lotion is covered by oiled silk to prevent evaporation. At the end of the fifteen minutes a sublimate lotion is applied and left on for twenty-four hours. The sublimate lotion contains 4 gr. hydrarg. perchlor. to an ounce of a mixture of equal parts of alcohol and distilled water. At the end of the twenty-four hours the nail is scraped again and the same procedure carried out. This is repeated until the scrapings show no evidence of the fungus. Sabouraud advises keeping the affected nails soaked in a weak iodine (5 per cent) solution under rubber finger-stalls. In bad cases I have removed the affected nails under anæsthesia and then applied the antiseptic dressings. The treatment of **Favus** of the nails is similar.

The alterations in the nails which occur in **Debilitating illnesses** demand no special treatment. As a rule they pass away on the improvement of the general condition, though somewhat slowly owing to the slow growth of the nails.

James H. Sequeira.

NASAL CATARRH.—(See RHINITIS.)

NAUHEIM TREATMENT.—(See SCHOTT-NAUHEIM TREATMENT.)

NEPHRITIS, ACUTE.—

The leading principles in the treatment of renal disease may be summarized as follows: (1) To diminish the work of the kidney as much as possible, and this includes diminishing not only the excretion of nitrogenous extractives, but also the other excretory activities of the organ, e.g., salts and water; (2) To promote, as far as may be, excretion by other channels; (3) The treatment of such associated conditions as dropsy and uræmia; (4) To check, so far as possible, the disordered metabolism.

The necessity for restricting, as far as possible, the excretory activity of the kidney, is greater in acute than in most cases of chronic renal disease, since the activity of the organ is usually more impaired in acute than in chronic affections. There are exceptions to this, namely, where an acute exacerbation or complication occurs superadded to a chronic lesion, and in the terminal stages of fatal chronic cases.

In acute renal disease it is possible to restrict the output of nitrogenous extractives, salts, and water, etc., to a greater degree than in chronic cases, owing to the transitory character of the affection. In chronic diseases, undue restriction of the ingesta may produce injurious effects by lowering the general health, and it may not be advantageous to attempt to produce an improvement in the urinary excretion at the cost of still further impairment of the general

nutrition. In acute renal disease the indications are clear, to restrict as far as possible the work the kidneys have to perform.

Food.—The food given in acute renal affections must be not only small in amount, but also of the simplest character, and readily digestible, owing to the frequent occurrence of gastric disturbance, and the accompanying nausea and vomiting.

All food rich in nitrogenous extractives is obviously contra-indicated, such as soups, broths, meat essences, as such articles of diet not only increase the work of the kidney, owing to their richness in nitrogenous extractives and saline ingredients, but also are of small nutritive value. Solid food is also inadmissible, owing to the gastric disturbance. Thus the diet is practically limited, if food be given at all, to milk. Three pints of milk per diem are usually looked upon as the minimum quantity necessary to maintain the nutrition of the body in an approximately normal condition, as this quantity will supply 60 to 70 grams of protein, usually regarded as the minimum necessary. In actual renal diseases lasting but a short time, probably no harm will result from diminishing the input to a still greater extent, and a pint to a pint and a half per diem is probably sufficient, at any rate for some days.

In cases where the acute nephritis is of a very severe type, leading, it may be, to practical suppression of urine, it is advisable to cut off all food, and simply to allow the patient to sip water. A few days' starvation will not produce any disastrous effects on the body generally, and it may turn the scale in favour of the patient, by still further diminishing the work of the kidney. Even in starvation, considerable quantities of nitrogen in the form of urea, etc., are excreted in the urine, especially during the first few days, so that even by starvation it is impossible to afford the kidney complete rest; but there is much to be said in favour of allowing only water in moderate quantities for two or three days in the treatment of severe cases of acute nephritis. In the majority of cases, however, the type of the disease is not so severe, and milk as mentioned above, in quantities of from one to one and a half pints per diem, may be allowed. After the lapse of a few days, the condition of the urine will probably improve, the amount of blood diminishing and the quantity of urine increasing, and further quantities of milk may be given, and some carbohydrate in the form of bread, arrowroot, etc., may be added. Great care should be taken not to increase the diet too rapidly, and to be guided mainly by the condition of the urine, trusting to make good the patient's condition subsequently, when the acute renal lesion has subsided.

Where the kidney lesion is less severe, and gastric symptoms are not marked, there is no objection to increasing the food by the addition of more carbohydrates and fats in the form of cream; but the quantity of protein food should be restricted as much as possible, and care taken not to give fluids in large amount. Where gastric symptoms are marked, it is advisable to pancreatize or artificially digest the milk, and usually a mixture of equal parts of gruel and milk make a more suitable food for artificial digestion than milk only. Such a mixture is much more palatable, and its nutritive value is greater, than if the same quantity of milk be simply diluted.

There is considerable difference of opinion with reference to the quantity of fluid that should be allowed to patients suffering from acute renal affections. Some writers advocate the free administration of water, with the idea of its elimination by the kidney leading to the washing out of the débris in the form of shed epithelium that is choking the renal tubules. Others consider that the administration of large quantities of water in acute nephritis is liable to be followed by the production of hydræmic plethora, owing to the diminished and imperfect elimination of water by the kidneys, and they regard this plethora,

if not as the actual cause, at any rate as a powerful predisposing cause, in the production of dropsy. It is probable that an indication as to the free use of water may be afforded by the state of the patient. If the acute renal affection is one where only urinary changes are present and dropsy is absent, water as a diuretic is probably useful. On the other hand, in the acute lesions where dropsy is a marked sign, fluids should certainly not be given freely, although it must be remembered that it is impossible to treat dropsy by the mere restriction of the input of water: such restriction leads only to great distress, and produces no beneficial results. No good results can follow the administration of large quantities of water in such patients, with the idea of flushing out the kidneys. The indiscriminate giving of fluids in large quantity may not only perhaps aid the development of dropsy, but the hydræmic plethora is also liable to be accompanied by cardiac dilatation, which is one of the most serious complications of acute renal disease.

Thirst should be treated, not so much by the giving of water, as by measures directed to promote the flow of saliva. Lemonade, and fruit juice of various kinds, are advisable for this purpose.

Measures directed to promote the excretion of fluids and salts by other channels than the kidney are of the utmost importance in the treatment of acute renal disease, and such excretion must take place by means either of the bowel or of the skin. Treatment of this kind is not only necessary for the relief of dropsy, and of uræmic symptoms when these are well marked, but it is also advisable in all instances where the excretory activity of the kidney is diminished, even if marked uræmic symptoms are absent.

In normal circumstances the activity of the skin is correlated with that of the kidney, at any rate in so far as concerns the excretion of water; but in renal disease, both acute and chronic, but especially the latter, it is often difficult to promote the secretion of sweat, the skin being unnaturally dry.

The intestinal mucous membrane may not only serve as the channel for the elimination of large quantities of fluid, but in conditions where the activity of the kidney is impaired, the fluid secreted by the bowel contains appreciable quantities of urea and other nitrogenous extractives, and quite considerable amounts of urea may be excreted even from the stomach in renal diseases. Measures directed to increase the loss of fluid by the bowel will therefore also remove from the blood considerable quantities of the normal constituents of the urine. Purgation is also useful, as it necessarily procures immediate relief of the hydræmic plethora so often present. The only contra-indication to free purgation in renal disease is the fact that enteritis may occur as a complication; and in some instances, but especially in chronic renal affections, this enteritis may be of an ulcerative type, and affect the lower bowel. The purgatives selected should be those tending to produce copious, watery motions without causing much griping, and saline purges are especially useful for this purpose. They should be given in a concentrated form, as it is desirable to produce a hydragogue effect. Sulphate of magnesia, sulphate of soda, phosphate of soda, acid tartrate of potash, are all useful. Sulphate of magnesia and sulphate of soda have the advantage of being more soluble than the others, and consequently it is easier to give them in a concentrated form, and thus a greater hydragogue effect is produced than with the use of phosphate of soda or acid tartrate of potash. Sulphate of magnesia has one drawback, that it has a considerable depressant action on the heart, far greater than that produced by any other saline cathartic. This objection is perhaps more of theoretical than of practical importance, the amount of sulphate of magnesia absorbed being probably very small. The saline purges should be administered in small doses at frequent intervals, rather than in large doses at longer intervals, and very good results

are seen by giving the drug in a drachm dose every hour, or every two hours, until the desired effect has been produced. Although saline cathartics are especially indicated in the treatment of renal disease, other purgatives having a hydragogue action are also useful, jalap being especially recommended for this class of case. Elaterium is occasionally used, but its action is liable to be unpleasantly violent at times, and its use is really more or less restricted to cases where marked uræmic symptoms are present, and where it is essential to produce a prompt evacuation of the bowels.

In some cases, purgatives are required to produce simply a free evacuation of the bowels rather than a marked hydragogue effect, and in such instances the traditional mercurial purge, either in the form of blue pill or a small dose of calomel followed by a saline draught, is the most efficacious. Some writers have objected to the use of mercury as a purge in almost all forms of renal disease, owing to the fact that in large doses it produces necrosis of the renal epithelium. Even if this objection were a valid argument against the use of mercury in routine fashion in cases of renal disease, it can scarcely be urged against the occasional use of the drug as a purgative. Although in large doses it does produce a coagulative necrosis of the renal epithelium, yet in small doses it is a very useful stimulant diuretic.

Sweating may be brought about either by the use of drugs or by hot baths. The promotion of sweating by the application of heat in moderation cannot but be beneficial, and for this purpose the hot pack may be used with advantage. Hot-air baths may also be useful, provided they are not employed at such a temperature as to cause syncope, or tendency to syncope, since many patients are very intolerant of the more extreme temperatures often employed in hot-air baths. Such a bath at a moderate temperature, 120°–140° F., can do nothing but good if it causes sweating, but, as already mentioned, the skin in renal disease is often unnaturally dry and harsh, and sweating cannot be produced even by the application of much higher temperatures. Great care should always be taken that the first hot-air baths given are at a comparatively low temperature, and the temperature should be gradually raised, and the patient should be watched all the time, to see if any feeling of faintness or acute discomfort is produced. Sweating may often be promoted by the giving of hot drinks during the bath or by the administration of small doses of drugs: acetate of ammonia, nitrous ether, or even pilocarpine. The use of hot-air baths at high temperatures, above 170°, is not altogether free from risk. Many instances of sudden death in the bath, in patients suffering from renal disease, might be quoted. It is true most of these occur where the hot-air baths are used for the treatment of uræmia in chronic renal disease, but cardiac dilatation is not very uncommon, accompanied with much circulatory weakness, in acute renal disease. It is doubtful whether much good is to be derived from persisting in hot-air baths in cases where the skin does not readily respond to such treatment.

Sweating can also be brought about by medicinal agents, but it is difficult to cause profuse sweating by this means without the occurrence of other, more or less undesirable, effects. Thus pilocarpine in full doses will produce very free sweating, but at the same time it may cause a considerable degree of bronchorrhœa, and so lead to marked respiratory embarrassment. Further, pilocarpine in full doses has a very marked action on the heart, and the profuse salivation and lacrimation, although not serious, are often very distressing. The bronchorrhœa is especially serious in waterlogged patients, and pilocarpine should be given in small doses in association with hot-air baths. There is no objection to the promotion of sweating by the administration of acetate of ammonia and nitrous ether, and hot drinks.

In acute renal disease of a severe type, where the urinary functions are not

only seriously hampered but may be suppressed, great benefit may be obtained from venesection. The circulation generally, and in the kidney, may be relieved by this means, and the amount of toxic material in the blood diminished. The blood is usually drawn from a superficial vein of the arm or neck, but according to some, it is desirable to bleed from the dorsal vein of the foot, with the idea that the circulation through the kidney is more directly relieved by such a procedure, and bleeding from the dorsal vein of the foot has been specially recommended in cases of acute hæmorrhagic nephritis, with more or less suppression of urine. In some instances of extreme congestion of the kidney, incision of the renal capsule itself has been recommended and carried out, with the idea of relieving the extreme congestion that is sometimes present, and very beneficial results have been claimed in such cases from this procedure.

Transfusion of saline solution is also useful in association with venesection, and is more especially indicated in cases where uræmic symptoms are marked; but transfusion, or even the subcutaneous injection, of salt solution is of material service where complete or partial suppression of urine without uræmia is present. In many cases where complete suppression occurs, either in acute nephritis or in other forms of renal disease such as calculous obstruction and occlusion of the renal arteries, uræmic symptoms are frequently in complete abeyance for many days, and it is not uncommon for death to occur in such cases without the development of ordinary uræmia. Transfusion is peculiarly useful in such cases, and by its aid life may not only be prolonged, but may also be saved in some conditions, e.g., calculous anuria, thanks to the patient being tided over a critical period. The transfusion would seem to dilute the blood, and thus prevent the development of serious toxic symptoms; and elimination may be promoted through the bowels, and the acute congestion, or other renal lesion causing the symptoms, may subside. In calculous anuria this method of treatment may enable the patient to tide over the time necessary for successful surgical interference.

In the convalescence from acute nephritis, the treatment must be directed with the aim of preventing, as far as is possible, any recurrence of the renal lesion. With this object, all possible exposure to damp and cold should be avoided, and it is in this class of case that residence in an equable climate during the winter is especially desirable. The South of England (e.g., Cornwall), Aix-les-Bains, Madeira, the Canaries, Egypt, are especially suitable for such patients. Their diet should be an ordinary plain, unstimulating one; but there is no necessity to avoid meat completely, and there would not seem to be any real advantage in recommending white meat, as is so frequently done. Such patients are commonly anæmic, and their general nutrition and power of resistance to disease have often been considerably affected by the acute malady; thus they require plenty of good plain food in order to regain health. Although a moderate diet is necessary with such patients, alcohol is probably inadvisable. Careful attention should be paid to the bowels, and a course of saline purges is frequently beneficial. Tonics, in the form of iron and arsenic, are useful, and the iron should be administered freely, but in a form that does not lead to gastric disturbance; for this reason the perchloride, although a powerful tonic, is very often unsuitable, and better results are obtained with the sulphate of iron, given as a pill. Some of the milder preparations, such as the citrate and tartrate, may also be employed, especially in the case of children, and some authorities think that the administration of small doses of iodide of potassium with the tartrate of iron is more beneficial than giving the iron by itself. Arsenic in small doses is also extremely useful in the treatment of the anæmia and debility following acute nephritis. Any preparation of arsenic, however, should not be administered for prolonged periods, as even small doses not infrequently cause

toxic effects; it is advisable to order the drug for periods of ten days or a fortnight, to be followed by an intermission of a week. Renal extracts, prepared in a variety of ways, have been recommended by some writers in the treatment of acute renal disease; these extracts are usually prepared from the kidney of the pig, and have been administered either in the form of glycerin extracts, or as broths or infusions of the macerated fresh kidney. There is a general consensus of opinion that the broths are useless, and that no results of any value are obtained from organs that have been heated or cooked. There is much difference of opinion, both from the experimental and from the clinical side, with regard to the efficacy of the fresh extracts; the watery extract prepared from the macerated fresh kidneys has been stated to be of value, both in the treatment of acute and chronic renal disease, especially where uræmic symptoms are present. The fresh infusion is extremely nauseous, and very repugnant to the patient both in appearance and taste, and not uncommonly leads to gastric disturbance and to cutaneous eruptions. Notwithstanding these obvious drawbacks, such extracts, given by the mouth, have been stated to produce beneficial results in cases where the secretion of urine was very scanty and the uræmic phenomena were marked. The subcutaneous injection of such extracts into animals produces very marked toxic effects, and later experiments would seem to have led to different results from those obtained at first. Brown-Séquard and others stated that the use of such extracts led to the prolongation of life in animals after double nephrectomy; but more recent results would seem to show that this is not so, and that the use of such extracts after experimental double nephrectomy in animals really tends to shorten rather than to prolong life, and that the supposed benefits at one time obtained were simply due to the fluid of the injection, inasmuch as better results follow the use of copious saline injections than the use of renal extracts. In the present state of knowledge it cannot be said that there is any clear and definite evidence in favour of the use of renal extracts in the treatment of renal disease, and the same remark applies to the use of blood-serum derived from the renal vein, which at one time was thought to possess marked beneficial properties.

J. Rose Bradford.

NEPHRITIS, CHRONIC.—The two most important forms of chronic Bright's disease are *chronic parenchymatous nephritis*, or the later stages of acute nephritis, and *granular kidney*. These two affections stand in marked contrast clinically and pathologically to one another, and in respect of treatment must be dealt with separately.

I.—CHRONIC PARENCHYMATOUS NEPHRITIS.

In chronic parenchymatous inflammation we have to do generally not with a slowly progressing, i.e., still active, inflammatory process, but with the result of an inflammation previously acute but not any longer active.

As the two stages pass gradually into one another, and it is impossible to say exactly where the acute stage ends and the chronic begins, so the treatment of acute nephritis gradually merges into that of chronic, and the question arises when and in what way the treatment of the acute stage may be modified, its restrictions relaxed, and the treatment of convalescence commenced.

In acute nephritis the circulation in the kidney is disordered, the cells are disorganized, and the tubules obstructed by disintegrated cells and exudation.

The treatment at this stage is to relieve the kidney of work by modifying the diet, keeping the skin and bowels active, and avoiding all renal irritation.

In the later so-called chronic or post-nephritic stage, the circulation has more or less recovered itself except for the hyperæmia necessary for active cell-growth. The obstruction to the tubules is relieved, and new cells are actively growing to

take the place of those which the inflammation has rendered useless. Thus cell-growth is the chief phenomenon of convalescence. For healthy cell-growth the body must be in a good state of nutrition, and the delicate young cells formed must be nursed and protected until they are seasoned and robust.

The problems, then, of treatment in chronic parenchymatous nephritis are to promote the growth of healthy cells, to avoid fresh irritation, and to lighten the work which the weak and delicate organ has to do.

One of the first signs of improvement is the disappearance of œdema. In the early stages, when the inflammation is active, the œdema is universal, and probably dependent upon widespread changes in the small arteries and capillaries; in the later stages, when the inflammation is past, the œdema is often of cardiac origin, and due to feeble circulation, and consequently its treatment in the two stages will differ.

Another sign of improvement is the disappearance of the high tension of the acute stage. The pendulum often swings the other way, so that the tension may fall much below normal.

For these two conditions—cardiac failure and low arterial tension—tonics and stimulants are necessary, and probably such drugs as digitalis, strychnine, and adrenalin will be beneficial.

The more the functions of the kidney are impaired, the more actively must the complementary organs, viz., the skin and the bowels, be worked. Conversely, as the kidneys regain their functional powers, the less energetic need this complementary treatment be. Active diaphoresis, bathing, and purgation become unnecessary—more than that, these methods are all lowering and depressing, and therefore, when the acute stage is past, they are usually contra-indicated. All that is necessary is that the skin should be kept gently active, the bowels moved regularly, and a Turkish bath ordered once or twice a week, or a hot bath on going to bed. The milder purges are sufficient, such as salines or rhubarb and aloes, but mercurials are best avoided.

In the urine, the most important indications of convalescence are given by the return to the normal of the amount of urine and of its specific gravity. It is well to make an estimate from time to time of the amount of urea and of the total solids passed. An increase in the amount of urine during early convalescence is normal, and need not be controlled. As the specific gravity is usually normal, it probably means that there is an accumulation of effete substances, which has to be gradually worked off.

The amount of urea, which may be taken as the measure of the nitrogen voided, is the great indicator of the excretory activity of the kidney. The amount of urea depends largely upon the diet, and as this is usually low in nitrogen contents, the urea percentage is generally small. A low percentage of urea, when the amount of urine is not increased, is sometimes used as an argument for the use of diuretics; but diuretics are likely to be harmful, for the kidney cells play an active part in elimination, and being still delicate must not be worked too hard. They will work well as soon as they are sound, if they are not hustled and hurried.

The gradual reduction in the amount of albumin in the urine is rightly regarded as the best indication of the progress of the disease towards recovery, and when albumin is permanently absent the case may be regarded as cured.

Albuminuria is really a *symptom*, and an indication, but it is often regarded and treated as a disease.

To treat albuminuria as a disease is a mistake; too much is often made of it, to the detriment of the patient. The actual amount of albumin lost is insignificant. Even 1 per cent in 1500 c.c. of urine amounts to less than $\frac{1}{2}$ oz.

of albumin in the day, or what could be made up easily by the taking of an extra pint of milk, or the white of two eggs.

Moreover, clinical experience proves that patients after acute nephritis may continue to pass albumin for years, even in considerable amount, and yet remain in good health and lead active, strenuous lives.

Treatment must be guided by general considerations rather than by the amount of albuminuria.

Recovery from acute nephritis is largely a question of the growth of the cells. The old cells have to be removed, and new ones produced. The kidney cells are highly specialized, and therefore are very slowly regenerated. When grown, they still take some time to become seasoned and resistant. Till then the kidney remains delicate, and will not stand over-work or irritation. Thus the problem in recovery from renal disease is to get the cells well grown and seasoned, and the treatment in general should be that of convalescence.

The first important question in the treatment of chronic parenchymatous nephritis is that of **Diet**. When and in what way may that be improved? Patients are often kept upon a milk diet as long as albumin is present in the urine. Milk is good enough for little children, and in acute disease adults have to be treated like little children. Yet for both alike the time comes when the diet must be strengthened, for if restricted to milk alone, the nutrition suffers, the tissues become flabby and soft, and the patient anæmic. Life may, it is true, be maintained for a long time on milk alone, especially when supplemented by starchy foods, but the body is not vigorous and the general tone is poor. Fortunately, adults get so tired of milk alone that they often take the matter into their own hands and modify the diet for themselves. The benefit of change of diet in chronic parenchymatous nephritis is a matter of daily experience. The patient's condition often remains stationary till a more liberal diet is given, and then improvement begins at once.

The effect of change in diet is to be judged by the general condition and feelings of the patient, and not by variations in the amount of albumin. Weight is obviously no guide, for patients who are losing their œdema would be losing weight, though getting better.

There are certain articles of diet which should be avoided in all cases of kidney disease: *alcohol* in all forms; *meat extracts*, whether in the form of soups or broths, or of the much-advertised and popular extracts of meat; fruits and vegetables which are rich in irritating salts, e.g., tomatoes, asparagus, gooseberries, etc.; and for a similar reason salted, dried, and preserved meats.

Why *eggs* are taboo I cannot understand, for they yield a very easily assimilated form of albumin and form an excellent supplement to milk. Nor can I see any reason for the prejudice which exists against *red* as distinguished from *white meats*, unless it be that some patients may find the one more easy of digestion than the other. Red meats contain no more extractives than white. In both cases, boiled meats are better to begin with than roast, as in boiling some of the extractives are dissolved away. The patients often crave for a little red meat, and I do not know any good reason for refusing their wish.

Fish, though rich in nitrogenous extractives, is a good article of diet, as it is light and easily digested.

The order of change of diet might be tabulated somewhat after this fashion:—

1. Milk.
2. Milk, with farinaceous foods.
3. Milk, farinaceous foods, with an egg or two and some cream.

4. Milk, farinaceous foods, an egg with beans, peas, potatoes, or green vegetables.
5. The previous diet, with the addition of fish.
6. Boiled meats (white or red), fresh pork, etc.
7. White or red meats, roast or boiled.

The effect of any change of diet may be judged from the urine, but a single examination on the day after the change must not be regarded as conclusive, for any sudden change in diet is associated with a general disturbance of chemical equilibrium, which would betray itself in the urine for a few days, until equilibrium re-established itself. Thus, the addition of a single egg may lead to the sudden increase of the percentage of urea in the urine from 1.5 to 3.5, though in three or four days the percentage gradually returns to the normal 1.5, in spite of the offending egg being continued all the time. Still less can albumin be taken as the test, for even if the amount should be temporarily increased by the change, the improvement in the patient's condition occurs and is maintained; but as a matter of fact the change of diet is often unaccompanied by any alteration whatever in the amount of albumin passed.

The next practical question that arises is, **When may the patient leave bed and get about?** The risk is that of catching cold, and every precaution must be taken to avoid this. The difficulty with children is often so great that bed is rightly regarded as the safest place. So it might be with a careless adult, but prolonged confinement to bed affects the health injuriously, though children bear it better than adults.

The change from recumbent to erect position is very likely to be accompanied at first by an increase in the amount of the albumin, which, however, may slowly decrease again as the body accommodates itself to the altered conditions.

Fresh air is a very important factor in the treatment of the convalescent, though in kidney disease it is often not thought of, the patient being confined to one room, which is often kept too warm and not sufficiently ventilated. Even if the patient be in bed, the windows may be opened and as much fresh air as possible given, provided there be no draught. In suitable weather, kidney cases may even be carried in the bed out of doors, and lie all day in the sun. The *open air cure of nephritis* is as important and advantageous as in many other diseases, provided draught and exposure be avoided.

The **Drugs** useful for the later stages of parenchymatous nephritis are chiefly of the nature of tonics. Among these, *iron* comes first and is the most valuable. The more astringent preparations, such as the perchloride, are the best if they do not disagree. Iron is especially useful when the patients are taking nothing but milk, for on a milk diet not enough iron is provided for the body needs, and anæmia may develop in consequence. *Digitalis* may be associated with the iron; in small doses it assists the heart and raises the vascular tension, which in the convalescent stage is low. It is contra-indicated if the tension be high.

R Tincturæ Ferri Perchloridi ℥xv | Spiritus Chloroformi ℥x
Glycerini 3j | Aquæ Destillatæ q.s. ad 3j

Ter die, post cibum. Or with Tinctura Digitalis ℥xij.

Sulphate of magnesia may be added if the medicine has a constipating effect.

Extracti Aloes gr j | Pilulæ Saponis gr ij

Fiat pil. t.d. sum.

The Liq. Ferr. et Ammon. Acetatis U.S., formerly known as Basham's Mixture, is a useful combination, tonic, diaphoretic, and diuretic, as follows :—

R Tincturæ Ferri Perchloridi	℥x	Elixir Aromatici	℥ss
Acidi Acetici Diluti	℥xv	Glycerini	℥ss
Liquoris Ammonię Acetatis	℥ij	Aquam Destillatam	ad ℥ss

Arsenic is often associated with the iron as a general tonic, but the dose should always be small, as it is an irritant to the kidney. Arsenic is often best avoided, and in no case should its use be continued for long without intermission.

Diuretics are unnecessary, for the amount of the urine is generally already above normal, and diuretics are mainly renal irritants. The most useful is caffeine, because it is a good cardiac stimulant also. A cup of weak, freshly made tea is greatly enjoyed in the quite early days of convalescence, and does good.

Many of the patent and popular remedies are only preparations of caffeine, or of theobromine in different combinations, such as theobromine sodium salicylate.

The administration of drugs with the object of causing the disappearance of the albumin is based upon an incorrect theory, and is much more likely to do harm than good. Thus tannin and other astringents, fuchsin, and similar preparations, have been tried and found wanting. Such will be the case, no doubt, with calcium and its salts. Of course it is important in chronic parenchymatous nephritis to assist the kidneys by keeping the skin and bowels in regular action.

Diaphoretics.—A hot bath should be given two or three times a week, or even every day if not found too weakening; a diaphoretic mixture may be given at night when the bath is not taken. It is not wise to give this during the day, if the patient be up, on account of the risk of chill, but instead the body may be well rubbed with a hot dry towel before dressing.

Purgatives.—The bowels should be moved freely at least once a day, not merely with the object of keeping the bowel empty and so avoiding absorption of any toxic material, but especially to encourage elimination by the intestine of some of the substances which ordinarily would be removed by the kidneys. Further, free purgation diminishes vascular tension, but in chronic parenchymatous nephritis this action is not indicated as it is in the acute stage or in granular kidney. The best purges are the salines, which may be usefully combined with aloes. Even mercury in small doses may be useful now and then, but should always be followed by a saline purge. The favourite kidney purge for regular use is the compound jalap powder.

Violent purges should be avoided for ordinary use, as they produce griping and intestinal irritation, and may seriously disturb the digestion.

The drug treatment, then, of chronic parenchymatous nephritis is that of convalescence from any severe disease, and needs to be modified only so far as the organ which has been attacked—in this case the kidney—requires.

When convalescence is established, the question arises of going away, or **Change of Air**. During summer, the choice in this country is ample, there being many suitable places inland or on the sea-coast. In winter the selection is more difficult. The object is to obtain as equable a climate as possible, with the maximum of sunshine and protection from cold winds. The choice will generally fall upon some seaside place on the south-west coast. Many of the places in the west where the Gulf Stream touches the coast are suitable, but unfortunately, though warm, they are often wet.

Abroad there is a choice of climates. Madeira, the Canaries, and the Azores are within easy reach of England. Algiers and Egypt have the advantage of a dry and sunny climate, but the difference between the day and the night temperatures is considerable. The Riviera is unsuitable, on account of its violent changes in temperature. The West Indies can be strongly recommended, and as to climate seem to leave little to be desired. Even when convalescence has been complete, great care should be taken during the next cold season. The following winter should be spent, if possible, in a good climate abroad.

The treatment of chronic parenchymatous nephritis has been considered so far on the assumption that the case is progressing towards recovery. **When the course is in the downward direction**, the treatment must be modified to deal with fresh symptoms as they arise.

Chief among them is increase in dropsy. It is extraordinary how extremely dropsical a patient may be, and yet recovery take place in time. Ascites must be treated on general principles, and tapped whenever necessary. Any attempt to get rid of it by violent purgatives or diaphoresis will be disastrous; such methods are ineffectual, and will besides produce great depression, the very thing to be avoided.

It should be borne in mind that all the dropsy which occurs in these cases is not renal. Much of it is often cardiac, and may be benefited by treatment directed to the heart rather than the kidney.

The following old-fashioned pill is excellent :—

R. Pulveris Digitalis	gr j	Massæ Hydrargyri	gr j
Pulveris Scillæ	gr j	Extracti Hyoscyami	gr ij
One twice daily.			

If the legs become so much swollen that the skin is greatly distended, they may be tapped. Pricks or incisions of the skin are undesirable, for the running from them is difficult to keep under control, and the insertion of fine or capillary tubes is preferable. These are best inserted at the side of the calf. The greatest care must be exercised to avoid septic infection, for once started an infective inflammation round the puncture may soon reach appalling dimensions. Death even may result, in consequence either of extensive sloughing of the skin, or of a clot forming in a vein and becoming detached. Still, with care and strict antiseptic precautions, great relief may be given by draining. The legs should, after puncture, be wrapped up in plenty of aseptic cotton-wool, through which the indiarubber tubing may pass to a vessel beneath the bed.

Renal Extract.—Assuming that the kidney has an internal secretion, renal extract might be useful in the later stages of chronic parenchymatous nephritis. The following case is of interest.

The patient was a man, aged about 35, who had been attacked with acute nephritis some weeks previously. He had passed into the typical stage of chronic parenchymatous nephritis. He was passing a very large amount of albumin in the urine, was extremely anasarcaous, with much ascites and a considerable pleuritic effusion on the right side. Both the abdomen and pleura had to be tapped more than once, but the fluid re-accumulated quickly. The man was sent into the hospital as a hopeless case. All the ordinary treatment was tried without success, the patient steadily went downhill, and the prospect seemed desperate. Renal extract was now given night and morning. In a few days the patient volunteered the statement that "Dr. Reynolds' extract," as he called it, was doing him good, and that he felt ever so much better. The improvement soon became obvious, the effusions and the dropsy disappeared, slowly at first and then rapidly, and in about three weeks had vanished. The albumin in the urine also rapidly decreased, and on leaving the hospital about six weeks later amounted to a mere trace. The man was carefully watched for some months. He went back to work and remained well.

The treatment of **Acute Uræmia** will be discussed later. It will be sufficient

to say here that the prognosis, though worse than in acute nephritis, is not as bad as in granular kidney. In the last affection it is almost invariably fatal. In acute nephritis many, perhaps 50 per cent, recover, and in chronic parenchymatous nephritis perhaps 20 per cent.

II.—GRANULAR KIDNEY.

As we do not yet know the primary or exciting causes of this disease, **Prophylaxis, or Prevention**, is at present beyond our powers.

But some of the **Contributory or Aggravating causes** are known, and these can be removed or treated.

Granular kidney is often associated with lead poisoning, chronic alcoholism, gout, syphilis, mental strain, overwork, and worry. Yet it is not so clear that it is actually produced or caused by any of them. For instance, lead, gout, and granular kidney stand in close clinical association, so that lead and gout are often spoken of as if proved causes of granular kidney. Yet the only fact established is their common association. It is equally possible that patients are specially prone to gout or lead poisoning because the kidneys are already granular. So with the other associated conditions. But as they may be, if not exciting, at any rate contributory or aggravating causes, it is clear that they should be treated, and, if possible, removed. Thus all exposure to lead should be avoided, and if necessary, the occupation changed; everything that tends to gout dealt with; syphilis treated; alcoholic habits corrected; and overwork, mental strain, and worry, as far as possible provided against.

We may now turn to the more special questions of treatment.

The objects to be held in view are:—

1. To relieve the damaged organ in every way possible, and to prevent any aggravation of the disease.
2. To guard against the accidents likely to occur. Chief among these are failure of the heart and rupture of vessels.
3. To relieve symptoms as they arise. These symptoms are extremely variable, and the treatment must correspond; but it is often surprising, when the cause upon which these symptoms depend has been recognized—that is to say, when granular kidney has been correctly diagnosed—how much may be done to give relief.

The course of the disease may be divided into three periods:—

1. *The early stage*, in which, though the diagnosis is clear, the symptoms are few or none.
2. *The intermediate or middle stage*, in which the symptoms vary in kind and degree.
3. *The late stage*, in which the symptoms are pronounced and may be urgent.

1. THE EARLY STAGE.

In the early stage the patient believes himself, and appears, to be in good health, and the disease is revealed by accident—examination for insurance for example, or some other accidental cause which takes the patient to the doctor—albumin is discovered in the urine, and the other signs establish the nature of the case. Then the patient rushes into one of two extremes, either refusing to believe there is anything wrong and that care is necessary, or being greatly alarmed and becoming a renal hypochondriac. The doctor's difficulty is to steer the patient between these two extremes: to alarm him sufficiently to make him careful, without making him unduly nervous.

Patients often resent being condemned as unsound when they believe themselves to be robust. Yet it is to their advantage, if they have a weak organ, to know, so that they may spare it.

Early diagnosis is not difficult, and it is in the early stage that the disease is to be arrested if that be possible, or at any rate retarded, as there is every reason to believe it may be, with care and good management.

Albuminuria is not the disease, but the sign or indication, and it is the difficulty of excluding granular kidney that makes the diagnosis of so-called physiological albuminuria in the young adult so uncertain.

Patients not infrequently come to the physician who have been thoroughly frightened, and, because of the albuminuria and the diagnosis of chronic kidney disease, have been placed upon an extremely strict regimen and made to live an invalid life, with the only result that their health, which was as they thought good, had become impaired, and their life, previously enjoyable, been made a burden. No wonder they regard the discovery of albuminuria as a misfortune. In the early stage of granular kidney such a strict regimen is unnecessary. The removal of the extreme restrictions is followed by improvement in health, and renewed enjoyment of life. The treatment of albuminuria as if it were the disease, and as if its disappearance would cure the disease, is not only theoretically unsound, but mischievous in practice.

At this stage, the patients must live moderate, careful, and temperate lives, be properly clothed, avoid chills and exposure, keep the skin in good action and the bowels regular; must avoid alcohol, especially spirits, eschew dissipation of every kind, and live as much as possible in fresh air and sunlight. Even their recreations need not be seriously restricted, provided they are not such as to lead to risky exposure or fatigue. Bathing in the open, of course, must be absolutely forbidden; also fishing, so far as it involves wading; shooting, except in fine weather; and hard hunting; but riding and all forms of gentle exercise, if chill, exposure, and over-fatigue are avoided, may be allowed and are beneficial. The early stage spreads itself over many years, and the strain of the disease is usually not felt until the age of forty or fifty. Till then, or till other symptoms develop, life, with care and good management, may be active and enjoyable, both in work and play.

During the early stage then the general health should be maintained in every way by appropriate dieting, by avoiding exposure, overwork, and worry, and by fresh air and regulated exercise. All this is compatible with an ordinary life, and though medical supervision and care are requisite, this need not be in special institutions or particular places.

The first great indication is to relieve the damaged organs in every way possible by maintaining the action of the skin and bowels.

Clothing.—The body should be properly clothed. The patient should wear flannel next the skin, winter and summer, day and night; if not flannel and all wool, at any rate merino, or a mixture of wool and cotton, or wool and silk.

The clothing should be varied with the weather. It is a great mistake to be too warmly clad, on account of the perspiration it causes, and the risk of a chill. A flannel band should be worn round the loins, as is the habit in the tropics; and with women low evening dresses should be prohibited.

It is most important to keep the feet and legs warm, as well as the body. This is often neglected, the body being wrapped up warmly while the feet and legs are kept cold; yet the legs form in bulk nearly half the body, and more chills are caught, perhaps, through exposure of the feet and legs than of the body.

The socks worn, in summer and winter, should be of wool or thick merino ; the boots substantial, and lined with cork or felt socks. Cold or chilled feet especially should be avoided, and above all things, if the feet get damp, the boots or shoes and socks should at once be changed. These may seem trivial details, but they are really of great importance, and it is astonishing how largely they are neglected.

Avoid Chills.—Everything must be done to avoid chill. Thus, care must be taken not to check the perspiration abruptly when the body has been heated by exercise, or during hot weather ; and great care should be taken against draughts after sitting in warm rooms, especially in the case of women who are lightly clad in evening dress. More chills are acquired, perhaps, in hot weather than in cold, on account of the free action of the skin and the draughts to which people expose themselves without sufficient protection. Many of these precautions will depend upon the climate or season. Abrupt changes of temperature are specially to be avoided, particularly if the air be damp. It is for this reason, and to search after a more equable and drier climate than we have in this country, that patients with kidney disease are so often advised to spend the winter abroad.

Climate.—The best that could be devised would be the one in which there were fewest changes, whether the air were moist or dry. Madeira, the Azores, and the Canary Islands have an equable climate, which is warm but very moist, and often too relaxing, so that the patients do not feel well in it. The Riviera, which has a less relaxing climate, is not altogether suitable, on account of the violent changes of temperature between the sun and shade, and between the morning and evening. The mountain resorts of California have been advocated. Perhaps the dry climates of Egypt and Algiers are the best of all, but even these require care, on account of the difference between the day and night temperatures. In my experience patients who have spent the winter in these last places have benefited most. It must be remembered that, with kidney disease, changes of temperature are felt of which the strong are not sensible, and it is on this account that care is always necessary, and a good climate desirable.

Skin Toilet.—Everything must be done to keep the skin in good condition. For this purpose, baths of every kind are useful, whether hot-water, Turkish, or vapour, provided that no chill be taken after. A hot bath regularly, two or three times every week on going to bed, is advisable. Turkish baths are excellent if not found too lowering, and not taken too frequently.

The permission to take a sponge-bath on rising in the morning must depend, to some extent, upon the patient. It is best, as a general rule, not to allow the bath to be taken quite cold, but with sufficient warm water added to take the chill off. A cold bath should be followed by a condition of reaction in which the skin glows and the whole body feels warm and comfortable ; but if the opposite occur, and the fingers become chill and dead and need an hour or two to recover, it is evident the bath is unsuitable. Many patients who cannot take a cold bath, find benefit from a hot one ; but, as a rule, if a sponge bath does not suit, it is better to be content with a rapid sponging over with tepid water, followed by a rubbing with a rough towel.

Bathing in the open, or even in swimming baths, is on all accounts to be prohibited. It may produce temporary albuminuria even in those who have nothing the matter with the kidneys, and it is fraught with mischief in every case where the kidneys are not sound.

Muscular Exercise.—There is no better way of promoting healthy action of the skin than by muscular exercise, if this can be borne without fatigue. It should be of such a kind and amount as to produce gentle action of the skin rather than violent perspiration. If there has been much sweating, a warm bath and a good rub down afterwards is an excellent procedure.

Diet.—In a protracted disease such as granular kidney, too strict a diet cannot be insisted on, and in order to maintain the patient in good health, it must be a properly mixed one. Milk, though a very useful diet for children, and for adults when acutely ill, is not a good food for adults for any length of time.

Although it is highly desirable that the amount of nitrogenous food should not be too great, it is possible to err on the other side, and make it too small. It is impossible, also, to prescribe one dietary which will suit everyone; idiosyncrasy must be considered in every case. The forms of albuminous food most especially to be avoided are the various meat extracts which are so popular. These contain a large amount of extractive substances, which are of little use as food, and have necessarily to be excreted largely by the kidney; the administration, therefore, of such things gives the kidney more work to do. The albumin is far best supplied in the ordinary form of well-cooked meat, fowl, and fish, but it should be in moderate amount. Meat once a day is sufficient; of the three ordinary meals—one should be fish, one farinaceous, and only the other meat.

There is no reason why red meat should be forbidden. If digested well, it produces no more irritation to the kidneys than white meat, and does not contain any more extractives. Nor is there any reason why an egg or two should not be taken, either raw or lightly boiled.

Fruit, vegetables, and salads are all good, provided they do not contain too much acid. On this account, tomatoes, gooseberries, and such-like should be avoided.

Even a strictly vegetarian diet has been advocated, but few patients can stand it for more than a short time. Farinaceous foods of every kind are clearly indicated, and milk and cream can be taken in quantities; for such fattening things tend to counteract the loss of flesh which is one of the tendencies of the disease as it progresses.

As the patients pass an excessive quantity of urine, they are often more or less thirsty, and may be allowed to drink pretty freely of water; but as a rule excess of fluid is to be avoided. Three pints in the day is ample. A good and popular remedy is a glass of hot water from time to time during the day, to which may be added a little lemon juice, citric acid, or tartaric acid. Stimulants, as far as possible, should be avoided, and above all, the rich and sweet wines of every kind. Dry sherry, Marsala, or light and sound claret are all admissible, but port, champagne, and the heavier Burgundies should be avoided. On the whole, perhaps, a little well-diluted whisky, taken with the meals is the most suitable beverage, but if the patient can do entirely without stimulants it is best of all.

The Digestive System.—The digestion should be carefully watched, especially if the patients are on a modified diet. The digestion, stomach and intestinal, is easily disturbed, and when imperfect leads to the production of substances many of which are toxic and very irritating to the kidneys. It is important that the bowels should be kept in regular action every day, and perhaps have a tendency to be somewhat loose. This is best provided for, if necessary, by the use of one of the aperient waters, or of Epsom or Carlsbad salts, taken in the early morning. If stronger aperients are required, the favourite remedies are the compound jalap powder, 20 or 30 gr. in cachet or confection, or pills containing jalap, or a little elaterium.

Every morning or every other morning.

A course of purgatives or purgative waters is distinctly to be avoided, for it lowers the tone and reduces the general health too much.

To sum up : The general health should be maintained in every possible way by appropriate dieting, by avoiding exposure, overwork, or worry, and by fresh air and exercise. All this requires medical supervision and care, but not necessarily in special institutions or places ; for if patients would only carry out the instructions given, they could often derive as much benefit by treatment at home as at the fashionable baths of this country or abroad, except, of course, so far as climate is concerned. It is because they submit to rules abroad which they will not listen to at home, that it is so desirable, in many cases, to send these patients now and then to foreign places for a course of treatment.

2. THE MIDDLE STAGE.

At this period, when the heart is markedly hypertrophied, and the arteries are much thickened, the treatment has to be directed, in addition, to guarding against the accidents that are now especially liable to occur. These are chiefly failure of the heart, rupture of vessels, and inflammatory affections of the kidney itself.

A hypertrophied heart has diminished reserves, and therefore is rightly regarded as in a pathological condition : it lacks the margin of power which the healthy heart possesses. Its reserves have been swallowed up in growth, and thus a hypertrophied heart will give way under a strain that would not affect a healthy heart at all. It is therefore especially necessary in this stage to avoid physical or mental strain and fatigue, and to watch the heart very carefully during any intercurrent illness, especially during convalescence.

The **Cardiac Treatment** is of the usual kind, but it is necessary to be careful with *digitalis*, because of its effect upon vascular tension ; for if the tension be already high, *digitalis* will increase it and throw extra work upon the heart ; while if the tension be low, it will raise it, and in this way assist the circulation. It may therefore do harm as well as good. *Citrated caffeine* is a better drug ; it is a mild diuretic as well as a cardiac stimulant.

When the heart once becomes weak, failure is often very rapid, and if the heart be much hypertrophied, how much margin of reserve is left cannot be easily estimated.

The **Changes in the Vessels** are degenerative in type ; the walls become brittle, and are likely to rupture. A man is often said to be as old as his vessels. Certainly the amount of arterial thickening is a good guide to the prospect of life.

Many cases of granular kidney at the age of forty have arteries as thick as those usual at the age of seventy. Consequently, the risk of hæmorrhage is as great as at the latter age, and the same precautions must be adopted in each case. All physical straining, as well as mental fatigue and excitement, must be avoided ; but with care and common sense, hæmorrhage may be staved off for a long time.

Hæmorrhage.—Hæmorrhage into the brain is dangerous because of its seat rather than of its amount ; but hæmorrhage from a surface is risky, because of

the loss of blood and of the exhaustion that will follow. Thus, copious *epistaxis* may be the beginning of the end; the patient may never recover from its effects, but die soon after of cardiac or general failure.

The ease with which the vessels may give way is often seen in the *conjunctivæ*, where chemosis may occur spontaneously, or from simple straining as in coughing or defecation, and also in the *retina*, where the hæmorrhages may be numerous, and sometimes of considerable size, though they may produce little or no defect of vision.

Hæmaturia is not uncommon, and is often misinterpreted. Many cases of granular kidney have been operated on in the belief that there was a calculus or growth in the bladder, yet the only lesion found post mortem—for most of these cases die if operated on—was granular kidney.

In the *hæmophilic condition* which develops in the latest stages, the hæmorrhage, which is rather a general oozing from the mucous surfaces than free bleeding, often yields to opium and digitalis, and especially to ergot and adrenalin. All these complications must be treated on general lines, and little can be done in the way of precaution against them except by guarding, as far as possible, against worry and mental excitement, violent physical effort, and straining.

The Vascular Tension may supply indications for treatment. The tension is normally raised in a granular kidney. It is best that a patient should not have granular kidney; but, having granular kidney, it is better that the tension should be somewhat raised. It is a mistake to attempt to reduce it if only moderate, for granular-kidney patients are not so well when the tension is low. Yet the vascular tension may be too high as well as too low, and should then be treated.

The tension can be easily raised by a richer and more stimulating diet, by stimulants, and by drugs, especially by *digitalis* and *epinephrin*. Where the heart is feeble and the tension low too, the following combination is useful:—

R Tincturæ Digitalis	℥v	Spiritus Armoraciæ Co. (B.P.)	℥j
Tincturæ Strophanthi	℥ij	Aquam Destillatam	ad ℥j
Caffeinæ Hydrobromidi	gr ij		

Three times a day.

Epinephrin may safely be given in much larger doses than are usually prescribed, up to 1 or 2 dr. by the mouth, and half these doses sub cutem.*

It is not so easy to *reduce a high tension* without affecting the general health as well. *Nitroglycerin* may be given regularly, and in full doses; *nitrite of amyl* is useful for an emergency, but its action is evanescent. *Nitrite of sodium*, or a mixture of nitrate and nitrite, has more prolonged action.

R Sodii Nitritis	gr ij	Aquæ Destillatæ	q.s. ad ℥ss
Sodii Nitratis	gr x		

Three times a day.

R Potassii Nitritis	gr ss	Potassii Bicarbonatis	gr xxv
Potassii Nitratis	gr xvij		

To be dissolved in a tumbler of water and taken every morning.

A less immediate but more prolonged effect can be obtained by erythrol nitrate $\frac{1}{2}$ to 1 gr., or mannitol nitrate 1 gr., in chocolate tablets twice daily. The doses of either may be gradually increased.

Iodide of potassium is more suitable for prolonged administration, and may be given in full doses, from 10 to even 20 gr. three times a day; but this is often attended with much depression. *Veratrum viride* has also been employed in doses of 10 to 15 min. of the tincture three or four times a day. It powerfully

* According to some authorities epinephrin raises the blood-pressure only when given intramuscularly or intravenously. By these routes, such doses are excessive.—AMERICAN EDITOR.

affects the tension, but at the same time acts as a cardiac depressant. It requires watching and care.

The reduction of tension is most simply attained by diminishing the amount of stimulants, placing the patient upon a bland or somewhat reduced diet, regulating the bowels, and keeping up the action of the skin. For a case of this kind a *course of baths and laxative waters*, under proper supervision, is frequently very beneficial.

In intercurrent diseases, especially if acute, it is most important to watch the weak spots, especially the heart and the vascular tension. Thus, should a patient with granular kidney be attacked with pneumonia, it would be necessary from the beginning to use stimulants freely, such as alcohol and strychnia, as well as stimulating cardiac drugs like digitalis and especially caffeine. The association of granular kidney with pneumonia is a very serious matter, but if the treatment be directed to the weak spots it is often successful.

Surgical Operations.—In cases where surgical operations have to be performed upon patients with granular kidney, a good deal of caution is necessary. The patients require to be carefully prepared, and got into as good a condition of health as possible before operation; but if this be done, an anæsthetic may be safely given, and the operation satisfactorily performed. A great deal depends in these cases upon choosing the proper time, but now that operations are attended with so much less risk than formerly, the importance of properly preparing the patient is often forgotten, and thus risks are incurred which might be avoided. On the other hand, with proper care and preparation, operations may now be safely performed in chronic renal cases to which, not long ago, the renal disease would have been considered a fatal objection.

The operation of **Decapsulation**, or splitting the capsule of the kidney, is quite out of place in granular kidney, whatever may be said in its favour in acute nephritis.

3. THE LATE STAGE.

CHRONIC URÆMIA—CHRONIC RENAL TOXÆMIA.

In the third or latest stage, the symptoms are pronounced, and are often described as **Chronic Uræmia** or **Chronic Renal Toxæmia**. They are very variable, and may point to almost any part of the body except the kidney as the primary seat of mischief. Symptomatic treatment is often unsatisfactory and unsuccessful, until the cause, i.e., the renal condition, is recognized and treated.

Yet, when the correct diagnosis is made, and the relation of the symptoms to granular kidney recognized, the adoption of appropriate renal treatment in addition to the general measures indicated, is likely to be, and as a matter of fact is in many cases, followed by very beneficial results.

In the later stages of granular kidney the **Arterial Tension** gives many useful indications for treatment. A patient with granular kidney ought to have an arterial tension which is above normal. From this pathological normal the tension may vary by way of excess or defect. The treatment of these extremes has been discussed above.

If it is desirable to **increase the quantity of urine**, *caffeine*, or *theobromine* and its combinations, such as *theobromine sodium salicylate*, are useful, as having a stimulating effect upon the heart as well as on the kidneys.

℥ x
q.s. ad 3 ss

Three times a day.

Of all drugs for chronic renal disease, I think *pilocarpine* the most useful. I cannot understand the prejudice that seems to exist against it in some quarters. I have used it very largely, and have never seen any disadvantage follow its administration; on the contrary, nothing but good. Apart from its general action, many of the symptoms are distinctly controlled by it. Thus headache, and the exhausting restlessness so common in the later stages of the disease, may be relieved by pilocarpine more immediately and persistently than by any other means, and even threatened uræmia staved off. I consider it the most useful renal remedy of all. I generally give it by the mouth two or three times a day in a dose of $\frac{1}{8}$ gr. of the nitrate; sub cutem $\frac{1}{12}$ gr. is enough to begin with. This produces nothing more than a gentle action of the skin. The profuse sweating or discharges from other parts of the body, often described, are not produced by such doses, even when repeated two or three times a day, nor have I seen anything like collapse or fainting follow them. Such results may follow the administration of infusion of jaborandi, but they are due to the varying strength of the infusions and to the action of other substances in the infusion besides the pilocarpine.

Restlessness, Sleeplessness, or even Delirium, often call for treatment in the later stage of the disease. *Chloral* and *bromide of potassium* are advocated by many writers, but I am not very fond of these remedies, because of their depressing after-effects if persisted with. Chloral, in these cases, often produces rashes, which, however, are of no special import.

All hypnotics which are but slowly eliminated, such as *sulphonal*, *trional*, and *veronal*, are best avoided.

Opium and its preparations may be employed without the risks formerly supposed to attend their use. Indeed, if this drug seems indicated, morphia by the mouth, or sub cutem, may be given without fear, and often with striking benefit, especially at night-time. It is probably safer in granular kidney than in acute nephritis, but it can be given without much risk in either.

As a hypnotic and general sedative in granular kidney, I attach the highest value to *cannabis indica*. This is best given in the form of the tincture, in doses of 15 min. or more at the time of sleep.

R Tincturæ Cannabis Indicæ	℥x-xv	Aquæ Pimentæ	q.s. ad 3j
Spiritus Chloroformi	℥x		

At bedtime.

Chronic Toxæmia.—The *asthenia*, *anæmia*, and *general failure of nutrition*, as well as the many other symptoms which develop in the later stages, are often referred to chronic toxæmia, i.e., to a condition due to the toxic effects of some substance of which the kidneys ought to get rid but cannot. But they bear so close a clinical resemblance to the conditions which arise from the failure of some internal secretion as to suggest that the kidney also has an internal secretion. Moreover, these symptoms stand in direct relation to the amount of destruction in the kidney. They do not develop until the degeneration of the kidney is far advanced, and they bear a resemblance to the condition which has been produced experimentally by the gradual removal of portions of the kidney in animals.

So far, we have no actual proof that the kidney has an internal secretion, however much inclined we may be by other considerations to believe that such is the case. But the connection between the thyroid gland and myxœdema was not conclusively established until it was shown that the administration of the gland substance cured the disease. The relation between disease of the suprarenal gland and Addison's disease is clinically established, though so far the administration of the gland or its derivative adrenalin has not cured the condition.

There is the same sort of relation established between the symptoms of granular kidney and the wasting of the kidney. The problem is to determine by clinical observation whether the administration of *renal extract* can be shown to be beneficial in renal disease.

There is a difficulty unfortunately in preparing a reliable renal extract. I have tried various methods, and for a time used a glycerin extract, but I have not succeeded in finding any preparation which is stable and can be preserved. I have consequently fallen back on an extract of kidney freshly prepared as required, using by preference the kidney of the pig as being a mixed feeder, rather than the kidney of a vegetable feeder like the sheep.

The great difficulty in obtaining evidence in favour of the usefulness of kidney extract in chronic renal disease lies in the fact that its use must be continued for some time before definite results can be expected; generally patience is exhausted before the time required, and the treatment given up because the signs of improvement are not immediate. I have already referred to the use of renal extract in chronic parenchymatous nephritis (v. p. 677). In granular kidney the cases usually come under observation late in the disease, when the mischief is so far advanced that much benefit can hardly be looked for. Yet even then I have seen some of the most troublesome symptoms, especially headaches, relieved by this means when they had resisted other treatment.

In earlier cases, this treatment has better prospects of success, and my own experience is distinctly encouraging, and such as to justify further trial.

Samuel West.

NERVES, PERIPHERAL, SURGICAL DISEASES AND INJURIES OF.

GENERAL TREATMENT OF NERVE INJURIES.

This consists in keeping up the nutrition of the parts supplied by the affected nerve and maintaining the paralyzed muscles relaxed until conductivity is restored, by nature alone or aided by the surgeon.

Treatment of Nerve Injuries in Wounds.—Primary suture should be carried out whenever possible. Careful examination is essential, especially in wounds in the neighbourhood of the wrist, for here the fact of nerve injury is often overlooked. Exploration of the wound should never be relied on to reveal a nerve injury; this should be established by examination before operation.

Rigid asepsis is necessary for complete recovery; in no branch of surgery does suppuration, even in a slight degree, so militate against success. The full recovery of the nerve is hindered, but not necessarily abolished, by suppuration; it is delayed and incomplete.

After free exposure of the damaged structures, the nerve is identified, the original incision being enlarged if necessary. If the nerve be found completely divided, no preliminary treatment of the ends is necessary unless they are lacerated. If this be the case they must be trimmed *with a sharp scalpel*; scissors should never be used for the purpose. The suture should be passed with a round needle through the substance of the nerve, and tied with sufficient tightness to bring the ends in apposition without causing strangulation of the tissue. One suture is, as a rule, sufficient. Care should be taken to avoid longitudinal rotation of the ends of the nerve. It should be our aim to bring the axis cylinders in the peripheral end of the nerve in contact with their own central ends, in order to ensure complete recovery of localization. If it is found that the nerve has been incompletely divided—and it is usually impossible to ascertain this immediately after the accident, apart from exploration—the gap should be carefully trimmed, if necessary, and closed by a suture inserted with a curved needle. Catgut should be used as suture material in all nerve cases;

if any strain is likely to be thrown on the stitch, catgut hardened so as to resist absorption is advisable.

It occasionally happens that the nerve is divided at two or more levels, a portion of it being loose ; this should be sutured in. At other times it is found that a portion of the nerve is destroyed, so that a gap is left that cannot be bridged over ; for the treatment of this complication the reader is referred to the section below on secondary suture. After suture the junction and the freed portion of nerve above and below should be wrapped in Cargile-membrane.

In all accidentally inflicted wounds of this nature it is advisable to insert a drainage tube ; this can usually be removed in twenty-four hours. The limb, with the joint or joints over which the nerve passes, must be put up in such a position as will avoid tension on the suture and overstretching of the paralyzed muscles ; this position, which is usually flexion, should be maintained by a splint until the wound has soundly healed.

Secondary Suture.—This procedure should become more and more rare. It may be unavoidable in cases of subcutaneous injuries, but where a nerve has been divided in an open wound, treatment should be adopted at the time.

It is necessary first to consider how long after the division of a nerve secondary suture can be carried out with any hope of success. Up to three years from the time of injury, the interval which has elapsed is of no moment. Cases of suture at more remote periods have been recorded, but in no case are the reports satisfactory. This applies especially to the motor side, for it is uncommon to find a patient seeking operation for sensory recovery only. But it may occasionally happen, for example after division of the sciatic, that the patient develops perforating ulcers ; it is then worth operating in order to prevent their further formation, even although no muscular recovery is expected.

Before operation, careful examination should be made to ascertain the electrical excitability of the affected muscles ; the prognosis will to a certain extent depend on the result of this. The condition of the opponent muscles and of the ligaments of the joints of the affected part must be ascertained. To take a common example : after division of the ulnar nerve, if the fingers are in the ulnar position, with contraction of the flexor and extensor muscles and palmar ligaments, it is extremely unlikely that the hand will ever regain its normal condition, although the function of the affected muscles may be restored. I have pointed out that the prognosis depends to a great extent upon the manner in which the original wound healed. Suppuration in the wound makes the chance of recovery doubtful. A complete examination is therefore necessary before expressing any opinion as to what can be expected from the operation.

The operation may be divided into stages : (1) Identification of the ends of the nerve ; (2) Freeing them ; (3) Uniting them. The incision should be made over the line of the nerve, and must be of sufficient length. The nerve should be found above and below the seat of injury, and traced into the mass of fibrous tissue with which the ends are usually incorporated. After freeing, the greater part of the bulb on the central end should be removed, in order to obtain normally coursing nerve fibres. From the distal end only the fibrous upper extremity need be removed ; the whole of the lower end of the nerve will be found in the same condition, so that it is useless cutting section after section in the hope of reaching a portion which looks less like fibrous tissue and more like nerve.

The ends of the nerve should never be trimmed with scissors, always with a sharp knife. Catgut should be used if possible for suture material ; if there is any tension, catgut which has been treated to resist absorption. If it has been necessary to free the nerve from surrounding fibrous tissue, care must be taken that it does not again become adherent ; for this purpose chromicized

Cargile-membrane, or a portion of one of the patient's own subcutaneous veins, should be wrapped around the point of suture and as much of the nerve above and below as has been freed. After closure of the wound, the limb must be put up as after primary suture. This position must be relaxed gradually after the wound has healed.

It is often the case that the ends do not come so readily into apposition as after primary suture. Preliminary stretching will gain an inch in the arm or leg quite readily; this, combined with relaxation of the joint or joints over which the nerve passes, will rarely fail to enable the ends to come into apposition.

If the ends of the nerve do not come into apposition, we have a choice of methods that have been used from time to time, more or less successfully, to bridge over the gap left; I shall mention only those of proved value. These are, the transplantation of nerve from another source; union of the nerve by catgut threads combined with tubular suture, that is, surrounding the ends of the nerve and the catgut with a tube composed of some material which will resist absorption for a length of time sufficient to prevent the ingrowth of fibrous tissue between the ends of the nerve; the union of the nerve to a neighbouring sound nerve; and finally, shortening the limb by removal of bone.

The nomenclature at present in general use requires simplification. The same terms have been used by different surgeons to denote dissimilar operations, with results which are bewildering, not only to the practitioner and student, but also to those engaged in research. I have suggested, and use, the following:—*Nerve transplantation*; *Nerve anastomosis*; *Nerve crossing*. I consider that the term "nerve-grafting" should be discarded: it has always meant to the English-speaking surgeon the insertion of a portion of nerve between the ends of a divided nerve; but with the recent extension of the field of operations on the peripheral nerves, it has been employed to denote also the anastomosis of one nerve to another, a meaning it conveys to Continental surgeons.

If the ends of the nerve cannot be brought together, transplantation is the operation of choice. The portion of nerve employed must be obtained from the patient or from an amputated limb. The results, both clinical and experimental, when a portion of an animal's nerve is used, are unsatisfactory. The nerve most often requiring this operation is the musculospiral. Here the operation is simple: The incision is prolonged downwards, the radial nerve exposed, and an adequate portion resected and sutured into the gap without tension. This nerve may be used in a similar way in injuries of other nerves. Removal of the upper two-thirds of the radial nerve produces no demonstrable effect upon sensation. The internal saphenous nerve may be used to fill in gaps elsewhere.

But this method may be inapplicable for anatomical reasons—for example, after division of the facial nerve in the middle ear; or from the size of the nerve—for example, the great sciatic; or on account of the distance between the ends of the nerve—if this exceeds four inches, it seems probable that no operation of this nature will succeed. Nerve anastomosis offers the best chance of success. In cases in which the gap between the ends is less than four inches, and yet, because of the size of the nerve or other reason, nerve transplantation is impossible, and no sound nerve is available for anastomosis, tubular suture should be performed.

Nerve anastomosis is divided into central and peripheral, either of which may be partial or complete (*Figs. 55–58*, in which the shaded lines show the affected nerves). In complete anastomosis the whole of the nerve to be implanted is divided; in peripheral anastomosis the distal end of the affected nerve is anastomosed to the sound nerve; in central, the sound nerve is divided and its proximal end anastomosed to the affected. In the case of small nerves, a vertical slit in the sound nerve divides enough of its nerve fibres; but when

the nerve is of large or medium size, a transverse cut should be made into it or a flap raised. Our aim in all these operations is to bring the axis cylinders of the affected nerve into end-to-end contact with some of those in the sound.

The complete peripheral operation is the one which is most often applicable to the cases we are now considering.

COMPLICATIONS ARISING DURING RECOVERY AFTER COMPLETE DIVISION.—Complications may arise during the progress of recovery. Pain as a rule is present in the distribution of the nerve during the first two or three days after

Fig. 55.—Complete Peripheral Anastomosis, showing the three methods of union.—A. Insertion of peripheral end of affected into vertical slit in sound nerve. B. Insertion of peripheral end of affected nerve into a gap in the sound nerve, produced by an oblique incision. C. End-to-end union with flap raised from sound nerve.

Fig. 56.—Partial Peripheral Anastomosis. Can also be carried out by methods B and C, Fig. 55.

Fig. 57.—Complete Central Anastomosis. Can also be carried out by methods B and C, Fig. 55.

Fig. 58.—Partial Central Anastomosis. Can also be carried out by methods B and C Fig. 55.

suture. This is due to irritation of the central end, and is rarely of sufficient severity to need treatment. If severe, it points to an infective neuritis; the wound should be inspected, and, if showing signs of infection, opened up and drained. If this has been necessary, the condition of the nerve should be explored as soon as the wound has healed (see also below, under *Hyperalgesia*). In other cases in which suppuration takes place, gradual deterioration of function due to involvement of the junction in fibrous tissue may occur after a period of improvement. This may arise also from inflammation around a silk

suture used to unite the ends of the nerve. It is for this reason that the use of silk is unwise, particularly in accidental wounds. In both cases the nerve should be exposed and dealt with.

Ulcers may arise at two periods: during the stage of complete insensibility to cutaneous stimuli slight injuries pass unnoticed; the patient burns himself not infrequently, or, if engaged in manual labour, may injure the affected limb, causing ulceration. These ulcers heal readily when the part is kept at rest and the usual means are adopted to render the ulcers healthy. To this group belong the so-called perforating ulcers which arise after division of the sciatic nerve. With the first sign of returning sensibility to prick, the patient not infrequently experiences pain shooting into the affected part; at this time blisters are liable to form spontaneously, the patient not uncommonly noticing them on rising in the morning. If not carefully treated these burst, leaving a raw surface, which readily becomes infected: the blisters must be protected from injury; under these conditions they dry, leaving a scab. After complete restoration of sensibility to prick, all tendency to ulceration ceases.

Tenotomy or tendon lengthening may be necessary in cases in which the limb has been allowed to get into a bad position.

TREATMENT OF CASES OF SUBCUTANEOUS INJURY.—As the result of a subcutaneous injury, all the signs of complete division may ensue; there is no sign which can tell us whether the nerve is anatomically or physiologically divided, that is, whether the nerve is ruptured or in anatomical continuity. These cases are not uncommon; they may result from pressure suddenly applied or long continued, or from traction.

It may be impossible to diagnose between complete and incomplete division until ten or fourteen days after the injury. If at this period the signs of complete division are present, no time should be lost; the condition of the nerve should be explored, and the appropriate treatment adopted. If physiological division is found, in most cases it will be necessary to resect the damaged portion and perform end-to-end suture. If this is not done, recovery will be incomplete. If on exploration the nerve seems little altered, although the reaction of degeneration is present, it is wise to leave it, wrapping it in Cargile-membrane to prevent adhesions to surrounding structures.

If the muscles still react to faradism at the end of a fortnight, recovery will ensue in the course of a few weeks if careful treatment is adopted. When the reactions which I have described as being typical of incomplete division are present, no operation should be done in a recent case, and the nutrition should be kept up, as I shall describe when speaking of after-treatment. If the nerve has become secondarily involved, or if improvement does not take place with careful treatment, operation should be performed and the nerve released from pressure of fibrous tissue, bone, or whatever the agent may be. Whenever this operation (neurolysis) is performed, the nerve should be wrapped in tissue to prevent it from again becoming adherent; failure to do this has necessitated repeating the operation.

Treatment of Nerve Injury complicating Fractures and Dislocations.—Nerves may be injured as the result of fractures; this is particularly liable to occur to the musculospiral in fractures of the middle and lower thirds of the humerus; next in frequency the external popliteal in fractures of the head of the fibula; and rarely the median in fracture of the lower end of the radius. The nerve may suffer at the time of the accident, or later from involvement in callus or the pressure of displaced bone; the latter may occur years after the fracture. Primary injury is probably more common than is suspected. If at the time of the first examination of a recent fracture, particularly of the humerus, symptoms of nerve injury be present, operation should be performed if there are no general

causes contra-indicating it. The condition found should be dealt with according to the rules I have laid down, and precautions taken to avoid the involvement of the nerve in fibrous tissue. If the fact of nerve injury be discovered, as it usually is, when the splints are removed, and examination reveal complete division, operation should be performed. If on the other hand the symptoms point to incomplete division, the appropriate non-operative treatment must be carried out; if no improvement take place after several weeks, the nerve must be exposed and the lesion dealt with. But if the signs of nerve injury develop later, when the patient begins to use the limb, operation must not be delayed.

In some instances, as will be mentioned when speaking of the ulnar nerve, interference with the function of the nerve takes place many years after the original injury. If the symptoms are slight, rest will undoubtedly relieve them for a time, but they are likely to recur. Operation is the most satisfactory treatment, removing the compressing agent.

It occasionally happens that nerves are injured as the result of dislocations, either by direct violence or from faulty treatment. This occurs most often in dislocations of the shoulder. The whole plexus may suffer injury, but most often the inner cord. (See also under BRACHIAL PLEXUS, *infra*). In subglenoid dislocations the circumflex nerve sometimes suffers; in the reduction of dislocations of the hip, congenital or acquired, the great sciatic or anterior crural nerves may suffer; in forward dislocations of the head of the radius, the posterior interosseous nerve. These cases are to be treated on the lines laid down in speaking of subcutaneous injuries in general.

COMPLICATIONS ARISING DURING RECOVERY AFTER INCOMPLETE DIVISION.—Although in a large proportion of the cases, recovery steadily advances and at length becomes perfect, occasionally, after a period of improvement, gradual deterioration of function takes place, the result of fibrous changes in the nerve. The nerve should be exposed and the condition dealt with, resection of the damaged portion being required in most cases.

Hyperalgesia.—Pain is more often associated with incomplete than with complete division. It may arise in cases of anatomical or physiological division, more often in the former, and is referred to the "full" distribution of the affected nerve. In many cases it is accompanied by tenderness of the skin, the pain and tenderness involving a larger area than that which becomes insensitive after complete division of the nerve; in a few cases it is accompanied by glossy skin. All are characterized by the latent period which exists between the injury and the onset of pain and tenderness. The sensory loss varies in extent and degree with the injury and the nerve involved, but is never complete.

In all cases the treatment is the same: the nerve is exposed, the damaged portion resected, and end-to-end suture performed. Neurotomy alone is futile; the pain returns on regeneration of the nerve; neurectomy alone leaves an area in which the sensibility may be permanently affected.

Irritation of one of the terminal branches of a nerve may cause pain and tenderness in the whole of the area supplied by the parent nerve, with twitching in the muscles in the case of a nerve containing motor fibres. These symptoms are most familiar in connection with the fifth nerve, but most often require treatment elsewhere. Terminal involvement of digital nerves is by no means uncommon after amputations for injury, and acquires great importance in connection with compensation. The pain is in the stump at first, but later involves the whole area supplied by the affected nerve, which area may be tender when the point of a pin is lightly drawn from sound to affected parts. The pain, if neglected, may spread as the result of an ascending neuritis. The skin of the stump is of a bluish-red colour, and this may later appear over the whole tender

area. On gentle examination of the end of the stump one or two tender spots are met with, pressure upon which causes acute pain. In late cases, paresis of the muscles supplied by the nerve affected may appear.

Treatment consists in excising the scar, together with the involved nerve twig. This should not be delayed, but carried out as soon as the diagnosis has been made. The limb should then be kept at rest on a splint, and massage employed until recovery is complete. In long-standing cases this may fail to relieve the pain. Intradural resection of the posterior roots from which the affected nerve springs offers the only hope of relief in these cases.

AFTER-TREATMENT.—The patient, and occasionally the surgeon, are prone to consider that when the anatomical continuity of a nerve has been restored by operation, nothing more remains to be done; but the final result depends on the thoroughness with which, for several years it may be, the after-treatment is carried out. That nerves regenerate when their ends are in contact is known, but it too often happens that by the time motor recovery has taken place, the muscles have been allowed to waste, and contractures have taken place in muscles and ligaments.

The parts supplied by the nerve must be kept in a state of good nutrition, and care taken to prevent over-stretching of the paralyzed muscles with contracture in their opponents. The affected muscles must be kept relaxed by suitable splints. Massage is invaluable in keeping up the nutrition of the skin and the muscles, and in cases of musculospiral or external popliteal injuries perhaps it is enough; but in ulnar injuries it should certainly be supplemented by daily stimulation with both the constant and interrupted currents. This should be done always under medical supervision. Complications must be treated as they arise, and with patience most cases of nerve injury will give a good result. Incomplete injuries not needing operation are treated in this manner. (See ELECTROTHERAPEUTICS.)

PROGNOSIS.—There are a few general points which must be referred to in regard to prognosis. In order that complete recovery shall ensue, healing must be by first intention, and care be taken that the nutrition of the muscles be kept up and contractures prevented. If these rules are followed, perfect recovery will take place in the majority of the cases of primary suture. In cases of secondary suture, the prognosis depends on the condition of the muscles at the time the patient comes under observation and the manner in which the original wound healed. With regard to time, up to three years from the injury it makes little difference to the regeneration of the nerve, but it may make all the difference in the amount of contracture which has taken place. It is unlikely that *perfect* recovery will ensue after secondary suture; if a patient is unfortunate enough to require secondary suture of the ulnar nerve, it is improbable that the hand will be restored to its normal condition. But after secondary suture of the musculospiral or external popliteal, imperfect sensory recovery is immaterial, and the contractures are slight and easily dealt with; so that the functions of the part, from the point of view of the patient, are completely regained.

SPECIAL METHODS OF TREATMENT.

Nerve Stretching.—This operation, at one time widely performed, has now fallen to a certain extent into disrepute in this country. On the Continent it has been lately brought into prominence in connection with the treatment of chronic ulcers of the leg, particularly by Chipault.

Nerve stretching temporarily abolishes conduction through the nerve, but this effect is as a rule too transient to be of much benefit in treatment. At first employed in many cases of spasmodic tic and neuralgia, it is now rarely used for

these purposes. In certain patients with sciatica it is of benefit, but in these it acts by freeing the nerve from adhesions in cases of perineuritis.

It has a temporary effect upon the nutrition of the parts supplied by it. This side of its action was first brought into prominence by Bastian as long ago as 1861, in connection with cases of infantile paralysis. Good results have been reported by many surgeons from its employment in cases of chronic ulcers of the leg. The usual treatment of the ulcer by rest to the part, etc., is supplemented by stretching the nerve or nerves supplying the area in which the ulcer is situated.

Neurotomy and Neurectomy.—The operations of dividing a nerve (neurotomy) and of removing a portion of it (neurectomy) have been chiefly employed in connection with the treatment of various painful and spasmodic affections.

Neurotomy has been superseded in the treatment of neuralgia by neurectomy, and the latter in many cases by division of posterior roots or removal of the posterior root ganglion. In certain cases, e.g. pain following a nerve injury, neurectomy is employed, the damaged portion being removed and the continuity of the nerve re-established by suture.

In performing neurectomy for neuralgia, as much as possible of the nerve should be removed, to prevent the possibility of reunion; in some cases the nerve may be pulled out (avulsion or neurexairesis). The same operation may be employed in cases of spasmodic affections, but, where possible, nerve anastomosis should be carried out.

Division of Posterior Roots.—Intradural resection of posterior roots is occasionally indicated for the relief of pain in long-standing cases of traumatic neuritis, due to wounds of nerves and to involvement of nerves following amputations; rarely for the relief of pain in malignant growths. Recently it has come into prominence in connection with the treatment of spastic paraplegia (Förster) and of the gastric crises of tabes. In both conditions considerable relief has been afforded. The case must be carefully studied and care taken to divide one root above and below those supplying the affected area. The laminæ over the region to be operated on are removed, the dura is opened, and the roots are divided with sharp scissors close to the cord and at their exit from the dura. In many cases it can be carried out by removing the halves of the laminæ on the affected side (unilateral laminectomy, Taylor).

Nerve Anastomosis.—The varieties and indications for the employment of this operation in injuries of nerves have already been described. But the operation is of value also in the treatment of paralyses due to central causes, particularly infantile paralysis, and also in the treatment of various spasmodic affections.

The suitable cases of infantile paralysis are those in which a group of muscles supplied by one nerve is affected, such as the peroneal group, or the Erb-Duchenne; or single muscles, as the tibialis anticus, soleus and gastrocnemius, or quadriceps extensor cruris. The operation must not be performed until treatment by massage and galvanism has been faithfully tried, the affected muscles being kept relaxed for at least two months; and in no case until six months have elapsed since the onset of the disease. But no time seems too advanced to try this operation with good hope of a successful result, provided muscle substance is left and the limb can be brought into a normal position.

Considerable success has followed this treatment in many cases, particularly in those in which the external popliteal group of muscles has been affected. So far no great success has been obtained in the upper limb.

The form of anastomosis suitable to the majority of the cases is the complete peripheral (*Fig. 55*). Our aim in this operation is to bring as many as possible of the axis cylinders of the nerve supplying the affected muscles into end-to-end

contact with cut axis cylinders in the sound nerve, at the same time preserving the muscles supplied by the latter nerve. In the case of small nerves, such as those supplying the tibialis anticus or muscles of the calf, a vertical slit in the sound nerve divides sufficient axis cylinders (*Fig. 55, A*). For example, in a case of paralysis of the tibialis anticus, the anterior tibial nerve is exposed, the branches given to the muscle identified and divided close to the nerve, and inserted into a vertical slit in the musculo-cutaneous nerve.

In the case of larger nerves, for instance the external popliteal, a flap consisting of about one-third should be raised from the sound nerve, and the peripheral end of the divided nerve supplying the affected muscles either sutured into the gap or united end to end with the flap—the latter is probably the best (*Fig. 55, B and C*). In paralysis of the quadriceps extensor cruris, complete central anastomosis may be performed, the superficial division of the obturator being divided and inserted into the deep portion of the anterior crural nerve.

Similar operations may be carried out in paralysis due to other central lesions, and in spasmodic affections.

The after-treatment must be carried out patiently, the nutrition of the affected muscles being kept up by means of massage and the constant current. When the first sign of voluntary power returns, the patient must be instructed to exercise the muscles systematically; in this way co-ordinate movements will be gradually restored.

The time at which the first sign of voluntary power is discovered depends upon the distance of the point of anastomosis from the nerve-endings in the muscles. Where this is short, as in the tibialis anticus or calf muscles, improvement should be noticed in three or four months; but in the case of the external popliteal or roots of the brachial plexus, twelve or eighteen months may elapse.

INJURIES OF SPECIAL NERVES.

Ulnar Nerve.—There are two affections of the ulnar nerve that need special mention: interference with the functions of the nerve coming on late, it may be twenty or thirty years after an injury, usually fracture in the region of the elbow-joint; and dislocation of the nerve from its groove behind the internal condyle.

Chronic Neuritis of the Ulnar Nerve in Connection with Old Injury in the Region of the Elbow.—This is a condition not infrequently overlooked. The injury may have been in childhood, and entirely forgotten. Sometimes after extra exertion, at other times—and more often—without any known cause, the patient complains of a feeling of pins and needles in the ulnar area, and of weakness of the hand. This should always lead the surgeon to suspect pressure on the nerve or on one of the anterior primary divisions of which it is composed. The course of the nerve should be traced upwards and the elbow joint examined; in the cases we are now considering, considerable deformity will usually be found in the situation of the internal condyle, often with partial or complete obliteration of the groove in which the nerve lies. The nerve can often be felt thickened in a spindle-shaped manner. As in all pressure injuries, the motor and the sensory fibres are equally affected.

If signs of complete division are present, operation must be performed without loss of time. The nerve should be exposed, and the damaged portion resected; before uniting the ends, the humerus should be examined and, if necessary, a groove made to receive the nerve. After suture, the nerve must be wrapped in Cargile-membrane to prevent the formation of adhesions, the wound closed, and the arm put up in extension to avoid traction on the nerve junction. Appropriate after-treatment must be carried out. In cases in which the lesion is incomplete, rest will often relieve the symptoms, but there is a great liability to recurrence as soon as the patient resumes the use of the arm.

It will save time if, in every case in which definite signs of interference with the functions of the nerve are present, operation is performed. The nerve must be exposed and the cause of the pressure removed, a new groove being cut for the nerve behind the internal condyle when necessary.

Dislocation of the Ulnar Nerve.—Abnormal mobility of the ulnar nerve is of common occurrence, and gives rise to no symptoms; it is found in individuals in whom the physiological cubitus valgus is more marked than usual, occasionally in those in whom cubitus valgus is the result of injury. This condition, which may be called subluxation of the ulnar nerve, is the predisposing cause of dislocation, and this name should be reserved for those cases in which the nerve travels over the internal condyle. This can occur only in flexion of the forearm, and in most cases a fall on the flexed elbow is given as the cause. This probably ruptures the fascia which keeps the nerve in position. The condition occurs most often in males between the ages of twenty and thirty. In most cases the symptoms come on immediately after the injury; occasionally some time elapses, the frequent injuries to which the nerve is subject in passing over the internal condyle causing fibrosis. In a few instances the condition originates without injury; in these patients the fascia which keeps the nerve in place is gradually stretched.

In a large proportion of cases it will be found that operation is necessary; if symptoms are present pointing to interference with the functions of the nerve, treatment must not be delayed. A long incision is made to expose the ulnar nerve in its groove behind the internal condyle, the groove deepened after freeing the nerve, which should then be wrapped in membrane to prevent its becoming adherent, and finally the groove formed into a canal by stitching a portion of the fascia of the triceps over it. In cases that have been neglected, in which a diffuse fibrosis is present leading to all the signs of complete division, it will be necessary to resect the damaged portion of the nerve; this will, however, rarely be required.

Note.—In the treatment of all cases of ulnar injury, great care must be taken to prevent the ulnar claw hand becoming permanent. Until the restoration of voluntary power, the interossei must be kept relaxed by means of a splint devised to maintain the fingers flexed at the metacarpo-phalangeal, and extended at the interphalangeal joints.

Musculospiral Nerve.—After the median and ulnar, this nerve is the one most frequently injured. It most often suffers in fractures of the humerus in its middle and lower thirds, and is the nerve commonly involved in crutch, sleep, and anæsthetic paralyses.

During recovery, whether from complete or incomplete division, the carpal extensors first regain power, then the extensors of the fingers, and finally those of the thumb.

Note.—Until the restoration of voluntary power the paralyzed muscles must be kept relaxed, the hand being held hyper-extended with the fingers extended by a suitable splint.

Circumflex Nerve.—Injury to the circumflex nerve is by no means so common as is usually supposed. It has been said to follow direct blows on the point of the shoulder; it is perhaps possible that the fibres of the nerve as they lie under the deltoid are injured, but in most cases the injury is to the anterior primary division of the fifth cervical nerve, and careful examination will show that the spinati also are affected. In other cases the wasting of the deltoid on which the circumflex injury was diagnosed is found to be, in common with all the muscles around the joint, the result of a traumatic arthritis.

The most careful examination is necessary before coming to a decision with regard to treatment; the testing must be carried out for all forms of sensibility.

If there be no loss of sensibility, and there is paralysis of the deltoid with the reaction of degeneration, it is extremely improbable that the circumflex nerve is injured; if the signs are those of complete section of the nerve, the age of the patient and his occupation must be taken into consideration. In most cases operation can be avoided by training the neighbouring muscles to take the place of the deltoid. If it is essential that perfect movement be obtained, operation must be resorted to. The nerve may be exposed through an incision half an inch behind and parallel to the posterior border of the deltoid muscle.

Long Thoracic Nerve (Nerve of Bell).—This nerve supplies the serratus magnus muscle. It is most often injured in males between the ages of twenty-five and forty, and usually on the right side. Generally caused by prolonged pressure in the supraclavicular region, it occasionally follows violent muscular efforts and direct violence applied to the shoulder. Paralysis of the serratus magnus is rarely isolated, but is usually combined with paralysis of the lower trapezius.

Careful examination is necessary in order to enable a prognosis to be made. If the case is seen early, avoidance of all injurious pressure in the supraclavicular region, and absolute rest to the arm, must be ordered. This must be followed by massage and stimulation with the interrupted current applied to the muscle.

If the paralysis persists, and the reaction of degeneration develops, nerve anastomosis should be performed, or the insertion of the sternocostal part of the pectoralis major may be transplanted to the lower angle of the scapula. It is usually impossible to deal directly with the damaged portion of the nerve or the branches of which it is composed.

Brachial Plexus.—The plexus may suffer injury (1) above or (2) below the clavicle; in the former case it is usually the anterior primary divisions of the cervical nerves entering the plexus that suffer; in the latter, the cords of the plexus. Most of the injuries are subcutaneous: above the clavicle, the result of traction; below, usually the result of pressure. Penetrating wounds are rare in civil practice.

1. **SUPRACLAVICULAR INJURIES.**—*Complete Plexus.*—The majority of cases of injury in this situation follow violence applied in such a way to the head or shoulder as to stretch the plexus. The injury first affects the fifth and then the other primary divisions in order, from above downwards.

Of isolated lesions, the fifth cervical and the first dorsal are the only common ones.

Nerve Symptoms due to Presence of Cervical Rib.—When symptoms result from the presence of a cervical rib, in seventy per cent of the cases they are nervous in nature. They occur more often in women, and on the right side. Symptoms usually appear in early adult life, and are due in most cases to pressure upon the lowest trunk or nerve entering the plexus.

Treatment consists in removal of the supernumerary rib and the periosteum covering it. This must be followed by the appropriate after-treatment directed to the affected muscles. Before resorting to operation, the possibility of the wasting of the intrinsic muscles of the hand being due to some other condition must be carefully considered. I have recorded a case in which syringomyelia was complicated by the presence of cervical ribs, and it is on record that cervical ribs have been removed for symptoms proved after operation to have been the result of this disease.

2. **INFRACLAVICULAR INJURIES.**—In the majority of cases these are the result of pressure, most often from the head of a dislocated humerus, occasionally from reduction of the dislocation by the "heel in axilla" method. In other cases they may be due to fracture of the humerus or of the neck of the scapula.

The whole plexus may be injured, but the inner cord is most often affected, then the posterior, and finally the outer.

Diagnosis.—In every case of brachial plexus lesion, in addition to the fact of complete or incomplete division, the exact point of injury must be worked out; cases are not unknown in which the plexus has been explored below the clavicle when the lesion has been supraclavicular. Careful examination will alone avoid the mistake.

There are four important leading symptoms in this examination: (1) The condition of the scapular muscles. It will be found that the nerve of Bell is an important guide; if the serratus magnus is unaffected, we know that the lesion is not of the anterior primary divisions; next the spinati muscles—it is sometimes possible to locate an injury to between the points at which the nerves supplying these muscles and the serratus magnus are given off. (2) The grouping of the paralyzed muscles; for instance, it is obvious that no combination below the clavicle will paralyze the Erb-Duchenne group. (3) The condition of the pupil, and (4) The presence or absence of anæsthesia.

After diagnosis of the exact spot, treatment must be carried out along the lines already laid down; complete injuries must be explored and the appropriate treatment adopted. When the whole plexus is affected as the result of indirect violence, e.g., falls on the shoulder, exploration should be undertaken immediately without waiting to ascertain whether the division is complete or incomplete. In no instance in which operation was undertaken at a period after the accident has the result been satisfactory. There is, however, an exception to the rule that incomplete injuries should not be treated as a routine by open operation. I have already pointed out that an incomplete division of the fifth root may be followed by the development of the reaction of degeneration in the deltoid and spinati. This should always be treated by operation, and the damaged portion, which will be found on the upper and outer aspect of the nerve, resected, and a portion of the radial nerve transplanted; or this damaged portion may be anastomosed to the anterior primary division of the sixth cervical nerve.

With regard to prognosis of injuries of the brachial plexus, this is unfavourable, and is due in the first place to the nature of the injury. In a large proportion of cases the nerves are overstretched, and this results in hæmorrhage into the sheath and consequent fibrosis; in addition, if it leads to rupture the fibres give way at different levels; hence spontaneous recovery is unusual when the signs of complete division are present, and is apt to be imperfect in cases of incomplete division. Again, it is possible that the injury in some cases tears the roots away from the cord. Even after operation the prognosis is not so good as, for example, after secondary suture of the median at the wrist, or the musculospiral. This has to do to a great extent with the length of time necessary to complete recovery; in many cases the patient ceases to attend for efficient after-treatment, and when recovery of the nerve has finally become complete, the muscles are atrophic, and contractures of the opponent muscles render the regeneration of the nerve futile. Careful treatment at the time of the injury, and unceasing, patient after-treatment, will improve the prognosis. It cannot be too strongly impressed upon the patient that the operation only puts him in a condition favourable to recovery, and that possibly years of patient treatment must be carried out if success is to be obtained.

Sciatic Nerve.—Injuries of this nerve are rare in civil practice. Penetrating wounds of the upper part of the thigh are uncommon, but injury has followed traction, the result of the bloodless method of treating congenital dislocations of the thigh. Lesions of this nature usually result in incomplete division, and the external popliteal portion of the nerve suffers most, sometimes exclusively.

Treatment is carried out along the usual lines, but it must be remembered that an incomplete injury of the sciatic may be a complete injury of the external popliteal, so that it may be necessary to expose the great sciatic nerve and deal with its external popliteal half.

External Cutaneous Nerve.—It is but rarely that this nerve is divided: it sometimes suffers section in opening a psoas abscess, but the resulting anæsthesia causes little inconvenience. This nerve is of importance from its involvement in disease; Bernhardt's disease, or Meralgia Paræsthetica, is characterized by pain in the distribution of the external cutaneous nerve of the leg, usually with alteration in sensibility. It is most common in males, and many patients give a history of injury; or it results from the pressure of an ill-fitting truss. Symptoms begin with a feeling of tingling or of coldness in the distribution of the nerve; this increases, and pain, which disappears on resting, is experienced on standing or walking. A tender spot is sometimes present just where the nerve issues from under Poupart's ligament, and the area supplied by the nerve shows changes in sensibility. As a rule it is tender, and sensibility to touch and pain is defective.

Treatment is unsatisfactory. Rest should be first tried; if this fails the nerve should be injected with 80 per cent alcohol. Operation should not be resorted to unless this fails and there is a distinct history of injury, or a thickening of the nerve is felt. In these cases excision of the damaged portion of the nerve is likely to relieve the condition, but in some of the patients submitted to operation the cause of the condition was not discovered; excision of a portion of the nerve afforded relief for a short time, but the pain recurred.

Facial Nerve.—Facial paralysis may result from a lesion above or at the nucleus of the nerve; between the nucleus and the internal auditory meatus; during its passage through the temporal bone; and externally. In lesions at or above the nucleus, the orbicularis palpebrarum escapes. Its course below this point can be divided into three stages: above the geniculate ganglion; between the ganglion and the point at which the chorda tympani is given off; and below the chorda. In all these situations division of the nerve produces complete facial paralysis, but in the first and last taste is not affected, while if divided between the geniculate ganglion and the origin of the chorda, that is, in the middle ear, taste will be lost over the anterior two-thirds of the corresponding half of the tongue.

Apart from the so-called "rheumatic" affections of the nerve (Bell's palsy), which are the common cause of facial paralysis, interference with the function of the nerve in the middle ear is the most usual. This may result from disease, or from operation. The nerve may suffer in fractures of the base of the skull primarily, or more often from involvement in callus. Outside the skull it is often injured during operations in the parotid region or in the removal of tuberculous glands, or from forceps pressure during childbirth; in most of these cases the nerve injury is incomplete, and recovery ensues.

In every case of facial paralysis, the site of the lesion should be discovered; this is often obvious from the history of middle-ear disease or operation. In other cases, attention to the symptoms given above will lead to diagnosis of the seat of the lesion. The degree of the injury sustained by the nerve must next be ascertained, whether complete or incomplete division, by testing the reactions of the affected muscles.

In cases of incomplete division the usual treatment directed towards maintaining the nutrition of the paralyzed muscles must be adopted. When due to middle-ear disease the complete mastoid operation must be carried out; facial paralysis is an indication for this operation. When the reaction of degeneration

is present, showing that complete division, either anatomical or physiological, has occurred, the treatment to be adopted depends on the cause. If it follows a radical mastoid operation, the sooner treatment is carried out after the wound has healed the better; in cases of Bell's palsy it is justifiable to wait for six months before operating. If the nerve is divided during the course of mastoid operation, the ends should be adjusted in the aqueduct, when restoration of function may be expected unless neuritis is set up as the result of sepsis. If discovered after the operation, the reaction should be tested at the end of a fortnight; if the reaction of degeneration is present, the wound should be opened up and an attempt made to adjust the ends. If this fails, nerve anastomosis must be undertaken. It must be remembered that the injury during mastoid operation is in most cases incomplete, and that spontaneous recovery follows the usual non-operative treatment.

In many cases of facial paralysis submitted to operation, end-to-end union is out of the question, and a neighbouring nerve must be utilized. The nerves that have been used are the spinal accessory or one of its branches, and the hypoglossal; they have been completely divided, and end-to-end union performed with the peripheral end of the facial (nerve crossing), or united to the side of the nerve (anastomosis). The hypoglossal is the nerve of choice; dissociated voluntary movement is restored more quickly after anastomosis to this nerve than when the spinal accessory is used. Nerve anastomosis, and not nerve crossing, should be performed; there is no necessity to sacrifice the hypoglossal nerve: emotional dissociated movement will return without. It is probably better to make an incision into the hypoglossal nerve, and not simply a vertical slit, for return of co-ordinate voluntary movement is more rapid when axis cylinders in the affected nerve are divided. (See *Figs. 55-58.*)

In order to carry out the operation, a long incision should be made extending from the mastoid at the level of the external auditory meatus down to the great cornu of the hyoid. The anterior border of the sternomastoid is pulled back, and the posterior belly of the digastric identified after separation of the parotid. The digastric is then pulled backwards, and if large it may be necessary to divide its upper border. The facial nerve is next identified, this being most easily done by feeling for the styloid process of the mastoid; the nerve passes out immediately in front of this and enters the parotid gland. The nerve is freed, and an attempt is made to pull the stump out of the foramen in cases in which there is reason to believe that the nerve was divided in the course of an operation on the middle ear. If this cannot be done the nerve is divided in the foramen as high as possible with a tenotomy knife. The hypoglossal must next be identified; the transverse process of the axis is first felt, then the occipital artery is sought, which usually runs upwards and outwards across the process. The internal jugular vein is next found and retracted inwards; this exposes the hypoglossal nerve. With it is running the vagus, but the hypoglossal is easily identified from the course it is taking. It is freed, and brought towards the facial; an oblique cut should be made through about one-third of its trunk and the peripheral end of the facial sutured in with fine catgut. If there is any tension it is better to raise a flap consisting of one-third of the hypoglossal, and unite it end to end with the facial. The raw surface and the junction should be surrounded with Cargile-membrane. The wound should now be closed, putting in a tube for twenty-four hours if necessary.

The after-treatment must be patiently carried out. The nutrition of the muscles must be kept up by means of massage and the application of a constant current until such time as voluntary power begins to be restored. As soon as power of voluntary movement returns to each group of muscles, they must be exercised systematically until the patient regains complete control.

The prognosis varies with the cause of the paralysis, being better when the division results from injury than when it is the result of neuritis. Suppuration of the operation wound renders success doubtful. If the case is to recover, the first sign usually appears about the third or fourth month, the face while at rest becoming more symmetrical, although there is no return of voluntary power. Within a few weeks it is noticed that the angle of the mouth can be moved, at first only with movements of the tongue; then the muscles of the upper lip, and finally those of the forehead. With exercise, the movements become dissociated, and finally emotional movement returns.

For a few weeks after operation, the side of the tongue supplied by the hypoglossal nerve which was used is paralyzed, causing difficulty in speech and deglutition; this passes off in a few weeks, but the affected side of the tongue remains smaller for a considerable time.

Lingual Nerve.—It is occasionally necessary to resect a portion of this nerve for neuralgia involving the tongue, or for the relief of pain in inoperable carcinoma. The injection of 80 per cent alcohol should always be tried first.

The nerve may be exposed through a trephine opening in the ascending ramus of the lower jaw, the centre of the opening being at the meeting of a line drawn backwards from the alveolar margin with one drawn vertically upwards from the angle of the jaw. The nerve will be found lying in front of the inferior dental nerve; about an inch should be resected.

Division of the nerve through the mouth should be avoided; it is uncertain, and the wound is liable to become infected.

Cervical Sympathetic.—The sympathetic cord in the neck may be injured as the result of penetrating wounds, surgically or accidentally inflicted. It may be pressed upon by or involved in tumours of various kinds, or its white rami communicantes injured as they pass out in the first and second dorsal roots. (See BRACHIAL PLEXUS, *supra*.)

Section of the sympathetic in the neck produces slight enophthalmos and pseudo-ptosis (the upper lid droops but can be elevated voluntarily). The pupil is smaller than on the sound side, and does not dilate when shaded, or in response to cocaine or to pinching the side of the neck (ciliospinal reflex). The affected side of the face does not flush or sweat. Stimulation of the cervical sympathetic is sometimes observed as the result of the pressure of tumours or the traction of adhesions. It results in exophthalmos, widening of the palpebral fissure, and dilatation of the pupil.

The cord and ganglia may be removed through an incision along the posterior border of the sternomastoid. The carotid sheath and its contents are exposed and drawn forwards and inwards, and the sympathetic found behind it.

Resection in whole or in part has been performed, with results that are open to question, in cases of idiopathic epilepsy, glaucoma, Graves's disease, and epileptiform neuralgia. The surgery of the sympathetic is still in the experimental stage.

Spinal Accessory Nerve.—The external or spinal portion of this nerve is not infrequently divided during the course of operations upon the neck, particularly during the removal of tuberculous glands. It must not be forgotten that the spinal portion of the nerve may be involved in the vertebral canal. It supplies the sternomastoid, together with branches of the second and third cervical nerves; and the trapezius, with the aid of fibres from the third and fourth cervical nerves.

Many of the cases of accidental section, particularly those due to extensive operations upon tuberculous glands, affect at the same time the branches of the cervical nerves to the trapezius, producing its complete paralysis.

If the nerve be divided during the course of a surgical operation, it should be immediately sutured. The deformity resulting from paralysis of the trapezius is marked, and an attempt should be made in every case to deal with it by operation. The spinal accessory nerve should be exposed through an incision along the anterior border of the sternomastoid, and an attempt made to perform secondary suture. If it be impossible to bring the ends into contact or to find the upper end, the peripheral end should be anastomosed to the anterior primary division of the third or fourth cervical nerve. When the cervical branches are divided in addition, an attempt must be made to obtain the nerve supply again from the third and fourth cervical by suture or anastomosis.

To expose the spinal accessory nerve, an incision is made along the anterior border of the sternomastoid with its centre opposite the angle of the jaw. The border of the muscle is defined and pulled outwards, and the nerve is often seen entering it. If this fail to bring it into view, dissection at the posterior border of the digastric, remembering the direction of the nerve, will expose it as it passes out from under the muscle. James Sherren.

NEURALGIA.—The commonest manifestation is that which occurs in the distribution of the trigeminal nerve from dental irritation, the pain being referred to any of the three divisions of the fifth nerve. Other forms of irritation in the distribution of the sensory division of the fifth will give rise to neuralgia, as for instance irritation about the nose, pharynx, eyes, and ears, and exposure to cold and injury. Brachial and intercostal neuralgia are also relatively common manifestations of the disease.

Neuralgia may be due to rheumatic, gouty, diabetic, malarial, or syphilitic conditions. Anæmia—by whatever cause produced—will often provoke an attack. The successful treatment depends on finding the source of the peripheral irritation, which is by no means always in close relation to the seat of the pain. In neuralgia of the face, the teeth have to be carefully examined, not only for caries, but also for other abnormalities of the roots and gums. The possibility of an impacted wisdom tooth must always be borne in mind. The eyes have to be carefully examined, not only for the more marked degrees of errors of refraction, but also for the slighter degrees of hypermetropia, which readily escape observation. Other more obvious conditions of the eye, such as iritis and glaucoma, may be the cause of "neuralgia."

Suppuration in the antrum and sinuses also gives rise to neuralgia ; or again, it may be the earliest symptom of intracranial disease and of tumours, syphilitic or otherwise, situated at the base of the brain. Brachial neuralgia may be due to the presence of a cervical rib. In many cases, however, after the most careful examination, no cause can be ascertained ; such cases need symptomatic treatment. In many of the above conditions the diagnosis is greatly helped by an x-ray photograph.

The treatment of neuralgia may be dealt with under two heads : (A) *Local Treatment* ; (B) *General Treatment*. Under the former, the application of heat and cold, the local application of drugs, counter-irritants, electricity, hypodermic injection of drugs, and surgical treatment, will be considered ; under the latter, the administration of drugs, diet, massage, and change of climate.

A.—Local Treatment.

1. *The Application of Heat* over the affected nerve, or the "tender point," will often afford considerable relief. The application of heat by means of a hot-water bottle is simple and often effective. The heat produced by the

electric current in an electrotherm is easy of application, and the temperature can be regulated and maintained at a constant for any length of time desired. After removal of the hot application the part should be covered with dry wool.

Cases of brachial neuralgia are best treated by a hot-air bath in which the required temperature is attained by means of an electric current—a temperature of 300° to 400° F. may be used. After the bath, the arm should be carefully and firmly bound up in a flannel bandage, and kept at absolute rest by means of a sling. Cold may be applied by means of an ice-bag, or by the spray of ether or ethyl chloride, but is seldom so serviceable as heat in the relief of neuralgia.

2. *Local Application of Drugs.*—Drugs may be applied locally, either on account of their sedative action, or to act as counter-irritants. Into the former category would come such remedies as belladonna, aconite, and opium, whilst in the latter may be mentioned turpentine, mustard, chloroform, camphor, oil of wintergreen, iodine, mesotan. Mesotan should be diluted with equal parts of olive oil and be painted over the affected part, but should not be rubbed in, as in certain individuals it gives rise to considerable irritation of the skin.

3. *Counter-irritants.*—The application of two or more leeches is a most valuable remedy in acute attacks of neuralgia, but is of less service when the symptoms recur with comparative frequency. In these cases a blister is more useful; such may be produced by the application of the ordinary liq. epispasticus (B.P.) or collodium vesicans (B.P.), or by the application of the actual cautery. For intercostal neuralgia the cautery is to be preferred, two small strokes being made on one, or other side of the spine, and the application repeated on a fresh place every other day.

4. *Electricity.*—Faradism, galvanism, diathermy, high-frequency, static, and sinusoidal currents, and the vibration produced by the rapid revolution of a small motor have all had an extended trial. In individual cases some success has been attained by the use of the galvanic current. The positive pole should be applied to the tender spot, and a weak current from 2 to 5 milliampères allowed to pass for five to ten minutes. This should be repeated every day for fourteen days at least. In the case of brachial neuralgia, the current may be used in a bath. Ionic medication (kataphoresis) with iodide, sodium salicylate, etc., is of value in some cases (for details as to the application of this method reference should be made to *ELECTROTHERAPEUTICS, Ionic Medication*, p. 311).

5. *Hypodermic Injection of Drugs.*—The local hypodermic injection of drugs has been used in some cases. Cocaine in doses of $\frac{1}{8}$ to $\frac{1}{4}$ gr. may be of some service, but seldom gives the marked relief afforded by injections of morphia. On the other hand, the probability of producing a morphia or cocaine habit is equally great with either drug, and this should be borne in mind when recommending this form of treatment. The injection of the trigeminal nerve and Gasserian ganglion with 90 per cent alcohol is one of the most successful methods of dealing with cases of trigeminal neuralgia (tic douloureux). The injection of the third division is not difficult. The injection of the second division, owing to the proximity of the optic nerve, is attended by some risk. The injection of the Gasserian ganglion is not always possible, owing to the variations in the position of the foramen ovale; if it can be successfully accomplished it is attended by good results—especially if no damage is done to the first division, so that the sensation of the cornea is preserved.

The injection of the third division and Gasserian ganglion is performed by inserting a needle (8 cm. by 1.25 mm.) into the ovale area, bounded above by the lower border of the zygoma and below by the incisor notch of the lower

jaw, at a spot 1 inch in front of the anterior wall of the meatus. The nerve should be punctured at a depth of 4.5 cm., but this varies slightly in different individuals. The injection can be done either under a general anæsthetic, or under morphia (gr. $\frac{1}{3}$) and hyoscine (gr. $\frac{1}{150}$) with a local injection of 0.5 c.c. of a solution of 5 per cent novocain— $1\frac{1}{2}$ to 2 c.c. of alcohol being injected into the nerve. The advantage of performing the injection under hyoscine and morphia anæsthesia is that the amount of anæsthesia produced can be limited to the second and third divisions of the nerve, whereas under a general anæsthetic this cannot be determined. The disadvantage of the hyoscine-morphia method is that some pain is caused, and this in a nervous patient may make the operation difficult. For a detailed description of the method reference should be made to Dr. Harris's paper (*Lancet*, 1912, i, 218, and 1913, i, 881).

6. *Surgical Treatment*.—Nerve section or stretching may afford temporary or permanent relief when the pain lies within the territory of the branch of one nerve. In severe trigeminal neuralgia the removal of the Gasserian ganglion affords relief in cases in which all other remedies, medical or surgical, have failed. In brachial and intercostal neuralgia the division of the posterior root, or excision of the posterior root ganglion, may afford relief.

B.—General Treatment.

1. *Drugs*.—Many of the milder forms of neuralgia yield to simple medical treatment. The administration of iron, arsenic, strychnine, quinine, and cod-liver oil, by improving the general health, cure the anæmia and remove the neuralgia. In other cases, sodium salicylate, salicin, and acetyl-salicylic acid (aspirin), in 5- to 10-gr. doses three times a day, are of service. For the immediate relief of the more severe paroxysms, phenacetin, phenazone, acetanilid, or butyl-chloral may be given.

Other drugs, such as caffeine, aluminium chloride, belladonna, valerian, and phosphorus should also be given a trial. Gelsemium, in doses of 10 to 15 min. of the tincture, every four hours, is often successful, the quantity being gradually increased until the pain is relieved or toxic symptoms are produced.

2. *Diet*.—This should be carefully attended to, but no one form is applicable in all cases. In patients who are thin and pale a generous diet may be advised, milk, cream, and butter being important elements. In those who show a tendency to gout or rheumatism, a modified diet suitable for such conditions should be ordered. With the object of improving the general health, alcohol may be given, but the resort to alcohol for the relief of pain should be carefully guarded against.

3. *Massage*.—Carefully regulated exercises, short of fatigue, in the fresh air are most beneficial, and the health may be greatly improved by general massage. Local massage to the affected part may be used in long-standing cases, but in the acute cases it often increases the pain.

4. *Change of Climate*.—A warm dry climate is most beneficial, and cases which have for a long time hung fire, rapidly improve and get well when placed under such conditions. Various forms of warm, salt, and mud baths may be used.

Shortly, it may be said that the treatment of neuralgia should be directed to (1) Improvement of the general health and removal of any source of possible irritation; and (2) The relief of pain by the application of heat, counter-irritants, electricity, drugs, and, in true cases of trigeminal neuralgia, by the injection of 90 per cent alcohol into the trunk of the nerve or Gasserian ganglion. Failing a successful result from these remedies, nerve section and removal of the Gasserian ganglion should be advised. (See also ELECTROTHERAPEUTICS and NEURALGIA, EPILEPTIFORM.)

F. E. Batien.

NEURALGIA, EPILEPTIFORM (Tic Douloureux, Major Neuralgia.—

This disease must be distinguished from the minor neuralgias common in the face. It is a disease which attacks adults and appears without apparent cause. The sufferers are, as a rule, in perfect health, and are not the subjects of neurotic inheritance. The disease usually manifests itself in the distribution of the second or third division of the nerve; the first, so frequently affected in minor neuralgias, usually escapes or is involved late. The attacks of pain are paroxysmal, and occur at first at long intervals, but the severity of the pain tends to increase and the intervals between the attacks to diminish. The pain usually spreads in a definite order, branch after branch becoming involved in a regular march. As time goes on the paroxysms of pain are excited by any stimulus, so that eating, speaking, or a loud noise may be sufficient to start an attack. As a rule, before the patient comes under the care of the surgeon, teeth will have been extracted, and all drugs, except perhaps morphia, employed; the latter is the only means of combating the pain, short of surgical measures. The severity of the disease is such that suicide or the morphia habit is the end of those patients who are not surgically treated; the disease does not cease spontaneously, and medical treatment is of no avail.

This is the disease to which the following treatment refers. It must be first settled that the case belongs to this group. When the condition has existed for some time there can be no mistake; the appearance of the patient, together with the history, leaves no doubt that we are dealing with a case of true trigeminal neuralgia. In the milder instances this may not be so easy; but the onset of the disease without apparent cause, the absence of anæsthesia such as is met with in cases in which the nerve is pressed upon by growth, and the absence of all exciting causes in the teeth, jaws, and sinuses, should lead to the correct diagnosis.

TREATMENT.—While we are still unacquainted with the cause of this complaint, the best form of treatment is a matter for discussion. All the evidence at our disposal seems to point to the disease being situated, at first at any rate, distal to the ganglion. No definite pathological changes can be demonstrated in the Gasserian ganglion in early cases uncomplicated by previous peripheral neurectomies. Extracranial section of the affected nerves abolishes the pain for a time depending upon the amount of nerve removed and the distance from the periphery of the point of section. Pointing to the same conclusion is the fact recorded by Cushing that peripheral neurectomies are of no value in post-herpetic neuralgia, a disease which the researches of Head and Campbell have shown to be due to changes in the ganglion of the posterior root.

The problem of treatment resolves itself in early cases into the best means for preventing the passage of afferent impulses from the territory supplied by the branches involved. In no case should this be done by operation until the effect of alcohol injection has been tried. The injection of alcohol into a nerve destroys the axis cylinder at the seat of injection, and in most cases the pain is relieved for nine or ten months. The injection can be repeated as often as necessary. It should be followed by loss of sensation in the territory supplied by the branch or branches affected—if injection fails to relieve, operation should be carried out. Considerable practice is necessary if success is to be obtained. A stout needle, 10 cm. long and 1.5 mm. in diameter, fitted with a blunt stylet and marked in centimetres up to five, is used. As a rule a general anæsthetic is not necessary. When the point of the needle is through the skin the stylet is pushed in. When the end of the needle has reached the proper depth, the stylet is withdrawn and a glass syringe filled with solution fitted to the needle, and the injection made.

When the pain is in the area of the second division of the nerve, the injection

is made into and around the nerve as it emerges from the foramen rotundum. The needle is inserted at the lower border of the zygoma, $\frac{1}{2}$ cm. posterior to a line drawn downwards from the posterior border of the orbital process of the malar bone. It should be directed inwards and slightly upwards for about 5 cm. To inject the third division, the needle is inserted at the lower border of the zygoma, $2\frac{1}{2}$ cm. in front of its descending root. Its direction is backwards and upwards till the external pterygoid plate is reached, then upwards and backwards to the foramen ovale. This is usually reached at a depth of 4 cm.

Mr. Hutchinson has laid down rules which are an advance upon the usual teaching, and simplify the operative surgery of the fifth nerve. He recommends resection of the infra-orbital nerve if the neuralgia is limited to that nerve, by following it back in its canal in the floor of the orbit. If the palatine branches also be affected, intracranial resection of the superior maxillary trunk should be carried out. If the inferior dental nerve be affected, resection should be performed through a trephine opening in the lower jaw. If the whole of the inferior division of the nerve be affected, intracranial resection of the trunk and adjacent part of the ganglion should be carried out; in all other cases, removal of the two lower divisions together with the corresponding part of the ganglion. Removal of the whole ganglion is unnecessary unless all the branches are involved.

It is becoming more usual now to perform Abbe's operation, intracranial resection of the second and third divisions of the fifth nerve, with the interposition of rubber tissue at the foramina rotundum and ovale to prevent reunion of the divided nerves. This is the operation which in my opinion should be performed in early cases. In this operation and in resection of the lower part of the ganglion there is less shock; injury to the cavernous sinus and the nerves in its wall is avoided; and corneal complications need not be feared.

With regard to the best route through which to perform the intracranial operations, considerable difference of opinion exists. Practically all operators are agreed that the temporal route is the best. I consider Cushing's direct temporal, infra-arterial method, with removal of the zygoma, gives the most direct access with least disturbance of the parts. Theoretically, section of the sensory root posterior to the ganglion is the ideal operation. For the Spiller-Frazier method, first performed by Frazier in 1901, the following advantages are claimed. There is less hæmorrhage; it does not expose to injury the cavernous sinus and the nerves in relation to it; it may be possible to spare the motor root; there is less likelihood of corneal ulceration.

The results of removal of the Gasserian ganglion are good; recurrence does not take place. With regard to the removal of the lower two-thirds, no recurrence occurred in Mr. Hutchinson's series of cases, two of which were watched for seven and seven and a half years. The results should be equally good in Abbe's operation, provided care is taken to prevent reunion of the severed divisions. The mortality in skilled hands is extremely small, and will compare favourably with any major operation. Mr. Hutchinson has operated on 31 cases without a death; Sir Victor Horsley on 149 with a death-rate of 7 per cent, but no patient under fifty years of age died; Cushing on 156 with 2 deaths. (See also NERVES, PERIPHERAL.)

James Sherren.

NEURASTHENIA.

It cannot be too strongly insisted upon that, before a patient is treated for what appears to be simple neurasthenia, the greatest care should be exercised in excluding the possibility that some organic disease underlies the condition. Not only must organic diseases of the nervous system be carefully sought for and excluded, but organic disease of other organs may also account for the symptoms which are so commonly met with as a result of uncomplicated nervous exhaustion. A like search must be made for

some form of infection that may be responsible for the state of ill-health that exists, in which connection the state of the gums, the accessory sinuses, and the intestinal tract is most important.

A large number of patients suffering from neurasthenia are strongly convinced that their condition is unique, and that no one else has ever had to consult a doctor for symptoms of a similar kind. Moreover, they are so impressed with the intricate nature of their case that they wish to enter into most minute details in regard to their various complaints. This state of things makes a severe call on the patience of the medical man, but nevertheless, if he wishes to be successful in his treatment, he must conceal any anxiety he may feel in regard to the possible length of the interview. The patient cannot believe that a doctor who is hurried in dealing with his case can possibly master the intricate details; he thus loses all confidence in him, and, without confidence, treatment must fail. It is better to interrupt the interview, and make another appointment for a day when more time can be given to the very careful consideration of the case, than to show any signs of hurry or desire to cut short the consultation. Although it is a mistake to appear hurried, and it is best to listen with patience and attention to the history, it is often wise to interpose a well-directed question now and then, or to suggest a few of the symptoms in a way that makes the patient feel that the person who is being consulted has grasped the nature of the case, and is familiar with many of the features of the illness. The patient is thus inspired with the necessary confidence. To ignore the symptoms, to treat them lightly, or in an off-hand manner, or perhaps even jokingly to try to belittle them, is worse than useless. The proper course is to assure the patient that you fully appreciate the severity of his sufferings, but that you are equally certain they do not depend on any organic disease of the nervous system. The fears these patients usually harbour are, that they are going to die; lose their reason; have a fit; that a tumour is forming in the brain; or that they are liable to a stroke of paralysis. They must be reassured as much as possible, and told that none of these things is in the least likely to happen, but that their symptoms are due to an exhausted condition or poisoned state of the nervous system, a state of things from which they can and will make a satisfactory recovery, although the illness may be tedious, and convalescence prolonged.

In the treatment of every case of neurasthenia it is of importance that the cause should be diligently searched for and, if possible, corrected; but intimately connected with this question is the need for exercising prophylactic measures when there is reason to suspect a congenital weakness of the nervous system, owing to known hereditary influences, for which neurasthenia itself, or some allied neurosis, may be responsible. Such individuals must, of course, be protected as far as possible from the prejudicial influences which are known to beget neurasthenia, but in spite of every precaution, they may inevitably drift into this unfortunate state of ill-health from no fault of their own.

When some form of infection has been determined, it must be dealt with by local measures, when these are possible, and by vaccines when the indications point to the need for these in the treatment of the case.

In searching for causes of this affection, and in attempting to correct them, some discrimination must be exercised, or more harm than good may result. It would be obviously harmful and cruel to tell the unfortunate city clerk that he must stop all work for a long period, and go away for rest and change, when he has a wife and family to be supported on a salary so slender that monetary anxiety has already had much to do with producing his unfortunate illness. The knowledge that it is impossible for him to do what is essential to get well plunges him into greater despair, and aggravates his condition. Far more good will be done in such a case by trying to so arrange matters as to permit him to continue his work, and yet take steps to improve his health.

It is not only by medicines that such patients can be helped. Much can be done in teaching them how to utilize their leisure to the best advantage for the improvement of their health. Some exercise is, of course, necessary; but where there are symptoms of physical exhaustion, it is best to be content with light dumb-bells, or the use of a Whiteley's or Sandow's exerciser in the morning before dressing, rather than that they should walk part of the way to and from business and wander about the streets during a portion of the time that they

have for their mid-day meal. When this is feasible, the outside of a bus is the best way in which they can travel to and from their work, and such time as is not required for actual eating should be spent in resting rather than in roaming the city streets. On reaching home at night, the patient should go to his bedroom and lie down quietly for an hour before the evening meal, provided he does not return from the city too late to permit of this. In the summer, the rest may be taken in the open air, if the conditions are such as to make a real rest possible in this way. Saturday afternoons and Sundays are best spent quietly in the country or by the sea, when either is possible without entailing great physical labour or financial strain. For those who have the opportunity and can afford it, golf is much the best form of exercise in the open air, as the amount can be regulated not to cause undue physical fatigue, and the game demands an amount of attention that is well calculated to take the patient's thoughts away from his anxieties and worries, and prevent him from analysing his symptoms. Gardening and other out-door pursuits are advantageous; but long walks for walking's sake, similar bicycle rides, and long tiring days on the river, do no good. Lawn tennis, although an excellent form of exercise, is too severe for patients in whom the symptoms of physical exhaustion are prominent, and the strain put upon the heart in cases of the kind may do serious harm. When the mental symptoms are chiefly in evidence, and the physical state presents little that is amiss, lawn tennis, rowing, and other forms of active exercise may be indulged in with advantage.

These patients must be strongly advised to give up all philanthropic and other work, apart from the business upon which they have to depend for their livelihood. They must also be encouraged to make a supreme effort to finish all they have to do while at work, and neither to allow arrears to accumulate, nor to take work home with them with a view to its being done in the evenings, or on Sundays. It is similarly important that they should not attempt any study in the evenings with a view to making themselves more proficient at their work. All reading at home should be, as far as possible, for recreation and amusement. While light literature of the right kind has the advantage of abstracting the mind from self, it is important that it should not be of an exciting character too near to bedtime, as this is calculated to interfere with sleep, which these patients oftentimes find difficult to secure. For the same reason, exciting games in the evening are best avoided.

The wife of the man who is unable to afford to send her away from home for the rest and change, or other treatment, that she may require, can be similarly assisted to make her life more endurable, even if she cannot be cured, by the half measures that may be possible to her. How much of the following she can carry out depends on the number of children she has to care for, and on what help she can get from relatives and friends.

If possible, she should remain in bed for breakfast, and so order her day's duties as to allow of her getting out for fresh air some time in the morning, and again in the afternoon. She should lie down in her bedroom for an hour before her mid-day and evening meals, and should rest in the semi-recumbent posture, on a sofa or in a comfortable chair, for half an hour to an hour after the mid-day meal. When the rests before the meals are impossible, an attempt should be made to obtain a longer rest in the bedroom in the afternoon.

Where the patient's circumstances will permit of it, complete rest from all work is an important factor in the treatment of a large number of cases of neurasthenia. How the leisure is to be spent, and what special form of treatment is likely to do most good, vary in different cases, but in a large number the best results are obtained by a course of Weir-Mitchell treatment, otherwise known as the "rest cure." Experience has proved that this treatment can rarely be

conducted with advantage in the patient's own house, and it is most important that the details should be thoroughly understood in the nursing home that is selected, if success is to attend its use. The treatment is best conducted in a good nursing home in the country, but infinitely better in a good one in town than in many of the indifferent homes that exist in country places. Quiet is, however, an essential in many cases, especially when there is much nervous irritability, hyperacuity of hearing, headache, or insomnia. A home where no surgical cases are received is best, for the treatment cannot be satisfactorily conducted in a surgical home, where the sounds of preparation for operation and the odour of anæsthetics reach him, and where the nurses can rarely be relied on to keep silent tongues, and to avoid giving the patient news of what is going on in the house.

Important as it is to select a good home, it is still more so to secure that the nurses in charge should be thoroughly competent to deal with such patients. This experience can be gained only by previous training with similar cases.

The patient should be completely isolated from all outside influences, and left entirely to the care of the nurses. No visitors must be allowed, and no letters received or written by the patient. Such restrictions prove vexatious to many patients because the reasons for them have not been adequately explained. Above all things, it must be made quite clear that the treatment is not recommended because of any idea that the condition is hysterical, or that any of the symptoms are due to fancy. It must be pointed out that the object of the various restrictions is to endeavour to obtain the maximum amount of physical and mental rest possible, and that without them it is impossible to prevent accidental outside influences operating prejudicially during the treatment. Moreover, patients must be made to understand that they are not prisoners, but free agents, and that they can interrupt the treatment whenever they think fit, if they feel unable to tolerate the restrictions it imposes. Another point about which there must be no ambiguity is, that a compact has been formed between them and their medical adviser, in which they undertake to do all in their power to co-operate with him in his endeavours to help them, while he on his part undertakes not to keep any important information from them the ultimate knowledge of which might reasonably be expected to undo any good that may have resulted from treatment. Thus, the husband must be assured that any serious illness of his wife, or of one of the children, would mean that his treatment would at once be interrupted, and the news conveyed to him; while a like assurance must of course be given to a wife. A man of business must similarly be assured that any unforeseen eventuality involving momentous questions on which it is imperative that he should be consulted, would mean that he would be informed of the circumstances, and allowed to discontinue the treatment. In these ways, the patient's mind is set at rest on points that might otherwise prove worrying.

The degree of exhaustion may be such as to make it necessary to enforce absolute rest in bed during the whole of the twenty-four hours, except perhaps when the bed is being made at night or in the morning. It is, however, not often necessary to insist on such absolute rest as to make it inadvisable for the patient to get up to go to stool. In the majority of instances, a commode should be used in the room, and even when the lavatory is so conveniently situated that the patient can be allowed to go there, it is best for a commode to be used, so as to allow the nurses and medical man to examine the stools. In less severe cases, and towards the end of a course of treatment, patients who have been kept absolutely in bed at first may be permitted to sit up at a table for the mid-day and evening meals. Later still, before leaving the home, the patient may go for drives in the afternoon, but must return to bed or lie on a

comfortable sofa for a long rest on coming in. It may often be advisable to allow the patient to have a short walk in a park before driving home, but no shopping must be permitted, and crowded and busy thoroughfares should, as far as possible, be avoided during the drive.

In severe cases, the patient must be content to do nothing, and it may even not be advisable to allow the nurse to read to him, in which case the less talking that goes on between them the better. It does not frequently happen that such rigid rules are necessary, so that the nurse may read to the patient from time to time, and in a good many cases the patient may be allowed to look at picture papers and read a little, provided light literature is selected. Nothing requiring any mental effort should be allowed, and whether the daily paper is to be permitted or not must largely depend on whether news of a character that is likely to be disturbing to the mental repose of the patient is to be expected from this source. It is usually best not to allow the daily paper in the case of business men, and even when allowed, the page which deals with stocks and shares should be first extracted, an essential when the patient is connected with the Stock Exchange, as so often happens. Exciting literature must also be forbidden. Many novels and other works of fiction are unsuitable for such patients. Writing must not be permitted, but some patients who sketch or paint may be allowed to indulge in these pastimes in moderation. Any serious work of the kind cannot, however, be allowed, and the artist who depends on his pencil or brush for a livelihood must of course be advised not to attempt any pictures or studies of these during the cure. Fine needlework, or any kind of work that requires close application, should be avoided, but netting, knitting, and any form of coarse fancywork, may be permitted in moderation. Games of all kinds must be very carefully regulated when the patient is well enough to be allowed to indulge in these, as the element of excitement, which is inseparable from most games, is harmful. Even patience, which is so commonly allowed, is not without its drawbacks, so that the patient must be enjoined not to try to worry out complex problems, but to be content with the simplest examples of the game, and always to desist if the slightest feelings of mental effort are induced. Much discretion is needed in deciding how much or how little patients may be allowed to attempt, but it must be remembered that when they are intensely bored by doing nothing, or get into a state of restlessness and irritability, more harm may be done by too many restrictions than if a few concessions are judiciously granted.

Diet is a very important item, and requires great care if harm rather than good is not to be the outcome of the attempts to improve the patient's nutrition. A great many people suffering from neurasthenia have lost weight, and one of the essentials in the treatment is to restore this. But no greater mistake can be made than that of indiscriminately pouring large quantities of milk into such patients, and otherwise attempting to improve their nutrition by a process of stuffing, without any regard to the state of their digestive tract and their powers of assimilating the large amount of nutriment with which they are being crammed. When milk is well borne, no better article of diet can be found, and the best plan is to begin by placing the patient on milk alone for twenty-four or forty-eight hours. Commencing at 8 a.m. and continuing until 10 p.m., five ounces of milk should be given every two hours, and a rusk may be allowed with every other glass of milk. On each successive day, one ounce of milk must be added to each glass until the patient is taking ten ounces every two hours, in addition to three good meals daily. The milk may be diluted if necessary, when barley-, lime-, or ordinary water may be used. Even soda-water may be allowed, but is best avoided, as the effervescing waters are calculated to increase flatulence, which is often troublesome enough without this.

Solid food should be commenced at the end of the first twenty-four or forty-eight hours, and the meals should be small and light at first, and gradually increased day by day until the patient is taking three good meals in addition to the milk. All made-up dishes and indigestible foods must be avoided, and the chief meat meal should be taken in the middle of the day, when some form of butcher's meat, such as steak, chop, or a cut from the joint, should be given, unless there are any reasons against this. The evening meal should be light, and should consist of fish, poultry, or any form of game that is not too rich or indigestible. A milk pudding of some kind should be given at one of the meals, and stewed fruit and cream at the other; and unless there are indications to the contrary, uncooked fruit may be taken, and is especially to be recommended at breakfast. The fruit proves helpful in counteracting constipation, which is often troublesome, and thus lessens the need of aperients.

No alcohol is required usually. Indeed, it is often contra-indicated, as the patient has been relying on alcohol to increase his energy, to remove the mental depression, and often-times as a substitute for food, for which there has been no appetite. Even tea and coffee are best avoided, except that a small cup of black coffee often proves helpful when given in the early morning. Coffee after dinner must be strictly forbidden, and afternoon tea is best avoided.

The times for giving the milk should, if possible, be arranged so that part is taken with the three meals. Indeed, it often happens that a patient who is unable to take ten ounces of milk every two hours is nevertheless able to drink the same total amount by taking more than ten ounces at the meals, notably at breakfast, when as much as a pint may sometimes be comfortably dealt with. Some form of meat extract may be given between meals. In any case, ten ounces of raw meat-juice may be given with advantage twice a day, as a substitute for two of the glasses of milk.

The fewer drugs that are given during the course of Weir-Mitchell treatment the better. The bowels must, however, be carefully regulated by cascara, aloin pills, or a saline in the early morning. In any case it is well to commence the treatment by a dose of 2 or 3 gr. of calomel, or blue pill, followed by a saline, and this should be repeated about once a week. It is also usually best to prescribe a simple alkaline mixture before meals, to prevent the stomach from becoming rebellious, in which case the following will be found most effective :—

R	Acidi Hydrocyanici Diluti	℥iij	Aquæ Chloroformi
	Sodii Bicarbonatis		vel
	Sodii Sulphocarbolutis	āā gr xv	Infusi Gentianæ Co. (N.F.)
	Tincturæ Cardamomi Co.	℥xx	q.s. ad ʒj

Three times a day twenty minutes before meals.

When the patient's condition calls for a little bromide, 10 to 15 gr. of the sodium salt may with advantage be substituted for the sulphocarbolute of soda, and it is sometimes an advantage to add 10 or 15 gr. of bismuth to the mixture.

Insomnia is often a distressing symptom in neurasthenia, but should, as far as possible, be counteracted by massage and measures other than the administration of drugs. When, however, all other means fail, and it becomes imperative to have recourse to drugs, medinal (7 or 10 gr.) or trional (10 to 20 gr.) usually proves the best hypnotic in these cases, and it rarely happens that these drugs fail to effect what any drug other than morphia can. Luminal is also effective, but may cause a skin eruption if taken for any time. Morphine should be avoided at all costs in the treatment of neurasthenia, for the danger of the morphia habit being acquired is much too great. (See INSOMNIA.)

Massage is an essential in the treatment. The nurse on day duty may be a masseuse, and may carry out this treatment in the case of female patients; but even with them, it often happens that it is better to introduce another masseuse, who comes to the patient twice a day. This makes a pleasing break in the monotony of the day; but individual cases must be treated on their own merits, and in any case the masseuse must be carefully selected, and must clearly understand that she is not to be the bearer of news which could not otherwise reach the patient. In the case of male patients it is always well to introduce a masseur in this way, with the same injunctions.

It is well to arrange for the patient to be massaged between breakfast and lunch, and at some time in the afternoon, except when insomnia is troublesome: the massage may then be better given in the evening instead of in the afternoon. The former plan has the great advantage of dividing up the day for the patient, and thus helping to pass the time. The massage, however, must not be given too soon after a meal, and at least an hour should elapse, after the treatment, before the next meal is taken. Ten or eleven in the morning, and four or five in the afternoon, are good hours for this treatment. It is usually possible to commence by giving massage for half an hour twice a day, but this may be too much in cases of extreme nervous exhaustion, when it may be possible for the treatment to be given only once a day. The amount is gradually increased, so that, as a rule, in favourable cases it occupies an hour twice a day by the end of the first week. During the second week, passive movements may be added, and by the third or fourth week, resistance movements may be commenced, assuming that the patient's condition is such that a course of six weeks' treatment is all that is needed. In more severe cases this may be too soon for the resistance exercises to be commenced, and indeed in some this part of the treatment has to be omitted altogether.

In some patients general faradism may be added with advantage during the third week of treatment, when the interrupted current should be substituted for half-an-hour's massage in the morning, and the electrical treatment should be immediately followed by the massage, so that any chilling effect from the exposure during the electrical treatment may be counteracted. In many cases, however, electricity in any form proves too stimulating, and is best avoided, as far more good is derived from the massage alone than when it is combined with electricity.

After the treatment the patient should be left wrapped in the blankets in which the massage has been carried out, and should be encouraged to sleep. The room must be darkened, and whether sleep is obtained or not, the patient must lie quietly resting for at least an hour after the treatment, during which time no talking, reading, or any other form of occupation is to be permitted.

Towards the end of the course of Weir-Mitchell treatment, when the patient is being allowed to go out for drives, massage should be given only for an hour every morning, and if electrical treatment has been hitherto carried out, it should now be omitted. It sometimes happens that it is desirable to have the patient massaged for half an hour in the evening instead of in the afternoon, but in no case should the afternoon massage be continued after the patient has begun to go out, although a little massage to the head and spine may be permitted at bedtime, if required, as an aid to securing sleep.

After a course of treatment of this kind, the patient should be sent to the seaside or to some bracing inland place for a few weeks; in some cases a more prolonged rest is needed, when one of the health resorts in Switzerland, or a sea voyage, is to be recommended, and if the degree of nervous exhaustion be but slight, this may be all that is necessary. As a rule, however, patients who are ill enough to require a sea-voyage or a long rest at a mountain

resort, do best if they commence their cure by a course of Weir-Mitchell treatment.

This is the plan of treatment that proves most successful when the neurasthenic state has been induced by the shock of an accident, so that whenever it is possible, all cases of traumatic neurasthenia should be subjected to a thorough course of Weir-Mitchell treatment as early as possible. It cannot, however, be said that treatment on these lines is sure to effect a cure, even when the disturbing influences of litigation do not exist, so that many of the other forms of treatment recommended in neurasthenia may have to be tried. None of these, however, offers such a good chance of success as a "rest cure" properly carried out on the lines already indicated. It is a common experience that, as long as litigation is pending, little good results from treatment of any kind, and it has, accordingly, often been suggested that a large cheque in compensation proves the best cure for traumatic neurasthenia. True as this is in some cases, it is by no means always so, and, moreover, it must be remembered that many people who have nothing to gain by being ill suffer from traumatic neurasthenia, and that some of these are very anxious to get well in order to be able to enjoy the form of sport in which they were engaged when they met with their accident.

In sending patients to the mountain cures, due regard must be paid to the state of the heart, and as to whether insomnia is a notable symptom. Neurasthenics with weak, irritable hearts do badly at high altitudes, and insomnia is aggravated under like conditions; so that, whereas St. Moritz, Mürren, and Caux are excellent places for many patients, the altitudes are too great for others, who do infinitely better at places like Montreux and Territet.

When the patient is well enough, the outdoor pastimes of skating, tobogganing, etc., should be indulged in, but care should be taken not to overdo these, as it is essential that all exercise should be indulged to a point short of undue fatigue.

Other health resorts to be recommended are places like Pau and Biarritz, but in most cases the patients must be under conditions that permit of their seeing all that is going on around them without its being necessary for them to take too active a part in the life and amusements, as these may be too fatiguing for them. Golf is the best outdoor exercise for patients at both these places.

When too ill to tolerate the active life going on at resorts like the foregoing, Argelès and St. Jean de Luz supply the conditions of restful repose that many of these people need.

Others, not ill enough to make a "rest cure" necessary, do well under a course of hydropathic treatment. On the season of the year must largely depend which establishment is selected for the cure, but it is as a rule best to avoid a hydropathic during the usual holiday season in the summer, as these places are then much too crowded to secure for the patients the restful conditions that are so necessary if the hydropathic measures are to succeed.

Baths of various kinds do good, notably electric baths and the needle bath, while the alternate hot and cold douche to the spine is especially efficacious in many cases. When baths and douching prove too exhausting, wet packs often do good, and in any case packs for the liver are especially advantageous when it and other organs of digestion are in a torpid state, as so often happens. Hydropathic measures may with advantage be followed by ordinary rubbing, or skilled massage.

Irrespective of the particular form of treatment, it is essential that the patient should be made to rest in the recumbent posture for at least an hour after it. Without this rest, the treatment aggravates rather than ameliorates the condition of many patients.

Mucous colitis forms a prominent part of the clinical picture of some patients

suffering from neurasthenia, and those who regard the bowel condition as primary, recommend that the colon be washed by the Plombières douche, either at Plombières or at some other spa where the treatment is in vogue.

In like manner, treatment at many spas proves advantageous to certain people suffering from neurasthenia, and a case eminently unsuited to the Weir-Mitchell treatment may do well at Harrogate, Homburg, Karlsbad, Marienbad, or similar places. Many neurasthenics require treatment that is directed towards aiding in the elimination of deleterious products from the system, rather than rest in bed and overfeeding. Indeed, overfeeding, excess in alcohol, and want of exercise, have much to do with the neurasthenic state into which many such patients have fallen. Harrogate or Homburg will do far more for such a case than the most carefully conducted "rest cure." Care is, however, required not to deplete these patients too energetically and rapidly. Due regard should be paid to the fact that the element of nerve fatigue has to be contended with, as well as the effects of effete products which are acting harmfully on the system. The Turkish bath is a useful measure in this class of case, and patients who are unable to go to a spa may take one or two Turkish baths a week with advantage. The Russian bath, which may be taken in the patient's own house, is a good substitute, and radiant heat baths of various kinds are of like advantage. In addition to these, light baths have a sedative effect in many cases, but it may not be desirable to continue them to the stage of causing very profuse diaphoresis. The stimulating influence of the carbonic acid baths of Nauheim is most useful, and a cure at this spa is especially to be recommended in cases in which the heart is weak. When a good reaction is obtained after it, a cold bath in the morning is excellent, but in many neurasthenics the circulation is too feeble to permit of this, in which case a tepid bath may be taken, followed by a cold sponge, or spray, down the back. If insomnia is one of the symptoms, a hot bath at night is often most successful. When an ordinary bath of this kind does not have the desired effect, the patient may be advised to remain immersed in the water for about half an hour, as this plan may succeed when an ordinary bath fails.

Various applications of electricity are recommended in neurasthenia, and do good, notably when combined with other forms of treatment. It is, however, exceptional for electrical treatment to do all that is required unaided. Static electricity and high-frequency currents prove successful in some cases. Usually, however, all that the latter effects is a temporary sense of refreshment and a feeling of well-being, without any permanent good resulting. Those who recommend this method of treatment lay stress on the importance of the state of the blood-pressure as to whether or not good is to be expected. Faradism, combined with massage, in the Weir-Mitchell treatment, has already been referred to, as have the good effects of the electric bath among hydropathic measures that have been found of service.

The Swedish method of treatment by massage, exercises, and vibration proves beneficial in some cases, as do the mechanical methods of the Zander Institute. But these procedures are apt to prove too fatiguing, except in the slighter cases, or those which have reached a certain stage in their recovery under more restful measures, and who now require some new form of treatment to help them further. Change of method is often essential if the patient is to be helped to get well, so that those who have to deal with neurasthenia cannot have too great a variety at their command when dealing with obstinate cases.

Suggestion plays a large part in the good that is effected in many cases; so that where one method of treatment fails to impress the patient, another may succeed. Suggestion and hypnotism both find a legitimate place in the cure of

neurasthenia, provided they be judiciously employed in suitable cases. In suggestion we have a means of dealing with the fixed ideas and obsessions that haunt many of these unfortunate patients that cannot be equalled by any other method of treatment, and in hypnotism we have a means that may succeed in procuring sleep when drugs have failed to do so. The latter method cannot be so lightly undertaken without risk of harm as the former; but even hypnotism, properly conducted, and in suitable cases, has its place among the therapeutic measures that may be employed to relieve such patients of their distressing symptoms.

What has been said in regard to the Weir-Mitchell treatment gives a good idea of what is needed in the dietary of a patient, but it is necessary to refer again to the fact that in many cases the neurasthenia has been largely produced by over-eating and excessive indulgence in alcohol. In many patients of this class, much good is effected by total abstinence from all stimulants, and it is often advisable not only to reduce the total quantity of food taken, but to withhold butcher's meat altogether for a time. Fish, white meat, vegetables, and milk puddings supply most of what such people need. What vegetables are to be permitted, and whether farinaceous puddings are to be allowed, must depend on the individual case, and be decided by the usual rules, irrespective of the neurasthenia.

Orchitic extract, administered by intramuscular injection, alone or in conjunction with extracts of certain of the glands of internal secretion and strychnine, does undoubted good in some cases. Intramuscular injections of strychnine also do good in suitable cases, and a useful combination has been found in cacodylate of strychnine and glycerophosphate of soda.

Drugs, however, play but a minor part in this malady, but they can rarely be dispensed with at some time or other during the treatment. Enough has been said of the need there is for aperients, and of the value of calomel. Many patients suffer from dyspepsia, when the alkaline mixture that has been recommended in connection with the Weir-Mitchell treatment is most useful. In other cases good is effected by a mixture of strychnine and hydrochloric or nitrohydrochloric acid after meals. Great caution is needed, however, in the use of strychnine in neurasthenia, as in many cases it increases the nervous irritability, and when insomnia is a feature it aggravates this symptom. When the drug is otherwise well borne, but disturbs sleep, a good plan is to give a dose in the morning and after lunch, but none later in the day. Nux vomica may be added to the alkaline mixture before meals, with advantage in many cases, provided the same precautions are observed. Arsenic is excellent in many cases, and has the advantage that it does not interfere with sleep, although it may have to be discontinued owing to intolerance by the stomach. Phosphorus is another tonic that is recommended, and lecithin, ovo-lecithin, and phytin all do good. Iron does good where there is anæmia, if the stomach is not intolerant of the drug and constipation is not troublesome, while hæmoglobin also is useful. The glycerophosphates alone, or combined with arsenic or strychnine, are most useful, and the combination of acid glycerophosphates with formates deserves a trial, as do the preparations of the polyformates. Two or four tabloids, each containing 5 gr. of the polyformates, may be given three times a day before food. The remedy is supposed to be especially serviceable in increasing nerve energy, and in thus improving the symptoms of physical exhaustion, which are often so prominent. Neurosin is another much vaunted remedy which deserves a trial. The bromides are most useful if judiciously employed, and under their influence, not only may insomnia be combated, but the nervous irritability may be subdued, and even mental depression removed. The sodium or ammonium salt should be employed, and except when given for insomnia, it is well to combine the

bromide with arsenic alone or with nux vomica also. Belladonna or sumbul is a useful addition in some cases, and when there is an emotional tendency, the inclusion of valerian in the prescription is beneficial. Bromocarpine is an excellent substitute when the bromide salts are not satisfactory. Heart weakness may call for the use of drugs like digitalis or strophanthus, but more usually strychnine does all that is needed. When strychnine is contra-indicated, however, either of the other two drugs may be given to improve the condition of the heart. The addition of nitroglycerin is sometimes of advantage in aiding the circulation, but apart from this, a few doses of this drug alone, or in combination with strychnine, may remove the feeling of cloud in which the neurasthenic's brain so often seems involved, and the most refreshing sense of well-being may follow this plan of treatment. When other measures fail to secure sleep, the best hypnotics are medinal or trional, though any of those commonly in vogue may be tried if these fail. It cannot, however, be too strongly insisted that morphine should be avoided, as these patients so readily acquire the drug habit. For the same reason it is most inadvisable to prescribe cocaine, although it is certain that a sense of well-being may often be secured by the use of this drug.

J. S. Risien Russell.

NEURITIS.—Under this term many conditions have been included which differ markedly, not only in their clinical manifestations and pathology, but also in their treatment. The following principles may be laid down as applicable to the treatment of the disease in general.

1. *Removal of the Cause*, whether due to metallic, organic, or other forms of poison. Workers in lead, painters, artists, should give up their work, or take precautions to prevent the metal entering the system. Possible poisoning by lead or arsenic taken as a drug or in beer, must be borne in mind. Chronic discharges should be treated, infected wounds attended to, and infected teeth removed.

2. *Rest*.—This is of the first importance; in most cases the patient should be kept in bed, but in cases of a localized neuritis, rest to the affected part may be sufficient.

3. *Diet*.—The use of alcohol in any form should be prohibited. A full and generous diet is in most cases advisable, but in gouty, diabetic, and rheumatic neuritis a diet suited to these conditions should be advised.

4. *Massage, Baths, and Electricity*.—These remedies should not be used during the acute stage, but later they are most valuable in promoting and restoring the function of the muscles.

Passing from such general considerations, the treatment of peripheral neuritis due to alcohol and metallic poisons may be taken as an example, and will be considered in detail. Since, however, the treatment varies with the course of the disease, it will be dealt with under three headings, according to the stage of the disease.

- 1st Stage.—Cases seen and recognized early, when there are pain and tenderness of the muscles with but little loss of power, and the reflexes are still present if not actually exaggerated, generally respond well to treatment. This should consist in placing the patient at rest in bed, diet being carefully regulated, and alcohol in any form absolutely excluded. It is especially important to see that these patients take their food well, and have what they like and can digest, for it not infrequently happens that by cutting off alcohol they lose their desire for food, and under such depressing conditions no improvement can be looked for. The administration of strychnine with some diluted phosphoric acid will often be sufficient to stimulate the appetite again, but in other cases some tincture of capsicum in an alkaline mixture with a small amount of sodium

bromide seems to act better. It is advisable also to give the patient a small dose of calomel ($\frac{1}{6}$ gr.), or blue pill, at bedtime. Sleeplessness is best treated by one of the salts of bromine, but paraldehyde, amylene hydrate, chloral formamide, veronal, trional, or chloral may be given if necessary. Paraldehyde and amylene hydrate are best given in capsules. Chloral formamide should be given with spiritus ætheris nitrosi in a dilute acid mixture; it is incompatible with alkali. It will be found that early cases rapidly respond to this form of treatment, and after a few days' rest in bed, gentle massage and exercise are beneficial. These patients, however, usually require prolonged supervision. They do well under the routine of hydropathic treatment, and the regulated mode of life ensured in such institutions is most beneficial.

2nd Stage.—In this stage there is considerable loss of power in the muscles, with very marked tenderness not only of the muscles but also of the nerve trunks, blunting of sensations over the peripheral portion of the limbs, and changes in the vasomotor condition of the skin: the patient should be kept absolutely at rest (preferably on a water bed), not only on account of the condition of the limbs, but also because of the liability to sudden syncope. He should not be allowed to sit up or strain at stool. The limbs should be wrapped in cotton-wool, and for the relief of pain hot fomentations or dry heat may be applied. During this stage also, the prohibition of alcohol should be made absolute, and other cardiac stimulants, strychnine, digitalis, and carbonate of ammonia, should be used to combat the depression which the withdrawal of alcohol is certain to produce. The legs should be placed on splints as soon as the acutest stage of the disease is over, in order to diminish as far as possible the tendency to muscle contraction; this can be most conveniently accomplished by a well-padded leather splint with foot-piece at right angles, kept in that position by two elastic springs, by a board placed at the bottom of the bed, against which the sole of the foot presses, or by a celluloid splint moulded to fit the limb. Diet is of the greatest importance, and great care has to be exercised in selecting suitable articles of food and such as are easy of digestion; for vomiting not infrequently occurs, and may be attended with considerable prostration. In persistent vomiting, it may be necessary to have recourse to rectal feeding. Massage and passive movements are now not only useless, but give rise to great pain and discomfort, and should not be employed. It is difficult to say exactly when massage may be begun, but as a rule when gentle pressure on the calf muscle can be borne, it is safe to begin a modified massage. Two to three weeks of complete rest may in some cases be sufficient, but a longer period is usually required. With regard to drugs, few are of much service, except those above mentioned, to which bromide may be added. Morphia may be necessary in some cases, to relieve pain.

3rd Stage.—In this stage of the disease, when there is marked wasting of the muscles, often with considerable contraction, massage, active and passive movements, and electricity in its various forms, should be employed. It is important in this stage also that the limb should be placed in a splint, so that the paralyzed muscle may be kept at rest and deformity prevented; and for this purpose a light celluloid splint moulded to fit the limb is most suitable. If the muscles no longer respond to faradic stimulation, or respond very feebly, a galvanic current is the most suitable application, and may be made direct to the skin or by means of a bath. If considerable contraction of muscle has taken place, tenotomy may be necessary, but it is surprising how much relaxation can eventually be obtained by the use of hot-air baths and passive movements.

In certain cases of peripheral neuritis in which there is loss of the sense of position to a considerable degree—so-called “neuro-tabes”—the use of Fraenkel's exercise board is of great service in re-educating the muscles in the

exact performance of their work ; and similarly, the use of a cribbage or solitaire board for the hands is of great educational value.

The outlines of treatment above indicated are applicable to neuritis due to metallic poisons, such as arsenic and lead, but it is important in these cases to supplement the treatment by drugs. It is generally held that iodide helps the elimination of lead from the body, and hence this drug is often given. Cod-liver oil, malt, iron, and hæmoglobin are also valuable adjuncts in treatment.

Two of the most troublesome symptoms in neuritis are pain and sleeplessness. With regard to the former, much can be done by careful support of the limbs, cradling them so that the bedclothes do not come in contact with them, and by a water bed. In addition, it is often necessary to use such drugs as phenacetin, acetyl-salicylic acid (aspirin), acetanilid, exalgin, and citrated caffeine. Morphia should if possible be avoided, but there is no doubt that it has more effect in diminishing pain than any other remedy.

In the treatment of sleeplessness, paraldehyde and amylene hydrate are useful drugs, and are to be preferred to chloral, veronal, trional, and sulphonal, especially at the period when there is danger of cardiac failure.

Apart from the general condition above described, neuritis may be, and often is, limited to a single nerve, such for instance as the ulnar or external popliteal, the former giving rise to wasting of the small muscles of the hand, the latter to a localized foot-drop. Such a neuritis may be due to a traumatic or local condition, or may occur in association with some general toxic condition, such as rheumatism, diabetes, or gout, and it is of special importance in these cases to search for the local cause. An ulnar neuritis may, for instance, become manifest many years after an old fracture of the elbow ; or again, wasting of muscles and alteration of sensation in the distribution of the first dorsal root or of the ulnar nerve may develop in association with the presence of a cervical rib. The above instances are given to enforce the point that a local cause should always be most carefully sought for in cases of local paralysis. The general lines of treatment above laid down should be adopted in these cases. Rest and warmth are of the greatest importance. Massage should be applied locally, and the nutrition of the muscles maintained by faradism and galvanism. The local hot-air bath is also of service. (See also ELECTROTHERAPEUTICS.)

F. E. Batten.

NEUROMATA.—Under the term neuromata, all nerve conditions which lead to tumour formation are included. They can be divided into the true and the false. A true neuroma is made up of nerve cells and nerve fibres ; it is an extremely rare tumour, and in four out of the five authentic cases recorded was connected with the sympathetic system. The false neuromata can be divided, as suggested by Alexis Thomson, into the circumscribed and the diffuse, and again into the innocent and the malignant. The circumscribed include all forms of innocent tumour growing from the connective tissue of the nerve, the so-called neurofibroma, myxoma, and also the painful subcutaneous nodule.

The symptoms, when a nerve containing sensory fibres is involved, are those of a tender tumour, the pain on pressure being referred to the peripheral distribution of the nerve. Sensation and motion are as a rule little interfered with ; if anæsthesia and muscular wasting are present, we should think at once of diffuse fibrosis of the nerve due to long-standing irritation, or of sarcoma.

The diagnosis rests on the discovery of a tumour in the course of a nerve, usually movable laterally, not in a longitudinal direction ; in a mixed or sensory nerve it is usually tender ; in the painful subcutaneous nodule the tumour originates around one of the terminal filaments of the nerve, and the diagnosis is made by the symptoms which correspond to its name.

The painful nodule should be excised, and the other tumours shelled out from the connective-tissue sheath of the nerve; this is rarely impossible; if it be, the tumour must be resected and the continuity of the nerve restored.

Under the heading of neuroma are also included the end bulbs formed on divided nerves. After amputations these may give rise to trouble. Their formation is physiological, and it is not until pressure or traction is brought to bear on them that they give rise to symptoms. Pain brings the patient under observation; it is usually of a shooting character, and may be referred to the absent limb or be accompanied by muscular spasms. The bulb should be freed and excised as high as possible. If this fail to relieve the pain in long-standing cases, division of posterior roots should be performed.

Localized malignant neuromata belong to the group of sarcomata, and grow from the sheath of the nerve. Unlike the innocent tumours, they cause progressive interference with the functions of the nerve. They are met with most often in connection with the sciatic nerve or one of its primary branches, but are fortunately rare. Conservative treatment has been of little avail. If it is considered a suitable case in which to try this, a large extent of the nerve must be removed and its continuity restored by one of the methods previously mentioned. In the case of the sciatic, amputation is the best treatment.

Under the term diffuse neuroma are grouped the conditions known as multi-form neuromata, molluscum fibrosum, plexiform neurofibromata, etc., and the secondary sarcomata which are liable to originate in them. Surgical interference in these cases should be entirely symptomatic, nothing being done unless individual masses are painful or in other ways interfering with the well-being of the patient. It has been repeatedly noticed that operative interference has been followed by increase in the size and number of the tumours.

James Sherren.

NIGHT TERRORS.—Bad dreams always indicate ill-health, which may be trivial and temporary, or serious and lasting. They should not be regarded merely as humorous consequences of over-eating.

Night terrors and nightmare differ only in the degree of intensity of the fears which they inspire. Stolid, unimaginative children may suffer from *nightmare*. They awake screaming, in consequence, but are little the worse next day. But neurotic children with active brains are afflicted by *night terrors* which haunt them during waking hours. Their dread of "witch-ridden pillows"—dread which they often keep to themselves—may destroy their health of mind and body. Even when the nature of the frightful dream-hallucination is forgotten, its effects may remain. Possibly chronic nervous dyspepsia and a large proportion of functional neuroses are traceable to repeated but unsuspected night terrors.

The classification of night terrors into "idiopathic" and "symptomatic" is artificial. All are probably symptomatic, in the sense that they are excited by local, dimly felt, external or internal impressions. All are idiopathic, in the sense that the interpretation of such impressions is entirely the dreamer's own.

TREATMENT.—Night terrors, being the result of dimly felt external or internal impressions upon a morbidly excitable brain, should be treated by correction or removal of exciting causes, and by endeavouring to quiet the emotional temperament of the child. In addition to bad atmosphere in the bedroom, and uncomfortable beds and heavy bedclothes, the chief exciting causes are adenoid vegetations, perhaps errors of refraction, and bodily pain of any kind. Many sufferers are undoubtedly rheumatic, and of the so-called gouty or uric acid diathesis; many are subject to what has been called "mucous disease," in which the bowels are constipated or relaxed, the motions contain excess of mucus, threadworms are often present, and complaint is made of abdominal

pain or discomfort. In other cases, also, cyclical albuminuria is met, with all its curious vasomotor disturbances. In many, delirium caused by pyrexia accounts for terrifying visual hallucinations. All such conditions require treatment, but it must be remembered that neither one nor all of them constitute the whole cause. Removal of adenoids, scybala, intestinal mucus, and parasites, correction of refractive errors, anti-rheumatic remedies and tonics, will not in all cases provide a cure. Children who brood all day over the recollection of some frightful dream, are apt at night, as Charles Lamb expressed it, to "wake into sleep, and find the vision true." The idea that they can be taught not to be afraid of darkness by exposing them to it, cannot be too strongly condemned. Yet many parents and guardians still persist in thinking that a neurotic child's plea for a night-light should be met with derision and scorn.

It is necessary to correct their morbid tendencies to gloat over terrors seen and unseen, to protect their active, sensitive brains from educational over-pressure, to shield them as far as possible from thoughts, words, sights, and deeds which are calculated to increase their emotional proclivities.

Treatment by Drugs.—Bromides are always essential. A dose of 5 to 10 gr. of bromide of potassium, an hour or so before bedtime, is often sufficient to secure a night's rest. Chloral hydrate, $2\frac{1}{2}$ to 5 gr., may be added. Fright usually upsets digestion, gastric and intestinal, and indigestion of either kind excites night terrors. When it can be ascertained that chronic fear and dread complete the vicious circle, bromides, besides wholesome consolation, suitable diet, and drugs which aid digestion and elimination, are needed. Bromides may be combined with bismuth, gentian, rhubarb, castor-oil emulsion, in gastro-intestinal troubles; with ferri et ammonii cit. in anæmia; with strophanthus, digitalis, citrated caffeine, when cardiac stimulants are required; or with nux vomica and hypophosphites in emulsion of cod-liver oil in debility. In rheumatic cases, salicylate of quinine and acetyl-salicylic acid (aspirin) in 5-gr. doses are valuable drugs. Quinine as a rule is not well borne by highly neurotic children; when given, it should be with hydrobromic acid.

In cases of mucous diarrhœa, citrate of potash often acts well, and is also useful when night terrors are associated with enuresis and the presence of concentrated, highly acid urine containing *B. coli* (see BACILLURIA).

Leonard G. Guthrie.

NIGHTMARE.—(See also NIGHT TERRORS.) A patient who suffers from recurrent nightmare should sleep on a hard mattress with few bedclothes, and should keep the feet warm either with bed-socks or a hot bottle. He should avoid lying on the back, if necessary by having recourse to some such device as tying an empty reel over the sacrum, and should eschew heavy suppers. If there be any tendency to constipation, a compound rhubarb pill should be taken at bedtime. If he wakes after the nightmare, he should get up and swallow half a tumblerful of hot water to which a teaspoonful of sal volatile has been added.

Robert Hutchison.

NIPPLE, DISEASES OF THE.

Cracks, Fissures, Eczema.—These conditions occur mainly in patients with retracted or imperfectly developed nipples, and during the first lactation. They cause much pain, interfere with suckling, and may give rise to acute mastitis or abscess. If the nipples are retracted the child has difficulty in seizing and retaining them, and its repeated attempts to do so lead to excoriation of the epithelium.

TREATMENT.—During the later months of pregnancy careful attention must be paid to the cleanliness of the nipples. All dried secretion must be regularly removed, and the nipple washed with a weak alcoholic solution, or with eau de

Cologne and water, in order to harden the epithelium. If the nipples are retracted, the patient should be taught to gently draw them out each day. This procedure will usually put matters right before lactation commences, but if it should fail, the best plan is to regularly draw them out with the exhausting pump. Care must be taken to see that the corsets do not irritate the nipples.

If cracks or fissures form, they should be treated at once, as the inflammation is liable to spread to the breast. One of the following applications should be used : (1) Equal parts of glycerin. ac. tannici and a solution of 1-20 of carb. acid. ; (2) Glycerin. borac. (B.P.) ; (3) Sol. 1-1000 biniod. merc. These should be washed off with warm water before the child next takes the breast.

If one nipple is sore, it should be rested for two or three days. If both are slightly sore, an attempt should be made to continue suckling. If both are severely affected, suckling should be stopped ; for three or four days the nurse should milk the breasts, so that their secretion be not arrested ; if, however, after this, the nipples have not recovered, the child must be weaned.

Obstinate fissures should be treated by the application of pure carbolic acid on a fine probe.

Paget's Disease of the Nipple.—This is a cancerous disease, and is secondary to a growth situated deeply in the breast tissue. The treatment is that of malignant disease of the breast ; the " radical " operation described elsewhere (see BREAST TUMOURS) should always be performed. Less extensive operations involve a proportionately greater chance of recurrence. Caustics, ointments, and other local remedies are useless.

T. Crisp English.

NOMA.—(See STOMATITIS.)

NOSE, ABNORMALITIES OF.—(See SEPTUM NASI, ABNORMALITIES OF.)

NOSE, ACCESSORY SINUSES OF.

ACUTE SUPPURATION.

In cases of acute nasal catarrh, if suppuration in one of the accessory sinuses be suspected, prompt and energetic treatment should be carried out to hasten the cure and to minimize the risk of the affection becoming chronic. The patient should be confined to a warm room, kept in bed when possible, and treated energetically as for a severe cold (see RHINITIS, ACUTE). Local pain may be relieved by the application of moist or dry heat to the affected area. Hot steam inhalations are often useful.

If there are symptoms indicating the *retention of pus* in a sinus, measures must be adopted to reduce the swelling round the outlet of the cavity, and thus to obtain a free escape for the discharge. Small pledgets of wool soaked in a solution of cocaine and suprarenal extract are packed up into the nose as near as possible to the opening of the sinus. After five to ten minutes these pledgets are removed and others inserted still further in. By this means it is usually possible to reduce the swelling around the ostium of the sinus, when a free flow of discharge at once commences, with immediate relief to the symptoms. When this has been secured, an attempt should be made to keep up the astringent effect by frequently washing the nose with a warm alkaline solution to which a few drops of extract of witch hazel have been added. The nose should also be sprayed frequently with a 2 per cent solution of menthol in oil, which is not only astringent but soothing.

If these means fail, local blood-letting should be tried. Incisions should be made along the under surface of the middle turbinate and along the outer wall of the nose. These incisions are usually followed by free bleeding which relieves the congestion.

If, after applying cocaine, polypi or œdematous hypertrophies are seen in the middle meatus, they must be removed. Also, if the middle turbinate is greatly enlarged and pressing against the septum, it will be necessary to remove its anterior end, but this should never be done until other means have failed.

When once a free escape for the discharge has been obtained, the natural tendency of acute cases is to heal spontaneously, although the discharge may continue for some days or even weeks. Occasionally there may be recurrence of the swelling with retention of the discharge, and yet ultimately complete recovery.

When there is a purulent discharge from a sinus, of recent origin, without any symptoms of retention, the treatment as for acute rhinitis should be pursued for a time, and when the patient's general condition improves, he should be given a tonic and sent away for change of air. For how long it is wise to continue this treatment is a most difficult question, and depends largely upon the patient's circumstances, and also upon the sinuses which are affected. For example, if the antrum is affected, it is wiser to take active measures to evacuate the cavity far earlier than would be done if the frontal sinus is affected. It will therefore be convenient to discuss the treatment of each sinus separately.

Antrum.—If signs of suppuration in the antrum continue three or four weeks after all signs of acute inflammation in the nose have passed off, it is, in my opinion, safest to puncture the cavity and to wash it out. It is true that spontaneous recovery may still take place; yet there is a certain, if small, risk of the disease becoming chronic, and the longer the pus is allowed to remain in contact with the delicate lining membrane of the antrum, the greater the chance of its being permanently damaged. On the other hand, puncture of the antrum is exceedingly simple, gives rise to little inconvenience at the time, and to no subsequent ill-effect, and often one puncture is sufficient to effect a permanent cure.

If the trouble is probably *nasal in origin*, and there are no carious teeth in proximity to the floor of the antrum, the puncture is best carried out through the inferior meatus. Pledgets of wool soaked in a solution of cocaine and suprarenal extract are packed under the inferior turbinate close against the outer wall of the inferior meatus. When the parts are anæsthetic, a small trocar and cannula, such as Lichtwitz's, is pushed through the thin antro-meatal septum, and the antrum irrigated through the cannula with warm boracic lotion. In recent cases one puncture is often sufficient to effect a cure, but the operation may have to be repeated at intervals of one or two days if there is sign of re-accumulation of the discharge.

If the disease be apparently due to *dental trouble*, the best plan is to remove the offending tooth, and to perforate the antrum through the tooth socket. The method is described in connection with chronic antral suppuration (q.v.). Irrigation is carried out with warm boracic lotion, and it is better to maintain the opening for a day or two by inserting a small tube until it is quite certain that all the discharge has ceased. The prognosis is exceedingly good: practically all cases recover if treated properly and in time.

Frontal Sinus.—In acute sinus suppuration the treatment depends to a large extent upon the nature and severity of the symptoms. If the patient complains of great pain, continuous or recurring daily, and so severe as to incapacitate him completely, when the means above described have definitely failed, external operation must be carried out. If the pain and other symptoms are not very severe, the anterior end of the middle turbinate should be removed and the patient treated with nasal sprays and lotions, with general tonics, and change of air. If this treatment fails, external operation is necessary. In the still milder cases, which are commonly seen, in which the patient has a headache or feeling

of severe discomfort for an hour or so every morning, followed by nasal discharge, expectant treatment should be adopted. The patient should be given a plentiful, nutritious diet, a strong tonic, such as iron and strychnine, and if possible should be sent away for change of air. Any dry, warm, healthy place may be chosen, but a sea voyage, if it can be taken in comfort, is especially to be recommended.

Ethmoidal Cells and Sphenoidal Sinus.—The treatment of acute ethmoidal or sphenoidal suppuration is essentially similar to that of chronic (q.v.). If there is no immediate danger, the disease should be treated through the nose; if orbital, cerebral, or other urgent complications are present, an external operation is necessary.

CHRONIC SUPPURATION.

Although it is convenient to describe the treatment of each sinus separately, it must be remembered that frequently many sinuses are simultaneously involved, and the disease must be treated as a whole rather than as a series of unconnected affections. The cure, even the diagnosis, of suppuration in one sinus often depends upon the recognition and treatment of suppuration in the others. The treatment is essentially surgical, and its objects are: (1) The removal of any intranasal disease, and especially the removal of any polypus or œdematous hypertrophy, so as to make a free approach to the nasal opening of the affected cavity; (2) The evacuation of the discharge and the cure of any pathological condition within the cavity, such as disease of the lining mucous membrane or bony walls of the sinus. When these means fail: (3) The provision of permanent free drainage; or (4) The obliteration of the affected cavity. In the first place the milder measures, (1) and (2), should be tried, and if these fail, the more radical treatment should be recommended. It need hardly be added that every means should be adopted to keep the patient in good general health. General treatment will not only expedite a cure, but will often render successful a smaller operation than would otherwise be necessary.

When many sinuses are affected, in the absence of any urgent symptoms indicating a particular sinus, the order in which they should be treated must be considered. If the anterior set of sinuses is involved, it is generally best to open the antrum first; then if pus still continues to come from the nose, the anterior ethmoidal cells should be attacked, and finally the frontal sinus should be explored. If, on the other hand, there is extensive polypoid degeneration, it is best to commence the treatment by performing a radical operation upon the ethmoidal region. As this requires general anæsthesia, the opportunity should be utilized of exploring the antrum, and of draining it if necessary. If all the sinuses are affected, it is best to treat the anterior set first, then the posterior set.

Antrum, Maxillary.—If there are no external complications indicating disease of the walls of the sinus, one of the simpler methods should be invariably adopted in the first instance.

When carious teeth are present, and especially when it seems probable that the suppuration is of dental origin, the affected tooth should be removed and the antrum punctured through the tooth socket. It is easiest to puncture the antrum through the inner socket of the first molar, but the operation may be equally well performed through the socket of the second molar, of the second bicuspid, or even of the first bicuspid.

Nitrous oxide anæsthesia is sufficient. The alveolar process is grasped by the left forefinger and thumb, and a small antrum drill is pushed upwards and inwards with a rotary motion until the floor of the antrum suddenly gives way. Care must be taken to avoid injury to the floor of the orbit, by having a guard upon the instrument or by steadying it with the tip of the right fore-finger. The

cavity is syringed out with a solution of boracic acid or other mild antiseptic lotion. If pus be found, the opening is kept patent by inserting a small silver tube, such as Ellis's spiral wire tube, or a dentist may make a special gold tube and fix it to a neighbouring tooth. Twice daily the tube should be removed and boiled, the antrum syringed out with boracic lotion, and the tube replaced. As the discharge lessens it will be sufficient to syringe once a day, and if all goes well the intervals are gradually lengthened. If no pus is obtained after the syringing has been omitted for a week, the tube may be left out and the opening allowed to close.

If after careful treatment pus is still found in each washing, various other lotions may be used. Peroxide of hydrogen is one of the best; about two ounces should be introduced into the antrum and then quickly washed away with boracic lotion, as it gives rise to much smarting. A weak solution of sulphate or chloride of zinc or sulphate of copper (1 to 3 gr. of either to the ounce) may be used in a similar way. These injections should not be repeated more than twice a week.

The prognosis is always uncertain, but if the operation be reserved for cases of dental origin, at least fifty per cent are cured, and the more recent the disease the more frequent and the more rapid the cure, but no case is too chronic to be cured by this means. In cases of nasal origin the prognosis is less favourable. Lastly comes the question, For how long should the syringing be continued when it is apparently not successful? If there is much pus in each washing after three months, and certainly after six months' careful treatment, a cure cannot be anticipated. In these circumstances a radical operation may be recommended, but if a patient be averse to this he must continue the daily syringing, and with this small inconvenience may live comfortably for years with slight, if any, risk of complications.

When the teeth are sound or the disease is obviously of nasal origin, puncture through the inferior meatus of the nose should be performed. Pledgets of wool soaked in cocaine and adrenalin solution are packed in under the anterior end of the inferior turbinate and against the outer wall of the meatus. When the parts are anesthetized, a small trocar, such as Lichtwitz's, is directed about half an inch behind the anterior end of the inferior turbinate, as high above the floor of the nose and as strongly outwards as possible, and pushed gently into the antrum. The trocar is withdrawn, and the cavity washed out through the cannula with boracic lotion. If pus be found, the operation may be repeated daily, or as often as necessary. Prolonged treatment by this means is impossible, but three, four, or more punctures should be made before resorting to more severe measures. Most recent and a few chronic cases may be thus cured.

A radical operation is necessary when there is disease of the bony walls of the sinus, when there are polypi in the antrum, when it is impossible to syringe through the cavity owing to some obstruction of the natural ostium, or when the simpler measures above described have failed to effect a cure. The cure depends upon establishing a large communication between the nose and the antrum, so as to secure permanent free drainage. The operation, as usually performed, consists in making an incision in the canine fossa at the junction of the gum with the mucous membrane of the cheek, in reflecting the periosteum off the anterior wall of the antrum, and making a large opening through this wall. The interior of the antrum is examined and any polypus or obvious disease removed. The next and most essential part of the operation is to remove the whole of the bony wall between the antrum and the inferior meatus. The opening in the canine fossa is allowed to close, and the after-treatment is conducted entirely through the nose. The patient is taught to wash out the antrum daily with a mild antiseptic lotion until all discharge ceases.

It is much better to carry out this operation entirely through the nose. The anterior third of the inferior turbinate is removed, a large opening is broken through the antro-meatal septum with burrs, and the fragments removed with forceps and curette. The interior of the antrum can now be explored with the finger, and any polypus or other gross disease removed. The large opening thus made remains permanent, and the after-treatment consists in daily syringing until all discharge has ceased.

The results of these operations are good. By the latter method a more speedy cure is obtained, there is less reaction, and the painful swelling of the cheek and other inconveniences attached to the operation through the mouth are avoided.

Frontal Sinus.—Intranasal treatment should be adopted in the first instance, with the object of establishing a free outlet for the discharge into the nose by clearing the way to the lower end of the infundibulum. The anterior end of the middle turbinate and any polypus or other obstruction in the middle meatus should be removed. The anterior ethmoidal cells should be cut away under cocaine, or freely curetted under general anæsthesia. The case should now be left for a time, provided no urgent symptoms are present, and every means should be used to improve the patient's general health.

Occasionally, as the result of disease, a wide communication exists between the sinus and the nose, and a cannula may be passed up the frontonasal duct and the sinus irrigated. This is not an easy matter, and must always be carried out by one who is skilled in the work. No force must be used, as fatal damage may result. Daily treatment is necessary, and unfortunately the result is rarely successful.

When intranasal treatment fails, if the patient is simply suffering from the inconvenience of a little purulent discharge from the nose, he may be well advised to leave it alone, and the nose should be inspected from time to time, so as to prevent or remove any obstruction to the outflow of discharge. If, however, the patient is suffering from urgent symptoms or serious inconvenience, external operation must be considered. There may be severe and frequently recurring headaches completely incapacitating the patient, or the general health may suffer from excessive discharge or chronic septic absorption; there may be disease of the bony walls of the sinus, or an external fistula, when an external operation should be strongly advised. The objects of operation are to obliterate the sinus, or to establish free drainage and allow it to return to its original healthy condition. The former method leads to the most certain and speedy cure, but is liable to produce considerable deformity. The steps of the operation are briefly as follows:—

A curved incision is made in the line of the eyebrow from the supra-orbital notch, downwards and inwards, round the inner angle of the orbit. The periosteum is detached from the inferior wall of the sinus, and an opening is chiselled into it at a spot about the junction of the inner wall and roof of the orbit, immediately above the inner canthus. The mucous membrane is incised, the interior of the sinus inspected, and its extent gauged. If the sinus be large, the affection recent, with no sign of bone disease, and if the prevention of deformity be of importance, simple drainage may be resorted to. When the sinus is small it is best to obliterate it. Also when the disease is of long standing, when the bony walls are affected, or other complication is present, obliteration should be recommended, even though the sinus be large.

When it is intended to drain the sinus, the opening into it is enlarged sufficiently to enable the interior to be examined, and all gross lesions are removed. The infundibulum is freely enlarged with burrs, and a large drainage tube is passed down from the sinus into the nose. This tube is removed daily and the sinus syringed. After ten days it is replaced by a silver tube or rubber plug

shaped like a small tracheotomy cannula, which must be worn and the syringing continued until all discharge ceases.

Obliteration leads to a more rapid and certain cure. The skin incision is prolonged outwards to the outer limit of the sinus, and inwards and downwards well below the inner canthus, so as to give free access to the infundibulum. The periosteum is detached from the whole of the anterior and inferior walls of the sinus, and these walls are cut away with strong bone-cutting forceps. Great care must be taken to open up every recess, and then the entire mucous membrane is removed with curettes. The infundibulum is freely opened up, and the anterior ethmoidal cells exposed and curetted. The skin wound is sutured, but an opening is left for a tube, which should be passed down the infundibulum and worn for three or four weeks, or until all discharge has ceased. The after-treatment consists in applying the usual dressings and in removing the tube or plug, and syringing the sinus once or twice daily, according to the amount of discharge.

When the sinus is large, the deformity resulting from the sinking in of the soft parts after obliteration may be greatly lessened by leaving a bridge of bone running from the inner to the outer side of the sinus in the line of the eyebrow. The operation takes longer to perform, and healing is slower, but maintenance of the line of the eyebrow greatly improves the æsthetic result. It may be adopted in suitable cases, when the avoidance of any deformity is particularly desired and seems worth the extra risk. Also the depression left after an operation, if very unsightly, may be considerably lessened by hypodermic injections of solid paraffin wax.

Ethmoidal Cells.—The treatment depends upon the number of cells affected, and upon whether external complications are present.

1. When one or two cells only are involved, a small operation under cocaine is sufficient. The anterior end of the middle turbinate is removed. The affected cells are carefully located by probing, and their walls broken into with a Hajek's hook and cut away with Grünwald's forceps. This little operation may be repeated if necessary, and gives good results in cases of limited disease, but when many cells are involved it is impossible to effect a cure by this means.

2. When numerous cells are affected, and when there is extensive polypoid degeneration of the ethmoidal mucous membrane, it is better to give the patient a general anæsthetic and to curette thoroughly the whole of the ethmoidal region. The operation is performed with Meyer's ring knives, and the diseased mucous membrane and bone are thoroughly curetted until firm bone is reached. The greatest care must be taken to avoid injury to the cribriform plate, and for this reason the curette should never be directed upwards, but the cutting blade should always be turned outward towards the orbit.

The operation is accompanied by free bleeding, and therefore must be performed under very light anæsthesia and with the patient lying on his side. If the hæmorrhage persists it may be necessary to pack the nose, but this should never be done unless absolutely necessary. The healing may require one to two months, but ultimately the whole upper part of the nose becomes lined by thin white membrane, and all discharge ceases. Should pus still continue to come down into the nose, if it appears anteriorly it must come from the frontal sinus, and if posteriorly from the sphenoidal sinus, which cavities should next be opened.

3. When an ethmoidal cell is bulging into the orbit, when there is abscess or cellulitis of the orbit depending upon ethmoidal disease, or when an external fistula is present, it will be necessary to perform an external operation upon the ethmoidal cells. A curved incision is made around the inner angle of the orbit, commencing near the supra-orbital notch and terminating well below the inner

canthus. The periosteum is reflected from the inner wall of the orbit, thus exposing the orbital plate of the ethmoid. The ethmoidal cells are opened by cutting away this plate with chisels, and are then systematically broken down and removed with curettes or cutting forceps. The wound should be sutured and drainage provided as described in the after-treatment of operations on the frontal sinus.

Sphenoidal Sinus.—This, in spite of its apparently inaccessible position, is commonly one of the easiest sinuses to treat. Unless the nose be unduly wide, as in atrophic rhinitis, it will be necessary to remove the whole of the middle turbinate. The patient should be seated in the usual rhinoscopic position, or he may lie on his side. Suprarenal extract should be applied to the parts half an hour before the operation, and nitrous oxide administered. A spokeshave is passed over the posterior end of the turbinate and drawn sharply forwards, usually bringing away the whole structure. A few days later the sphenoidal region of the nose is carefully packed with pledgets of wool soaked in cocaine and suprarenal extract, to enable a good view of the part to be obtained. Light general anæsthesia may be induced if desired. A probe with hooked end is passed into the sphenoidal sinus to ascertain its extent, and then the anterior wall is broken down with a Hajek's hook. When the opening has been sufficiently enlarged, a pair of sphenoidal sinus forceps is introduced and the whole of the anterior wall of the sinus cut away. The interior is now inspected and any polypus removed, but the lining membrane should on no account be curetted. The subsequent treatment consists in irrigating the sinus with weak antiseptic lotions until a cure has taken place.

In a few cases it is sufficient simply to irrigate the sinus without enlarging the opening as above described, but as the operation is very simple, is free from risk, and gives rise to little or no pain, it is much better to carry it out in the first instance.

H. Lambert Lack.

NOSE, ATROPHIC OR PERFORATING ULCER OF THE SEPTUM OF.

—(See also RHINITIS SICCA and EPISTAXIS.)—This ulcer usually occurs in connection with dry rhinitis, is situated on the anterior part of the cartilaginous septum, and unless treated early results in a perforation. Some three-fourths of the perforations of the cartilaginous septum result from this cause. The ulceration is due to the formation of crusts of dust and mucus on the septal mucous membrane, and the detachment of these crusts by forcibly blowing or by picking the nose. It is necessary, therefore, to prevent the crusts, and to warn the patient against picking the nose, a habit which soon becomes unconscious. The nose must be cleansed two or three times a day with a simple alkaline lotion, and the anterior part of the septum should be well smeared over with a mild antiseptic ointment—such as weak boric acid or dilute nitrate of mercury ointment (B.P.). Strong applications, such as caustics, do harm. In this way the ulceration may frequently be made to heal, but treatment must be steadily and persistently carried out or a relapse will certainly occur.

H. Lambert Lack.

NOSE, FOREIGN BODIES IN.—Foreign bodies in the nose are most common in children, and comprise such small articles as boot buttons, fruit stones, fragments of wood, rubber, paper, and so on. Whenever a unilateral, purulent, fœtid nasal discharge is met with, the presence of a foreign body should be suspected, and the diagnosis completed by making an attempt to remove it.

The removal is best effected by means of a small blunt hook such as a strabismus hook, or a probe with its end bent at a right angle a quarter of an inch from the tip. The hook is gently passed through the middle meatus of the nose, over and beyond the foreign body, which almost always lies in the anterior third

of the inferior meatus ; its point is then lowered on to the floor of the nose, and it is drawn gently forward. With care the hook can usually be placed in position without frightening or hurting the child, and then, even if the child draws backward, it only helps the removal of the foreign body. If this manœuvre is unsuccessful, or if the child is very frightened, a little chloroform may be given and the removal attempted in the same way. Attempts at removal should never be made with forceps. It is very difficult to grasp a foreign body accurately without obtaining a good view of it, and owing to the purulent discharge and swelling in the nose it is generally impossible to get a good view ; moreover, forceps are very apt to slip off and push the foreign body further in. Attempts to remove a foreign body by syringing are dangerous, as much force is often required and the fluid is apt to be driven into the Eustachian tubes and cause acute otitis.

Rhinoliths, or nasal stones, may occur in children or adults, and give rise to symptoms similar to those caused by foreign bodies. Their treatment is essentially the same, but if the stone is very large it may be necessary to crush it or to cut off pieces before it can be extracted.

H. Lambert Lack.

NOSE, FRACTURES OF.—Fractures of the nose result from severe direct violence, such as falls in which the nose comes in contact with a hard substance, or violent blows. The injury may be limited to the cartilaginous portions, the cartilaginous framework may be separated from the bony framework, or the strong nasal bones themselves may be broken. This last requires immense violence. In addition to the external deformity, the nasal septum will be more or less crumpled. When first seen, the depression of the nasal bridge may be concealed by inflammatory swelling. This is important, because the ultimate result may show greater deformity than was at first suspected.

The best treatment is immediately to replace the parts in position as accurately as possible by manipulation with the fingers outside, and a pair of blunt forceps inside, the nose. The septum also should be replaced in position. To lessen the pain of these procedures the interior of the nose may be rendered anæsthetic by cocaine, but in children or nervous patients a general anæsthetic is advisable. Both nostrils should now be packed carefully with strips of sterilized gauze, enclosed in a rubber bag, or inserted between broad strips of green protective oil-silk, to facilitate its removal. The packing not only serves to keep the septum in position, but supports the bony framework of the nose : it must be changed every second day for a week, after which it may be omitted altogether. If possible, the patient should be confined to bed for a few days and the swelling of the soft parts reduced by the constant application of an ice-bag or an evaporating lotion ; an external splint is unnecessary. As a rule excellent results are obtained, being the nasal bones firmly set in about fourteen days. Occasionally the fracture of the septum results in an abscess (see SEPTUM NASI). When the cartilaginous portion of the nose is affected, the patient must be cautioned that even if there be no apparent deformity at the time, some may subsequently occur. Especially in children or youths, considerable progressive deformity may result, probably because the normal growth of the parts has been impaired.

When the fracture is not seen until some days have elapsed, the nose often seems firmly set in its new position. If less than two weeks has elapsed, the best plan is to give the patient an anæsthetic and then forcibly to replace the bones. Both nostrils should then be packed as above described, and as soon as the inflammatory swelling has diminished under the application of evaporating lotions a poroplastic splint should be moulded to the nose and kept in position with strapping. This splint should be worn at least ten days, otherwise there is some danger of the deformity recurring.

In old-standing cases, where the bones have become thoroughly set, little can be done. An operation on the deflected septum can be carried out so as to restore free nasal respiration, or if the deformity be merely a depression of the bridge of the nose it can be remedied by the subcutaneous injection of paraffin wax (see p. 725.)

H. Lambert Lack.

NOSE, POLYPUS OF.—The so-called “mucous” polypus of the nose is, in fact, a circumscribed œdematous area of the nasal mucous membrane, and in most cases depends upon a rarefying osteitis of the underlying bone. When the disease is extensive, or when there is frequent recurrence, marked bone disease will be found, and will require treatment to obtain a successful result. Polypi grow only from the ethmoidal region of the nose: most commonly from the middle turbinate or from the region around the hiatus semilunaris; more rarely from the roof of the nose or from the septum. The original cause is an acute inflammation of the nasal mucosa, which has been sufficiently severe to involve the underlying periosteum and bone, and may also have caused suppuration in some of the nasal accessory sinuses.

TREATMENT.—The successful treatment of nasal polypus depends upon the recognition of its pathology. The method to be adopted varies according to the extent of the disease.

When only a few polypi are present they may be removed with a wire snare under cocaine anæsthesia.

Fig. 59.—Removal of anterior end of middle turbinate.

A 10 per cent solution of cocaine is applied on pledgets of wool, which are packed round the growths, and it is well to use adrenalin also, as the consequent contraction of the mucous membrane permits a better view of the parts and diminishes the bleeding. In about half an hour, when anæsthesia is complete, the wire loop of a polypus snare, such as Blake's, is passed around a growth and hitched up as close as possible to its attachment.

The wire loop is then drawn tight until the pedicle of the polypus is grasped, when the pedicle may be cut through or the growth removed by avulsion. The latter method is the more thorough, but it is a little painful. This operation is repeated at one or more sittings until all the growths have been removed. After the operation the patient should irrigate the nose two or three times daily with a mild antiseptic, such as boric acid lotion. This treatment is most likely to be permanently successful when only one or two polypi of long standing are present. In such cases the active bone disease has often passed off and the bone has become sclerosed. If after removal of the growths it seems probable that active bone disease is present, the affected bone should be clipped away. The anterior end of the middle turbinate should be removed with cutting forceps and snare as shown in Fig. 59. Other portions of bone may be clipped away with Grünwald's forceps, aided if necessary by breaking open the ethmoidal cells with Hajek's hook, as described in the operations upon ethmoidal cell disease (see NOSE, ACCESSORY SINUSES OF). Further careful examination should be carried out to discover any sign of sinus suppuration, and any suspected cavity should be explored

and, if found diseased, treated. If in spite of this the polypus repeatedly recurs, or if the disease appears too extensive to be dealt with in a few sittings by the above method, the operation about to be described should be carried out. It is useless to apply strong astringents such as alcohol or tannic acid, or to attempt to destroy the "roots" of the polypus with the galvano-cautery or with caustics.

When there is *extensive disease*, when the upper part of the nose appears filled with small polypoid growths, when the bone seems extensively affected and its normal outlines are lost, or when there is evidence of ethmoidal or frontal sinus suppuration, a more extensive operation should be performed in the first instance, provided the patient's general condition is favourable. The operation should be performed also in milder cases when polypi constantly recur in spite of the operations described above. The chief contra-indications are age and ill health. I should never advocate the operation in patients over fifty, and should hesitate in patients over forty, unless the condition urgently demanded it. As age advances the ethmoid becomes more brittle and the operation consequently more dangerous. Moreover the bleeding is rapid and often severe, and might be alarming in a weakly person.

The operation consists in thoroughly scraping away all the polypi, diseased mucous membrane, and bone with a ring curette under general anæsthesia. This is a dangerous procedure unless performed with great care and by an operator with considerable experience of nasal surgery. The results, when the operation is thoroughly carried out, are excellent. A complete cure can be promised in most cases, even of extensive disease, and however many minor operations have been previously carried out. For full details the reader must consult special text-books. The chief dangers are perforation of the cribriform plate with meningitis or cerebral abscess, abscess or cellulitis in the orbit, sepsis, and hæmorrhage. The operation has, however, very little danger when properly carried out. When the patient is old or not in good health, the most that can be done is to remove the growths carefully, one or two at a time, with cocaine anæsthesia, until the nasal passages are clear. The operation must be repeated as the growths occur. In every case of nasal polypus careful search must be made for complications such as suppuration in one or more of the accessory sinuses, and these if found must be dealt with.

H. Lambert Lack.

NOSE, REDNESS OF.—(See also ROSACEA.) This is usually an indication of dyspepsia. The diet should be restricted as in chronic GASTRITIS (q.v.) and the bowels regulated by aperients if necessary. The following stomach mixture may be prescribed :—

R Bismuthi Carbonatis		Acidi Carbolici	℥ij
Sodii Bicarbonatis	āā gr. x	Infusum Gentianæ Co. (N.F.)	ad ʒss
Before each meal.			

The patient should be forbidden to blow tobacco smoke through the nose or to take snuff. Locally, one of the following applications may be applied at night after steaming the nose over boiling water :—

R Sulphuris Præcipitati		Acidi Carbolici	℥vj
Calaminæ	āā gr. xxx	Lanolini	ʒj
R Calaminæ		Pulveris Tragacanthæ Co. (B.P.)	ʒj
Bismuthi Subnitratiss	āā gr. x	Aquam	ad ʒj
Acidi Hydrocyanici Diluti	ʒij		

In bad cases it may be necessary for the patient to wear a nose-shield for a time in order to protect the nose against wind and weather.

Robert Hutchison.

NOSE, SYPHILIS OF.

Tertiary Syphilis.—Both general and local measures are required. The general treatment consists in the administration of anti-syphilitic remedies in large doses. If a gumma is seen in the nose or extensive ulceration is present, the patient should be given large doses of iodide of potassium (20 to 25 gr. three times daily). If this is not successful, mercury should be given in addition, a drachm of the liq. hydrarg. perchlor. (1-900) being added to each dose of the iodide. If the case still prove intractable, which usually means that the patient is in bad general health or is addicted to alcohol, it is best to keep him in bed, to feed him up by giving him three or four pints of milk daily in addition to plain ordinary diet, and then, after three or four days, to commence the iodide treatment again. In these circumstances it will usually succeed. After healing has taken place it is advisable to send a well-to-do patient to some foreign health resort, such as Aix-la-Chapelle, to undergo a thorough course of mercurial treatment. Where this is impossible, injections of salvarsan or neo-salvarsan will probably yield the best results.

The local treatment consists in cleansing the nose three or four times daily with a mild antiseptic lotion, such as a solution of boric acid. If very exuberant granulations be present, they may be cauterized, or a little calomel and starch applied. If a loose sequestrum be found, it must be removed with forceps or with a blunt hook (see NOSE, FOREIGN BODIES IN). It may be necessary to divide a large sequestrum with bone forceps to facilitate its removal. When healing has taken place, if there is much deformity, a plastic operation may be performed.

Inherited Syphilis.—The general treatment consists in the administration of mercury, either by the mouth or by inunction. Half-grain doses of hydrarg. cum creta may be given to an infant three times a day, or a few grains of mercurial ointment may be rubbed into the abdominal walls. If the affection do not rapidly yield to this treatment, one or two grains of iodide of potassium may be administered three times a day in milk. Every effort should be made to maintain the infant's general nutrition. If the nasal obstruction prevent the administration of food in the usual way, spoon feeding must be adopted.

In addition to these measures, local treatment must be carefully carried out. The nose should be syringed regularly once or twice a day. The infant should be held face downwards over a basin, and the fluid injected very gently into the nose by means of a small glass syringe with a short length of rubber tubing attached. The best lotion is a warm solution of salt and water (1 dr. to the pint), to which $\frac{1}{2}$ oz. sanitas or 5 gr. potassium permanganate may be added. This treatment, if regularly carried out, greatly hastens the cure and diminishes the risks of subsequent ill-results. Clearing the nose aids the administration of food and thus lessens the danger of malnutrition. The chief ill-results that may follow severe or neglected cases are ozæna or atrophic rhinitis, the direct result of long-continued suppuration, and a falling-in of the bridge of the nose, apparently due to arrested development of the nasal bones. This deformity, the so-called "saddle-backed" nose, has recently been treated with success by subcutaneous injections of paraffin wax.

H. Lambert Lack.

NOSE, TUBERCULOSIS OF (Lupus).—The most common forms of tuberculosis are an extremely slow but progressive superficial ulceration of the mucous membrane, and a hypertrophic form characterized by the formation of exuberant, pale, fleshy granulations. More rarely, a tuberculous tumour is met with, or a typical tuberculous ulcer with thin undermined edges.

The disease usually commences on the anterior part of the nasal septum, or the anterior end of the inferior turbinate. Thence it may spread back along

the septum, or forward into the vestibule and on to the face. The palate and larynx may become affected without direct continuity. The disease may cause a perforation of the cartilaginous septum, but rarely or never attacks the bone.

In treating this affection, general and local measures should be combined. The patient should be placed under the most favourable hygienic conditions, he should live as much as possible in the fresh air, and should take a plentiful and nutritious diet. Any disturbance of the general health must be rectified. The internal administration of arsenic frequently acts beneficially on lupus of the upper air-passages, and is well worth a trial. Three to five minims of liquor potassii arsenitis should be given three times a day immediately after food, and the dose slowly increased, provided no gastric symptoms or other evidences of poisoning are produced, until ten to fifteen minims are taken three times a day. Lupus has a greater tendency to recur in cold weather than in warm, and the patient must always be carefully watched during the late autumn months. If there is recurrence at this time of the year, the best plan would be to send the patient to a warm climate for the winter. If he keeps well for one or two winters, there would probably be no further trouble even in the cold weather. In intractable cases small doses of tuberculin may be tried (see SPECIFIC THERAPY), but lupus of the nose generally yields to local measures, and the results with tuberculin have not been sufficiently successful to recommend its general use. It may, however, be cautiously employed in conjunction with local treatment if the latter alone seem to fail.

The *Local Treatment* is most important. In the majority of cases the best results will be obtained by the application of caustics. The nose should be thoroughly anæsthetized by the application of cocaine and suprarenal extract. Pledgets of wool soaked in the solution and gently squeezed out should be applied to the parts for half to three-quarters of an hour, so that the tissues may be rendered as bloodless as possible. Any strong caustic would probably act well, but nitrate of silver, chromic acid, and chloride of zinc are the most convenient. A few crystals of nitrate of silver should be melted and fused on the tip of a silver probe. The surface of the ulcer or the granulations are freely cauterized, and the caustic-bearing point of the probe is also thrust deeply into the softened diseased tissues. The application causes very little bleeding, and a large area may be done at one sitting. After about ten to fourteen days, a second application may be made; three or four thorough applications of this kind will usually suffice to remove an extensive area of disease, even when covered with exuberant granulations. Chromic acid is applied in the same way, by fusing it on a probe; chloride of zinc should be made into a thick paste by pounding it up with a few drops of water and glycerin, and must be applied on a pointed wooden stick.

Whilst this treatment is being carried out, the nose should be syringed regularly with a weak antiseptic solution, and, if there be a tendency to the formation of crusts, oil or ointment, such as dilute nitrate of mercury ointment (B.P.), should be introduced into the nose. After all the obvious disease has been removed, the patient should be seen at intervals of three or four weeks, so that any recurrence may be dealt with at once. After a time it would be sufficient to see him once in two months, and then, if there is no recurrence for a year, treatment may be left off.

In cases of extensive disease, the general practice is to curette the nose thoroughly under local or general anæsthesia. This method may shorten the treatment a little where there are very exuberant granulations or extensive disease, but in my hands the results have proved disappointing, and I now rarely recommend it. In spite of the application of suprarenal solution, the bleeding is always brisk and quickly renders it impossible to see accurately what is being

done. Normal tissues may be scraped and disease left behind ; the raw surfaces are apt to become infected by the disease, and the lupus may soon recur as badly as before. Moreover, it gives rise to cicatricial contractions and deformities to a far greater extent than does the method above described. If the scraping be carried out, the nose should be frequently irrigated afterwards, and ointment applied to prevent crusts. As soon as the bleeding has ceased and the swelling has disappeared sufficiently to allow of inspection of the nose, cocaine should be applied, and any remaining disease destroyed with caustics. Afterwards the nose should be inspected at frequent intervals, so as to arrest any recurrence as early as possible.

If a tuberculous tumour be present, it should be removed with the snare or by curettage. Cocaine anæsthesia may be sufficient, and is to be preferred to general anæsthesia if the patient will allow it. This form of the disease is usually associated with pulmonary tuberculosis ; the patient does not stand operation well, and may run considerable risk if blood enters the lung. A few days after the tumour has been removed, the base of the growth should be anæsthetized with cocaine and thoroughly cauterized. This usually results in a cure. If an extensive superficial ulcer with undermined edges be present, cocaine should be applied, and the base and the edges of the ulcer thoroughly cauterized. In this condition phthisis is usually present, and therefore general treatment also must be carried out. (See also LUPUS VULGARIS.)

H. Lambert Lack.

NOSE, TUMOURS OF.

Benign Tumours.—With the exception of nasal polypus (q.v.), benign tumours of the nose are all rare, and may be very briefly dealt with.

Papillomata, when growing from the *vestibule*, should be snipped off with scissors, and the base dried and thoroughly cauterized. If the growth be sessile, and especially if it occur in a middle-aged or elderly patient, it is better to give a general anæsthetic and to excise it freely, together with a margin of healthy tissue. Pedunculated growths springing from the *mucous membrane* may be removed with a snare under cocaine, and their bases cauterized ; small sessile growths may be destroyed with the electric cautery.

Fibromata must be removed. If the growth be small and pedunculated, it may be removed with the snare under cocaine or under general anæsthesia. A strong snare threaded with thick wire must be used, as the growth is generally tough. The growth should be slowly cut through, so as to lessen the danger of hæmorrhage, and its base freely cauterized. If a large growth with extensive attachment be present, it will be necessary to open up the nasal cavity by an operation such as is required for malignant disease of the nose (q.v.), in order that the origin and attachments of the growth may be freely exposed to view. The growth can then be radically removed, with as much of its attachments as seems necessary, and any bleeding (which may be free) can be dealt with in the usual way.

Enchondroma and *Osteoma* are very rare ; they usually spring from the ethmoidal region and project into the orbit or one of the nasal accessory sinuses. They always require removal, and it is generally necessary to perform an extensive operation, the exact nature of which depends upon their size and position. If the ethmoidal region be involved and the growth project into the orbit, a free incision curving round the inner side of the orbit should be made and the neoplasm freely exposed and removed. A growth involving the frontal sinus requires an operation on that sinus similar to the radical operation for frontal sinus operation (see NOSE, ACCESSORY SINUSES OF).

Fibro-angioma of the septum is a rare tumour growing from the anterior part of the septum just behind the vestibule. It must be thoroughly removed, as it has a considerable tendency to recur. The best plan is to anæsthetize the parts

with cocaine and suprarenal extract, and then, under good illumination, an incision is made with the cautery point through the healthy mucous membrane all round the growth at a slight distance from its attachment. The mucous membrane and the perichondrium of the septum are then, together with the growth, detached from the underlying cartilage. The after-treatment consists in applying oil or ointment to the wound, until complete healing has taken place.

Malignant Tumours may be either sarcomata or carcinomata. In either case the treatment is the same, and the result equally unsatisfactory. Even when the growth can apparently be removed, recurrence almost invariably follows and proves fatal.

A growth springing from the floor of the nose or involving the septum or inferior turbinate is the most favourably situated for operation. It may be freely exposed by Rouge's operation. An incision is made through the gingivo-labial junction from opposite the first molar tooth on one side to the same point on the other side of the jaw, and then the upper lip, soft parts of the face, and nose are raised by detaching them from the bone. This gives free access to the anterior part of the nose. The antrum may be opened through the canine fossa, and the inferior turbinates, the outer wall, the floor, and the septum of the nose may be cut away as freely as necessary. After removing the growth the parts are allowed to fall naturally into position again, and as a rule there is very little deformity. An epithelioma in this region is often of very slow growth and not very malignant. It rarely gives rise to secondary growths in the glands or elsewhere, and hence is particularly favourable for operation. Even partial operations, such as scraping, are occasionally successful in relieving the patient and in considerably prolonging life.

Growths involving the ethmoidal region are less favourably situated. They are usually sarcomata or cylindrical-celled carcinomata. If not too extensive, they may be removed by a combined internal and external operation. A long curved incision is made round the inner side of the orbit, and the periosteum along the inner wall of the orbit separated as far back as possible. The entire ethmoidal region is now removed piecemeal, partly through the nose and partly through the external incision.

Malignant growths involving the posterior part of the nasal cavity, or springing from the sphenoidal region or the upper part of the postnasal space, are usually inoperable. Most of these cases are sarcomata, and radium treatment should be tried. It is quite easy to fix a tube of radium in contact with these growths for as long as may be desired, and the application may be repeated as often as necessary. At the present time, a large dose of radium, well-screened, is usually placed in position for twenty-four hours, and the dose repeated in five or six weeks. X-ray treatment has also cured a considerable number of these cases, even when the glands in the neck have also been enlarged. It is possible that diathermy may also be successfully applied.

Another form of malignant growth often met with in this region is the so-called "recurrent fibroma," which is probably an endothelioma. These growths are not very malignant; there are no secondary deposits or glandular involvement, although they have a great tendency to recur locally. If growing from the top of the postnasal space, they may be exposed through the mouth. A laryngotomy is performed, the mouth opened widely, and the back of the pharynx firmly plugged with large sponges to prevent blood entering the larynx. Then the soft and hard palates are divided in the middle line, the soft parts, including the periosteum, turned off the bone, and as much of the bony palate chiselled away as is necessary to get a good view of the tumour. An incision is made all round the growth, which is then cut or gouged away from the bone and afterwards the wound in the palate is carefully sutured.

Two modifications of these methods have recently been practised, and will probably be adopted generally in the near future. Instead of chloroform, ether may be given by the intratracheal method. This obviates the necessity of a laryngotomy and of plugging the pharynx with sponges, as there is no tendency for blood to enter the larynx. Also, after splitting the palate, the growth may be removed by diathermy. This method is entirely bloodless, and the base of the growth is well cauterized.

If the growth extend into the upper part of the nose, the above method may not give a very good exposure. In this case, Watson Williams' method may be recommended. The nose is opened by an incision along the line of the eyebrow, extending inwards to the middle line and then down the centre of the nose to the end of the nasal bones; with chisel and saw the bones as well as the soft parts are divided; next a small incision is made round the inner angle of the eye, and the lachrymal duct pushed outwards and the nose entered; through this opening a Gigli saw is passed, and the bone below it divided, and also the bone above which forms the floor of the frontal sinus; the flap is then turned outwards, and by removing the middle turbinate a splendid view of the back of the nose can be obtained. The growth can now be dealt with in the way considered most suitable.

Occasionally more extensive operations are required. Thus, if the growth involves the antrum, removal of the upper jaw is necessary. As a rule, however, when a nasal tumour is so extensive that the operations above described are useless, the case is too far advanced for any operation to be successful.

When a growth is inoperable radium may be tried. If this fails, all that can be done is to relieve the most distressing symptoms. Pain can be kept in check by opiates. The nose can be cleansed by syringing with boracic lotion, sanitas, or permanganate of potash; and bleeding, if excessive, must be checked by packing the nose with strips of gauze. If the growth projects into the mouth or pharynx, and causes much obstruction to breathing or swallowing, the best plan is to break away pieces of it with the finger. The growths are usually friable and break down easily, and this treatment is preferable to performing a tracheotomy or to subjecting the patient to tube feeding.

H. Lambert Lack.

NYSTAGMUS AND HEAD-NODDING (Spasmus Nutans).—These affections, with rotatory, horizontal, vertical, or oblique movements of head and eyes, appear to be due to want of correlation between the action of ocular and cervico-cranial muscles. They have been attributed to residence in dark rooms in which there are one or more spots of bright light, the fixation of which exhausts the retina, also to intestinal toxæmia, rickets, and of course to dentition. The evidence of such causation is in each case insufficient. In a few instances, nystagmus and head-nodding are associated with feeble-mindedness, and may be persistent; but in the majority the movements cease spontaneously, without special treatment, towards the close of the first dentition.

Bromides and antipyrin, which have been recommended, are quite unnecessary, and indeed are contra-indicated if the condition is, as maintained, an instance of imperfectly established co-ordination.

All that is necessary in most cases is attention to general hygiene, and provision of diet suitable to the ordinary child. The subjects of these affections are usually nervous and hypersensitive to noise.

Leonard G. Guthrie.

OBESITY.—In the majority of cases which present themselves for treatment, those, namely, in which the condition has supervened in the later part of middle life, the accumulation of fat is due to a disproportion between the intake of energy in the form of food and its output in the form of muscular work. The

proper way of dealing with such cases, therefore, is to cut down the diet, and to recommend the taking of more exercise. It is true that cases of obesity are sometimes met with in young subjects in whom there seems to be a tendency to the formation of fat even in the absence of any undue consumption of food. Such cases are difficult to explain, and may depend upon some congenital vice of metabolism or derangement of internal secretion; at all events they do not readily lend themselves to treatment.

1. Dietetic Treatment.—Of the nutritive constituents of food, the carbohydrates and fats, especially the former, contribute most to the formation of adipose tissue, and it is the consumption of these which it is most necessary to restrict. Various schemes of diet have been devised, which differ chiefly in the degree to which each of these constituents is reduced. The following are examples :—

	Protein. Grams	Carbo- hydrate. Grams	Fat. Grams	Calories
Normal Standard	125	500	50	3027
Banting	172	81	8	1110
Oertel (max.)	170	120	45	1600
" (min.)	156	75	25	1180
Ebstein	102	47	85	1300
Hirschfeld (max.)	139	67	65	1400
" (min.)	100	50	41	1000
Von Noorden	155	112	28	1366

It will be observed that in most cases the proportion of protein, as being least likely to form fat, is increased, whereas the carbohydrates and fats are reduced below the normal, although in varying ratio.

The arrangement of some of these schemes into meals is as follows :—

BANTING.

Breakfast.—4 or 5 oz. of meat or fish; 1 oz. of toast; tea without sugar or milk.

Dinner.—5 to 6 oz. of lean meat or fish; any vegetable except potatoes; 1 oz. of dry toast; some stewed fruits; 2 or 3 glasses of claret.

Tea.—2 or 3 oz. of fruit; a rusk or two, and a cup of tea.

Supper.—3 or 4 oz. of meat or fish.

EBSTEIN.

Breakfast.—2 oz. of bread with plenty of butter; a large cup of tea without sugar.

Dinner.—Soup; 4 to 5 oz. of meat; green vegetables; fresh fruit, and 2 or 3 glasses of light wine.

Afternoon.—Same as breakfast.

Supper.—1 egg; meat, ham, or smoked fish; 1 oz. of bread with plenty of butter; a little cheese; fresh fruits.

VON NOORDEN.

8 a.m.—3 oz. of cold lean meat; 1 oz. of bread; a cup of tea or coffee, with a spoonful of milk but no sugar.

10 a.m.—1 egg.

Noon.—A cup of strong soup without fat.

1 p.m.—A small plateful of clear soup; 5 oz. of lean meat or fish; 3½ oz. of potatoes; green vegetables; 3½ oz. fresh fruits.

3 p.m.—A cupful of black coffee.

4 p.m.—7 oz. fresh fruit.

6 p.m.—A glass of skimmed milk.

8 p.m.—4½ oz. of cold lean meat ; 1 oz. of whole-meal bread ; 2 or 3 spoonfuls of fruit, cooked without sugar.

In adopting one or other of these plans, the patient's tastes must be consulted, but Banting's system has the great advantage of being simple, and easy to carry out. One should make sure, however, that the kidneys are in a healthy state before recommending it, owing to the large excretion of waste nitrogenous matters which its adoption entails. It must be remembered, too, that they are all more or less "starvation diets," and should therefore not be persisted in for more than a few weeks at a time, during which the patient must be kept under strict observation, and the weight not allowed to run down too rapidly ; three pounds a week is a sufficient rate of loss.

In slighter cases, or in more pronounced examples of obesity after the weight has been reduced by one or two stones, a "subsistence diet" should be adopted for permanent use. This will resemble an ordinary diet, except that sugar, potatoes, sweets, and all rich or fatty articles or dishes are absolutely forbidden, and the consumption of bread is restricted to about 4 oz. a day.

In every case the patient must be instructed to live by rule and measure, and to weigh out the food he eats until such time as he can be trusted to estimate it approximately from experience. Too great variety should be avoided as tending to increase appetite, and for the same reason the use of pickles, condiments, and all articles that increase the desire for food, should be forbidden.

The Use of Particular Articles of Food.—Sugar, it need hardly be said, should be forbidden altogether, and saccharin employed as a sweetener instead. Milk also is a very fattening food. Visible fat should be removed from meat, and the richer meats, such as pork, goose, duck, etc., and the fatter fishes (e.g., salmon, herring, and mackerel) avoided. Puddings must be unconditionally forbidden. Bread is allowable only in weighed quantities, and toast, in spite of the popular impression to the contrary, is even more dangerous. There is an advantage in selecting the coarser sorts of bread, such as whole-meal, as being more "satisfying" in proportion to their bulk. Potatoes are not so harmful as bread, but, on the other hand, are less missed. Green vegetables may be allowed freely, and have the advantage, owing to their bulk, of producing a feeling of satisfaction. Dried fruits are too saccharine for the corpulent. Fresh fruits may be allowed in moderation, but if cooked should be sweetened with saccharin.

All beverages which contain sugar (e.g., the sweetened aerated drinks) should be forbidden. Alcohol, being a great sparer of fat, is best avoided altogether by the corpulent. If indicated on other grounds, it should be given in the form of plain spirit. Malt liquors are never permissible.

The belief that the restriction of fluids has a direct influence in reducing obesity is probably erroneous. Such a restriction acts only by making it more difficult for the patient to consume his customary quantity of solid food. Limitation of fluids should be insisted upon, however, when any of the following conditions are present : (1) Weakness of circulation ; (2) Excessive sweat secretion ; (3) Where it lessens the patient's desire for fatty foods. Where a Banting or any other very highly nitrogenous diet is being practised, the restriction of fluids is dangerous as being opposed to the free elimination of waste products.

The treatment of obesity, in its milder forms at any rate, is often more easily and more conveniently carried out at a health resort than at the patient's own home. Carlsbad, Homburg, and Marienbad are the best resorts for the purpose, although none of them is available in the winter or spring months.

2. Exercise.—If the patient is able to take active exercise, the treatment of obesity is greatly simplified. If the degree of corpulence renders this impossible, massage may be used at first as a substitute. Any form of active exercise is good, but gentle hill-climbing is particularly advantageous if the state of the patient's heart permits of it. It may be well to point out that riding is of little use in reducing obesity, for, as it has been well remarked, "It is the horse that gets thin, and not the man." The production of muscular contractions by the Bergonié system, which is an artificial substitute for hard exercise, is described in the article on electrotherapeutics.

Turkish baths are helpful in many cases, but they are directly contra-indicated if there be any weakness of the circulation.

3. Drugs.—Thyroid is the only medicinal substance known which has the power of increasing the destruction of tissue in the body. Unfortunately, however, it acts upon the nitrogenous as well as upon the adipose tissue, and for this reason it must be used, if at all, with great caution, and where employed, care must be taken that the amount of protein in the diet is in no way restricted. Five grains of the dried gland twice a day would be a sufficient dose. Of the drugs which have been recommended, such as *Fucus vesiculosus*, none is at all trustworthy; of the many patent and proprietary remedies for obesity which are sold, some contain *Fucus vesiculosus* (e.g., Trilene), some citric acid (e.g., Antipon) or sulphur, some in all probability (although this has not been proved) thyroid.

Robert Hutchison.

ODONTOMATA.—(See JAWS, TUMOURS OF.)

ŒSOPHAGUS (Medical Treatment).

1. Cancer of.—The diet must consist of nutritious liquids, such as eggs beaten up with milk, soup, and starchy food in the form of thin gruel. As a rule, a sufficient quantity of food to maintain life can be swallowed throughout the course of the disease, for the wasting and loss of strength that ensue depend more upon the cachexia of the disease than upon actual inanition. As liquid diet is bulky, and the quantity which can be swallowed at any time is limited, food must be given every hour, or every two hours, during the day-time. The quantity aimed at should be 4 pints of milk, 1 pint of soup, 1 pint of gruel, and 2 eggs. The patient may take thin purées of potato as a change from the gruel, and should be allowed tea or coffee with sugar, milk, and cream; koumiss or kephir may be tried, but is often objected to on account of its taste; somatose or plasmon may be added to the milk or soup.

It may be difficult to give a full amount of food in this way, in spite of every expedient; the tables in books make up the deficiency by recommending an impossible quantity of fat, in the form of butter or cream. Repeated small quantities of cod-liver oil may be tried (1 to 2 dr.), but not more, as it is doubtful whether larger doses are fully absorbed; and if this be true of cod-liver oil, it is still more likely with less easily assimilated fats.

Up to the present there is no trustworthy means of treating cancerous growths, the hopes held out by the numerous "sera" invented during the past few years having proved delusive. We are therefore reduced to using means to relieve pain and spasm, of which hypodermic injection of morphine ($\frac{1}{8}$ to $\frac{1}{4}$ gr.) is the best. This may be combined with atropine ($\frac{1}{120}$ to $\frac{1}{60}$ gr.), which is held to diminish spasm. Where swallowing causes pain and is consequently performed with difficulty, give a teaspoonful of a solution of anæsthesine in liquid paraffin or olive oil (3 per cent). Mechanical treatment of all kinds should be avoided, including the use of even the soft stomach tube, as accidents may easily happen.

In those cases in which the obstruction is so great as to prevent a sufficient supply of food being taken, a gastrostomy should be performed, but it must be undertaken so soon as the power of swallowing liquid nourishment is seriously impaired; it is useless when the patient is moribund.

Nutrient enemata may be used to supplement the nourishment taken by the mouth, but cannot be relied upon to any great extent, or for any length of time. The best nutrient enema is composed of one or two eggs beaten up with milk, a teaspoonful of dextrose, and a pinch of salt; the total bulk should not exceed 5 or 6 oz.; this should be injected slowly into the rectum at the temperature of the body; the milk may be peptonized. In order to favour the retention of the enema, the hips should be elevated, the patient lying on the left side, and a folded towel should be pressed against the anus for twenty minutes to half an hour after the injection.

Among reputed remedies for cancer which still possess some slight reputation, probably because in some cases they have only recently been recommended, are violet leaves (*viola odorata*)—of which the dose of the liquid extract is a teaspoonful, or a decoction prepared from the fresh green leaves may be given—*x* rays, and radium. In the absence of any other indication, it may be worth trying the effect of a short course of red iodide of mercury ($\frac{1}{12}$ gr.) with iodide of potassium (5 gr.), which at least can do no harm. The advantage of some medication is that it satisfies the natural desire of the patient and his friends that something should be done, and prevents his resorting to quack remedies, which may be injurious.

2. Ulceration of.—The only specific remedies are in the case of syphilitic ulcer, when red iodide of mercury ($\frac{1}{12}$ gr.) and iodide of potassium (5 gr.) should be given. In the others, the treatment must be mainly palliative and dietetic; injections of morphine ($\frac{1}{6}$ to $\frac{1}{3}$ gr.) and atropine ($\frac{1}{120}$ gr.) may be necessary to relieve the pain or spasm, and liquid diet should be ordered, as described for cancer. Anæsthesine in olive oil or liquid paraffin (3 per cent) should be given in teaspoonful doses before each meal to facilitate deglutition. Where swallowing causes pain, nutrient enemata may be given instead, so as to give complete rest to the œsophagus. The use of enemata is much more satisfactory here than in cancer, as the patient's general condition is usually good, and his strength is not being undermined by any grave disease, so that he may go on for two or three weeks if necessary with only rectal feeding.

3. Simple Stricture of.—The usual treatment is mechanical, that is to say, the gradual dilatation by means of sounds. MacCormac's dilator, with its set of olive-shaped terminations, is an excellent means for effecting gradual dilatation, but is not applicable in cases of impermeable stricture. If no instrument can be passed through the stenosis, gastrostomy must be performed, and an attempt made to penetrate it from below.

Prof. Klemperer speaks favourably of the use of hypodermic injections of thiosinamine (fibrolysin) as a means of softening the cicatrix and facilitating the process of dilatation.

4. Fusiform Dilatation of.—The treatment consists in dilating the cardiac opening by sounds, and feeding the patient on the fluid diet already described.

5. Saccular Dilatation of.—The only satisfactory treatment is by surgical operation, but it has been suggested that eversion of the sac may suffice if this can be performed.

6. Spasmodic Stricture of.—This is, as a rule, readily and completely cured by the passage of a large-sized œsophageal sound.

Robert Saundby.

ŒSOPHAGUS, FOREIGN BODIES IN.—(See FOREIGN BODIES IN THE AIR-PASSAGES AND ŒSOPHAGUS.)

ŒSOPHAGUS, SURGICAL DISEASES OF.—The general statement may be made that the successful treatment of diseases of the œsophagus connotes a high degree of technical knowledge, and that it is best conducted by surgeons of wide experience in the subject and expert in the direct endoscopic methods. The blind passage of bougies is not only fraught with considerable danger (e.g., in cases of sharp foreign body, ulceration, or malignant disease), but can seldom be relied upon to furnish a genuine diagnosis. The diameter, length, and situation of a stricture can often be determined with the bougie, but the nature of the disease remains unknown, and treatment therefore cannot be adopted with precision; moreover, the bougie can readily slip past a foreign body, an ulcer, or new growth of small size, with misleading results.

The surgeon who has not studied modern developments in this branch, and whose work lies in remote parts of the world, will undoubtedly have to deal with cases of foreign body in the gullet, the treatment of which is dealt with in another article (see **FOREIGN BODIES IN THE ŒSOPHAGUS**); but with regard to cases of disease, I would advise him to leave treatment alone as far as possible, or else to make a genuine study of the subject.

Certain conditions, however, will demand immediate attention.

Acute Œsophagitis.—1. *From corrosive chemicals.*—Direct the patient to sip the appropriate antidote, or gently introduce a stomach-tube and wash out the œsophagus. This must be done at once, for when the period of exfoliation or erosion has been reached, no further introduction of instruments should take place. Emetics must not be given. Absolute rest in bed is essential; and pain may be allayed by sucking ice, sipping iced soup, etc., and the exhibition of opiates. Rectal feeding may be necessary.

Inflammatory swelling of the larynx may be prevented by sucking ice, applying the ice-bag externally, and spraying with adrenalin. Scarification of the epiglottis and arytenoids, or tracheotomy, may be necessary. No bougie should be passed until four weeks have elapsed. It is not desirable to use the œsophagoscope in the early stages of these cases.

2. *From laceration by a foreign body.*—Successful treatment mainly depends upon correct diagnosis, but severe cases with much pain and fever have recovered, in the absence of strict diagnosis, where sedative and antiseptic measures have been adopted.

The possibility of extension to the larynx must be remembered, and preparations made for scarification of the arytenoids and epiglottis, and for tracheotomy. Ice may be sucked, the ice-bag applied, and epinephrin sprayed into the throat. Nourishment may be given through a rubber catheter cautiously introduced.

3. *From scalding drink and food.*—Iced drinks, rectal feeding, and sedatives should be used. The small larynx of a child may become obstructed by inflammatory swelling with great rapidity. Apply the ice-bag to the neck, spray with epinephrin, and give ice to suck.

4. *From acute infectious diseases.*—Inflammatory phenomena may occur in diphtheria, thrush, scarlet fever, small-pox, erysipelas, and typhoid, and require the treatment indicated in preceding paragraphs.

5. *From alcoholism.*—In alcoholics, both acute and chronic œsophagitis occasionally occur. Rest and sedative treatment is indicated both for the local and gastric condition. Inflammation may also occur after prolonged bilious vomiting.

Chronic Œsophageal Catarrh.—This occurs in alcoholics, after acute infectious diseases, and in conjunction with strictures both benign and malignant, and especially where dilatation exists and decomposition of retained food occurs.

The treatment is lavage with warm, dilute, alkaline, antiseptic lotions. The sipping of 3-vol. peroxide is valuable in many cases of malignant stricture.

Ulceration and Fissures.—The latter may occur in conjunction with chronic gastric disturbances. The treatment of choice is the local application of silver nitrate under accurate visual control through the œsophagoscope. The condition is rare, and many laryngologists have no practical experience of it.

Hæmorrhage.—Perforation of the great vessels by a foreign body, ulceration, and malignant disease must be borne in mind. Hæmorrhage may, however, occur from veins about the lower segment of the gullet in cases of cirrhosis of the liver, also from varices and from ulcerated areas. Ice may be sucked, epinephrin or ergotine administered, and the part kept at rest by rectal feeding.

Severe hæmorrhage has been controlled by plugging through the œsophagoscope.

Syphilis.—Where œsophageal symptoms exist in a case of active syphilis, I would emphatically urge the reader to rely solely upon the medical treatment, unless he be expert with the œsophagoscope. I have seen ulcerative perforation of the aorta in a case of syphilis where nothing more than slight discomfort in swallowing was complained of. With regard to the treatment of cicatricial stenosis, *vide* opening paragraph, and also page 741.

Tuberculosis.—Ulceration is occasionally found post mortem in tuberculous patients. Clinical experience is rare. One may assume from experience with pharyngeal cases that the ingestion of orthoform or of anæsthesine in the form of powder will allay dysphagia.

Œsophageal Obstruction.—It goes without saying that a certain number of cases of difficulty of swallowing, with or without pain, present no gross physical lesion and are genuine neuro-muscular phenomena. The matter of prime importance is the diagnosis, i.e., the definite exclusion of organic disease, and this can scarcely be done without considerable experience with the endoscopic methods. Every laryngologist has doubtless met with the case of obstruction at the cricoid region, occurring perhaps in a young or middle-aged woman of hysterical type, which has turned out on careful examination to be one of post-cricoid carcinoma; while most of his cases of supposed idiopathic cardiospasm have proved, on œsophagoscopy, to be dependent upon the presence of malignant disease, ulceration, or fissure. In a short article confined to treatment, as apart from diagnosis, it is therefore impossible to give much information of genuine value; and probably everyone concerned will be saved much distress, expense, and danger, if an opinion is obtained at the outset from an expert in this matter—and one at least may be found in any large centre to-day—and his advice carried out.

1. *Spastic stricture.*—In the case of anæmic women with defective teeth, in obvious cases of hysteria with partial anæsthesia of the pharynx, and in the case of highly-strung nervous persons suffering from the effects of mental strain, no harm can result from a short course of bromide and valerian, the supply of an adequate denture, and instructions concerning proper mastication. In this class of case complete relief may speedily result from such treatment, to be followed by speedy recurrence. Under such circumstances the gentle and repeated introduction of a large-sized bougie or rubber œsophageal tube may be of great service, and in conjunction with the other measures may lead to permanent cure. On no account should a small bougie be used, nor should any but the slightest pressure be employed. Even in so simple a matter as this there are profound pitfalls, and to emphasize what I have already said to this effect I will quote a pre-eminent authority, Charters Symonds, who considers that a bougie will pass a malignant stricture of the lower end more readily than it will pass a spastic one.

In this connection one must point out that genuine spastic conditions, which yield temporarily to sedative treatment and the bougie, are in fact often set up by, or at all events associated with, malignant disease which escapes detection

with the bougie ; it may indeed be said that in the majority of cases of difficult deglutition the diagnosis of malignancy is ultimately arrived at.

2. *Cicatricial stricture.*—Such a stricture, whether of traumatic or syphilitic origin, is still treated by the progressive use of bougies. The position and character of the upper orifice is determined by direct endoscopy, and the vertical length of the stenosis by means of Charters Symonds' olive-headed bougies.

Valuable information as to the size, course, and length of the stenosed passage is obtained with the *x* rays and bismuth paste. A stricture of short vertical extent can sometimes be dilated, without any special experience, by the passage of bougies ; but the surgeon must be prepared for recurrence, and it is well to see the patient every three months during the first two years.

In larger works, various ingenious devices will be found detailed ; but I would urge the reader to avoid the use of filiform bougies and mechanical dilators until he has mastered the direct method and made a study of the special literature.

3. *Malignant disease.*—In the hypopharyngeal or postericoid region, a type of epithelioma occurs which is of comparatively low malignancy. It is superficial in origin, and the submucous tissues and the lymphatic glands may remain for many months unaffected. It often occurs in young and middle-aged women, who may complain of nothing more than persistent pricking or of roughness on swallowing pungent or dry food. Sometimes pain is elicited by pressing the cricoid back against the spine. The laryngoscope may reveal nothing abnormal. Thanks to the fact that the area involved does not come within the influence of the aspiration of the thorax, these cases may be attacked by operation with a prospect of success. In suspicious cases, therefore, it is very desirable to secure a diagnosis by the direct method.

When malignant disease is confined to the ostium it may be removed with some possibility of success, but operation upon genuine thoracic cases is in the experimental stage at the present date.

A certain number of cases have been genuinely relieved by treatment with radium, and possibly a few have been permanently cured. The details as to dosage, screening, and the disposition of the tubes are highly technical, and the paper by William Hill (*Trans. Med. Soc.*, London, 1911) may with advantage be consulted. In some cases a functional lumen may be maintained by the daily passage of bougies, and even by repeated curettage through the œsophagoscope, needless to say at the cost of very considerable risks.

These strictures not infrequently occur at or about the level of the tracheal bifurcation (i.e., about ten inches from the teeth, or nearly twelve if the flexible bougie is employed), and in this situation Charters Symonds' short funnels may be retained with almost complete comfort for many months. The form with the terminal orifice should be used, and the special introducer employed. These short tubes are unfortunately seldom of use at the upper or at the lower end of the gullet. For strictures at these points a long tube (i.e., a simple red rubber tube ; or Hill's, which is stiffened with wire) should be inserted, and once inserted, retained as long as possible. The upper end may be attached to the upper teeth or brought out through the nostril. Gottstein considers it both better and safer to introduce drainage tubes by Von Hacker's method, leaving them *in situ* for a few hours, and repeating the process several days in succession. A sheath of stretched tubing is applied to a mandrin by hitching

Fig. 60.—Von Hacker's tube for dilating strictures.

the rubber over the pointed ends of the latter. The superfluous portions of rubber are cut off. After insertion of this comparatively narrow instrument through the stricture, the rubber tube is allowed to resume its full diameter by removing the mandrin. *Fig. 60* (from *Keen's Surgery*, page 783) indicates the method of stretching the tubing over the mandrin.

On theoretical grounds it would seem well to perform gastrostomy early, and so keep the œsophagus in a state of comparative rest; results in practice, however, are not very encouraging.

A good deal of the distress accompanying malignant stricture is due to septic inflammatory phenomena, and the patient, therefore, should flush his gullet with water after taking food, and also sip 3-vol. peroxide several times daily. When the *x* rays reveal the presence of a dilatation above the stricture, this should be washed out by the patient with a syringe and two-way catheter.

Some surgeons employ irrigation with dilute silver nitrate solutions; atropine may be used to reduce secretion, and opiates need not be withheld.

No fibrous food of any kind should be taken; semisolids rubbed through a sieve, and jelly, will often prove easier to swallow than fluids.

4. *Pouches*.—The so-called traction-pouches, usually the result of cicatrization about the bronchial glands in the neighbourhood of the bifurcation, are of no therapeutical importance, for they seldom produce evident symptoms.

The better-known pulsion-pouches may cause difficulty in swallowing, by compressing the œsophagus from without when distended with food. They are herniæ of the posterior wall of the hypopharynx, and arise above the band of muscle fibres which constitutes the ostium of the œsophagus proper, and as a consequence they can be removed with far less risk than that entailed by a genuine intrathoracic operation—although, in fact, the fundus of a large pouch may enter the thorax.

As a rule, a pulsion-pouch is a strictly cervical lesion, and when distended, may be felt as a projection, generally upon the left side of the neck. The diagnosis from a high dilatation of the œsophagus must be determined by the *x* rays and direct endoscopy.

The access is fairly good through an incision along the anterior border of the sternomastoid, and the point of origin, sometimes forming a fairly narrow pedicle, will be found about the level of the inferior edge of the cricoid cartilage. In a few cases where the pouch was small, a good and permanent result has been obtained by inverting the hernia into the œsophagus, and preventing its re-expulsion by suturing. As a rule the pouch should be removed, its pedicle closed with a purse-string suture, then inverted into the gullet, two or three layers of stitches being subsequently inserted to prevent eversion.

Butlin, on several occasions, failed to create a watertight closure capable of resisting the strain entailed by the act of deglutition. It is therefore highly desirable to keep the neck wound open and packed until the danger of mediastinitis has passed.

Where operation is, on general grounds, contra-indicated, the patient may live for many years well nourished and in complete comfort if the sack is washed out with a syringe and catheter. The latter always enters the pouch with the greatest ease, and never penetrates the ostium. In some cases this lavage must be performed during the middle of the meal, in order to enable the later courses to be swallowed; in others it is necessary only at the end of the meal, in order to remove food which otherwise would be retained and undergo decomposition. It is essential to wash out the pouch at bedtime, otherwise rest will be disturbed by the cough which is caused by the repeated rejection of foam and food. The escape of food into the pharynx during sleep may cause septic pneumonia.

In conclusion, I would warn the reader from obtaining an incorrect perspective concerning œsophageal obstruction. Text-book articles upon the subject very naturally dwell largely upon the curable conditions, and the reader may inadvertently be led by the authors to suppose that cicatricial and spastic obstructions are fairly common. Prolonged hospital experience leads me to a very different conclusion, which I find is shared by those who have devoted themselves to the subject. A few universally-recognized authorities and writers are entrusted with the treatment of a considerable number of benign cases, but unhappily the great majority seen in general practice will ultimately prove to be malignant.

E. B. Waggett.

ONYCHIA.—(See NAILS, DISEASES OF.)

OPHTHALMIA NEONATORUM.—(See CONJUNCTIVA, DISEASES OF.)

OPHTHALMIA, SYMPATHETIC.—(See also GONORRHOEA.)

PREVENTIVE TREATMENT.—It must be borne in mind that all eyes with a penetrating injury are liable to excite sympathetic disease in the fellow eye. Such injuries are especially dangerous: (1) If the injury produces entanglements of any part of the uveal tract (iris, ciliary body, choroid) or lens capsule, which is covered only by a thin layer of epithelium; (2) If the injured eye contains a foreign body; (3) If the injury results in a chronic iridocyclitis. (Eyes in which *suppuration* has taken place as the result of the injury practically never give rise to sympathetic ophthalmia, and need cause no anxiety.)

All eyes which have been so severely injured that the sight is irretrievably lost should be excised at the earliest opportunity.

When there has been a perforating wound with entanglements, and the eye has not quieted down in two, or at the very latest three, weeks, and if there is haziness of the cornea, muddy iris, and keratitis punctata, the question of removal must be seriously considered.

When sympathetic ophthalmia has already shown itself, as evidenced by circumcorneal flush, keratitis punctata, posterior synechiæ, and vitreous opacities, the question as to whether the exciting eye should be removed is often extremely difficult to decide. (1) If the exciting eye is blind, or practically so, and is painful, or contains a foreign body, it must be removed forthwith. (2) If the exciting eye has moderate sight, or an operation at a later period is likely to give useful vision, and if the sympathetic disease in the fellow eye is extremely acute, with intense iridocyclitis, it is wise to leave the exciting eye, which may finally retain the better vision of the two.

The treatment of the disease, once developed, must be both general and local.

GENERAL TREATMENT consists in a course of purging, diaphoresis, and the administration of mercury. A brisk purge must be given at the commencement of the attack, and care taken to secure a free daily action of the bowels. Diaphoresis is best promoted by the hot-air bath or the hot pack, fortified, if necessary, by subcutaneous injections of pilocarpine nitrate, $\frac{1}{12}$ to $\frac{1}{8}$ gr. Mercury must be pushed to salivation, and failing this, acetyl-salicylic acid and acetozone may be tried. Of late, salvarsan has been given with great success in a number of cases of sympathetic ophthalmia; an injection should be given directly the condition is verified, and this should be repeated once or twice.

LOCAL TREATMENT consists in the protection of the eyes by dark glasses, the use of atropine, hot applications, and leeching.

Every effort must be made to dilate the pupil with atropine, and if the weaker ointment (4 gr. to the ounce) fails to attain this object, the strength must be increased to 8 gr. to the ounce, careful attention being paid to the possibility

of toxic symptoms developing. If the atropine gives rise to marked local irritation, a substitute must be tried. (See IRITIS.)

The application of two leeches to the temple, repeated every other day if necessary, will assist the atropine in dilating the pupil, and at the same time greatly relieve the pain and congestion of the eye. Heat in the moist or dry form must be persevered with regularly, either by means of frequent hot boracic bathing, by the application of the Japanese muff-warmer, or the Maddox electric pad. (See IRITIS.)

In spite, however, of every care and attention, many cases of this terrible disease end in complete blindness.

Ilbert Hancock.
(Revised by *W. T. Lister.*)

OPIUM POISONING.—(See COMA ; DRUG HABIT ; POISONING.)

ORAL SEPSIS.

This is a condition in which there are present in the mouth one or more of the following :—

1. Pathogenic bacteria.
2. Bacteria capable of producing putrid decomposition of organic material.
3. Food débris.
4. Carious teeth, with their sequelæ—dental abscess, septic roots, etc.
5. Pyorrhœa alveolaris, with its undrainable pockets among and around the roots of the teeth.
6. Tartar.

Oral sepsis is the result of local stagnation. Germs and food débris collect around the uncleansed teeth, and tartar is formed by the slow hardening of lime salts deposited from the saliva ; the earliest deposit of tartar is soft and readily rubbed away.

Prevention of oral sepsis, as of dental caries, pyorrhœa alveolaris, and tartar, is wholly a matter of cleanliness. The entire intra-oral portion of each tooth must be cleaned at least once a day, beginning on the very day the tooth erupts. The neck of the tooth, where the gum embraces the tooth and forms the circum-dental sulcus, is the most important seat of stagnation, especially interdental. The interdental aspects of the teeth can best be cleaned by waxed silk thread, used so as to scour one surface of one tooth at a time.

† Prevention also includes the avoidance of every artificial source of stagnation. All fillings must be well polished and be flush with the tooth surface at all their edges ; gold caps, crowns, and the attachments of bridges must be so made that there is no overlapping of the artificial portion beyond the root or tooth, i.e., the join between crown or gold cap and root must be flush in its whole circumference, and the point of junction should be as far from the gum edge as possible.

TREATMENT.—Clear away all tartar ; replace or polish down flush any faulty fillings ; remove any ill-fitting gold caps, crowns, and bridges ; extract every root or tooth which cannot quickly be rendered and kept aseptic ; destroy all pyorrhœa pockets. Explain to the patient the importance of cleaning the *necks* of the teeth, and teach him to rub these and the edges of the gums with a piece of lint soaked in a weak antiseptic solution such as the following :—

℞ Sodii Bicarbonatis	gr x	Glycerini	℥j
Acidi Carbolici	gr vj	Aquam	ad ℥j

and to use dental silk. If he is clever with his fingers he may be able, by means of a silver or gold tooth-pick (which can be bent to any angle, and “flamed” to clean it), to pass between his teeth small rolls of cotton-wool soaked in the same lotion.

Before undertaking extractions in a septic mouth, some days should be spent in preparatory cleansing with mouth-washes and mechanically, every tooth, and especially the necks and interdental spaces, being well rubbed each day.

Joseph Geo. Turner.

ORBITAL CELLULITIS may result from :—(1) *Injuries* ; (2) *Extension of the inflammation from surrounding structures*, e.g., periostitis, empyema of the accessory nasal sinuses, more especially the ethmoidal, etc.* (3) *Metastases*, e.g., pyæmia, meningitis, etc.

TREATMENT.—In the subacute and chronic forms, surgical interference is seldom necessary. With attention to the bowels, hot fomentations, leeches to the temple, and quinine and iron internally, these cases generally end in resolution.

In the acute form, on the other hand, which is ushered in by a rigor, followed by fever, with great pain, brawny swelling of the parts, and marked proptosis, early operation is imperative to prevent extension to the meninges, and to save the eye from panophthalmitis or optic atrophy. It is not advisable to wait for the abscess to point, and its situation can often be inferred from the direction in which the eyeball is displaced. Thus, if the eye is displaced down and out, the abscess will probably be found up and in.

If there is no indication as to the position of the abscess, the incisions should be made through the skin of the upper and lower eyelid close to the orbital margin. A straight narrow bistoury must be used, and the knife plunged deeply into the tissues close to and parallel with the wall of the orbit, carefully avoiding the eyeball. Even if no pus is found, the operation, by relieving the tension of the parts, will often succeed in arresting the inflammation, speedy resolution following. The wounds must be efficiently drained, either by gauze or drainage tubes, until the discharge has entirely ceased, and hot fomentations applied until the swelling of the parts has subsided.

When orbital cellulitis is secondary to empyema of the accessory sinuses, it is important that an operator familiar with nasal surgery should be in charge, so that the sinuses may be treated at the same time as the orbital condition.

The general condition of the patient must be carefully attended to, and quinine and iron given internally. If panophthalmitis is present, the anterior segment of the eyeball should be completely divided and its contents evacuated. This is a safer procedure than enucleation, which may lead to meningitis from opening and infecting the vaginal sheath of the optic nerve.

Ilbert Hancock.
(Revised by *W. T. Lister*.)

ORCHITIS. (See also GONORRHOEA.)—Acute orchitis is treated in the same way as acute epididymitis. If the testicle remains large and very tender, with some œdema of the scrotum and a raised temperature, or if there are recurrent attacks of tenderness, swelling, and fever without external cause, and the testicle does not return to the normal size between the attacks, an abscess may be diagnosed. The pus may be pent up under considerable tension in the interior of the organ, or there may be scattered abscesses. The abscess should be opened as soon as possible, but if the testicle be destroyed by a large abscess or multiple abscesses, castration will be necessary. After incision of an abscess of the testicle, protrusion of the testicular substance (hernia testis) may take place. This eventually heals, sometimes after a large part of the testicle has been extruded and destroyed.

J. W. Thomson Walker.

OSTEO-ARTHRITIS.—(See RHEUMATOID ARTHRITIS.)

OSTEOMALACIA.—In slight and early cases one may try the effect of phosphorus (gr. 1-100 in pill thrice daily, increased up to gr. 1-20 in each dose). Epinephrin solution has also appeared to give good results in such cases. The dose is $\frac{1}{2}$ c.c. of a 1-1000 solution given subcutaneously at first every day, but

* A careful examination of the nose and accessory sinuses should always be made with a view to eliciting the cause of the cellulitis, and guiding one in both the immediate and after-treatment.

afterwards twice a day. In severe or old-standing cases which are not complicated by pregnancy one should consider seriously the advisability of castration, as great improvement or even cure has resulted from the operation. It is best performed soon after a pregnancy. If the patient be actually pregnant when she first comes under observation, treatment will depend upon the condition of the pelvis. If it be deformed, the propriety of inducing abortion or of performing Cæsarean section later must be considered. If the pelvis be normal the case may be treated with phosphorus until after delivery.

Robert Hutchison.

OSTEOMATA.—(See BONE, TUMOURS OF; JAWS, TUMOURS OF.)

OSTEOMYELITIS.—(See BONE, INFLAMMATIONS OF.)

OTITIS MEDIA.—(See EAR, AFFECTIONS OF.)

OVARITIS.—(See SALPINGO-OÖPHORITIS.)

OXALURIA.—The conditions which lead to an increased excretion of calcium oxalate in the urine are obscure, but in treatment it is important to forbid those articles of food which contain an excess either of calcium or of oxalic acid. Milk, eggs, jellies, tea, cocoa, sugar, green and root vegetables, and rhubarb should therefore be avoided, and the diet should consist of meat, fish, bread, rice and other farinaceous foods, butter, and coffee; potatoes and apples may be taken sparingly.

As magnesium oxalate is much more soluble than the calcium salt, it is advisable to give a small daily dose of a magnesium compound—30 grains of the sulphate or carbonate or of calcined magnesia, daily, should be enough. Potassium citrate also increases the solubility of the oxalic acid by the formation of a double salt. The general health should also be attended to, regular exercise insisted upon, and any dyspepsia corrected. With the latter object, a mixture containing nitrohydrochloric acid after meals is often helpful. (See also CALCULUS.)

Robert Hutchison.

PAGET'S DISEASE OF THE NIPPLE.—(See NIPPLE, DISEASES OF.)

PALMAR ABSCESS.—(See ABSCESS.)

PALPITATION.—Myocardial insufficiency, whether due to weakness of the muscle from anæmia, fatty changes, or want of tone, or to advancing sclerosis or valvular disease, is a common cause of palpitation. In such patients exercise is the usual exciting cause.

Nervous influences have also a powerful effect in its causation. Emotional stress, in nervous patients, may induce most serious attacks, and at the menopause, either natural or operative, palpitation is frequently most distressing, and the liability to it may extend over several years.

Reflex disturbances are also common causes of the disorder, the most common being flatulent dyspepsia, but almost any viscus may be responsible. Ovarian disease and floating kidney, for example, are well recognized as occasional exciting causes.

Coffee, tea, tobacco, and alcohol are often found to be causal agents.

It must not be forgotten that anything abnormal in the mechanism of the heart, especially if there is hypertrophy, is usually perceptible to the patient. Extra-systoles and auricular flutter and fibrillation give rise to abnormal sensations, generally precordial in site; these are palpitation, a peculiar fluttering, or recurring thuds.

When palpitation is the result of definite disease of the myocardium or endocardium, it diminishes or disappears as the general vigour or tone of the heart improves. (See MYOCARDIAL FAILURE, and HEART, CHRONIC VALVULAR DISEASE OF.)

For the treatment of palpitation due to extra-systoles, auricular flutter, or fibrillation of the auricle, see HEART, IRREGULARITY OF.

The most valuable drugs in the treatment of palpitation when found in nervous patients, especially at the menopause, are the preparations of bromine. The following is a useful combination of hydrobromic acid, arsenic, and strychnine :—

R Acidi Hydrobromici diluti	℥xv	Liquoris Acidi Arsenosi	℥iij
Liquoris Strychninæ Hydrochlorici	℥iv	Aquam Chloroformi	ad 3ss
(1 per cent)			

A tablespoonful to be taken in water thrice daily after food.

Ammonium bromide is probably the most valuable preparation, and when combined with valerian is very helpful, both in the case of hysterical patients and also at the menopause.

R Ammonii Bromidi	gr xij	Tincturæ Capsici	℥iiss
Tincturæ Valerianæ Ammoniatæ	℥xv	Aquam Menthæ Piperitæ	ad 3ss
Liquoris Potassii Arsenitis	℥iij		

A tablespoonful to be taken in water thrice daily after food.

Strophanthus can be added to the above when thought desirable. Neurotic patients should avoid tea, coffee, and tobacco, and should give themselves a cold sponge down every morning on rising. If they prefer it, they can sponge themselves down while standing in tepid water; this minimizes the shock. The whole process should not take more than one minute, and should be followed by a vigorous rubbing of the skin.

In these nervous patients palpitation does not contra-indicate moderate exercise in the open air. The more they live in the open, and the more natural and simple their life, the better.

When there is reason to believe that the palpitation is due to a toxin such as alcohol, tea, coffee, or tobacco, the indications for treatment are obvious. The further use of the poison must be prohibited and general tonic treatment given. A prescription such as the following is useful :—

R Ferri et Ammonii Citratis	gr vij	Tincturæ Cinchonæ Compositæ	3j
Tincturæ Nucis Vomiceæ	℥xviij	Infusum Gentianæ Compositæ	
		(N.F.)	ad 3ss

One tablespoonful to be taken three times a day in water after food.

The palpitation of thyroïdism demands above all things rest, both physical and mental, fresh air, and of course the medicinal and other treatment employed in Graves's disease. (See EXOPHTHALMIC GOITRE.)

When the patient tends to be disturbed at night by palpitation, the last meal should be light, and no tea or coffee should be taken with it.

A draught containing $\frac{1}{2}$ dr. of ammonium bromide in peppermint water is useful, taken at bedtime, or the more palatable effervescent preparation may be employed.

Where flatulence is the exciting factor, the condition of the stomach and intestines requires careful attention. The teeth must be investigated and the diet regulated, and the food must be well masticated and eaten slowly. When the feeling of distention is noticeable, a teaspoonful of the following mixture, well diluted, helps to relieve the distress :—

R Mentholis	gr. v	Spiritus Chloroformi	āā 3ss
Spiritus Ammoniaë Aromatici			

One teaspoonful well diluted with water to be taken when the flatulence is distressing.

In some patients sexual excess is very liable to bring on a tendency to palpitation; this should always be inquired into carefully, and the habits regulated accordingly.

John Hay.

PALSIES.—(See BIRTH PALSY; CRAFT PALSIES.)

PALSIES, CEREBRAL (of Childhood).—Under this heading are included the spastic paralyses of childhood, such as diplegia, hemiplegia, and so-called congenital spastic paraplegia. They divide themselves into three great classes:—

(1) *Those due to natal or pre-natal conditions*; (2) *Those due to acute diseases, with an onset in early childhood*; (3) *Those which are due to pathological processes, slowly acting but progressive in character.*

Cases belonging to groups 1 and 2 tend to improve; those belonging to group 3 tend to run a progressive downward course.

1. The cases due to natal or pre-natal conditions show an amount of paralysis and rigidity ranging from a slight spastic condition of the legs to a condition of extreme hyperextension or hyperflexion of the legs, inward rotation of the arms, and retraction of the head. In the latter case, but little can be done to relieve the symptoms; in the former, patience and perseverance may accomplish much.

Children suffering from this affection commonly come under observation during the second year of life, owing to their inability to walk; such a child may show other signs of cerebral and mental deficiency, but in many cases the condition is limited to the lower extremities.

Treatment is simple, but must be continued over a long period. It must in the first instance be directed to remove the rigidity which is present; this is accomplished by regular *passive movements*, which have for their object the overcoming of the spasmodic contraction of certain muscles. As a rule the adductors of the thigh are markedly contracted, and abduction and rotation outwards of the thighs are movements of especial importance. Again, the foot tends to assume a position of equinus, with which is often associated some cavus. Dorsiflexion movements of the foot are especially required in such a case. Warm baths preceding the passive movements are often of the greatest service. These movements should be carried out twice a day, and for periods of fifteen to thirty minutes.

No less important are the *resistance movements* which a child can usually be taught to perform. These are carried out by making the patient alternately flex and extend the leg against the resistance of the hand. Co-ordination is educated by making the child perform exercises similar to those described by Fraenkel. For the legs, a double board with round holes at a distance of 3 to 4 inches, into which the heel can be placed, serves for simpler forms of exercises. For the hands, a solitaire or cribbage board, on which the pegs are moved up hole by hole, is all that is required. Simple rubbing is useful, but is not nearly so important as the exercises above indicated.

The child should be encouraged to walk, and considerable aid may be obtained by a walking apparatus with a sufficiently broad base and easily running wheels. Tenotomy may be required in some cases. Light celluloid splints will often serve to keep the limb in the normal position, and a splint of some kind is required in all severe cases, whether a tenotomy is performed or not. Faradism, galvanism, and various forms of electrical treatment are of little service. Drugs also are of little use except to meet special symptoms.

A form of treatment first recommended by Förster is that of section of some of the posterior roots in the lumbo-sacral region of the cord. The

roots generally selected are the 2nd, 3rd, and 5th lumbar and the 2nd sacral. The section of these roots abolishes the hypertonicity of the muscles. A great deal of care is necessary in the selection of suitable cases for this operation. In cases with but slight spasticity the operation is *entirely* unnecessary, and good and better results can be obtained with tenotomies and exercise. In the severer cases, it is important to find out what amount of voluntary power exists; if this is good, the abolition of the spasticity will allow a freer and wider range of movement; but if voluntary power is deficient, the section of the posterior roots will cause a flaccid paralysis in the place of a spastic paralysis—a result not to be desired. It must be borne in mind that spasticity and voluntary powers are quite distinct functions of the nervous system, and the presence of spasticity does not mean that voluntary power is present. It is useless to perform this operation in cases in which the mental condition of the child is bad; it must, however, be remembered that the mental condition will greatly improve under careful instruction; and an opinion with regard to it should only be expressed after a careful, quiet, and, if necessary, repeated examination.

Nerve section is a useful procedure in selected cases, as, for instance, those with severe adductor spasm. The obturator nerve may be injected with alcohol so as to abolish its conductivity, and this gives rise to an adductor paralysis of some months' duration. Whilst recovery is taking place, the abductors are exercised and the balance of power restored.

For the more severe cases, in which there are retraction of the head and marked rigidity, with hyperextension of the limbs, very little can be done in the way of treatment, and it is a matter of careful nursing to keep the skin of these children free from sores.

2. In the second class of case, in which the cerebral condition has followed on some acute disease, treatment should be carried out on the lines laid down for cases in group 1, but with even more prospect of success, and especially in those cases in which the cerebral or cerebellar lesion is due to the virus of poliomyelitis.

3. For the third group little or nothing can be done to arrest the progress of the disease. In cases due to specific disease, salvarsan, mercury, and iodide may be given; the latter drug in drachm doses three or four times a day has been recommended. I have tried these large doses, and there is no difficulty in giving this amount, but I have never seen any beneficial result follow. Mercurial ointment should be rubbed into the calves of the legs every day for fifteen minutes. Cases presenting hemiplegic symptoms are treated in a similar manner to those presenting bilateral symptoms.

F. E. Batten.

PANCREAS, DISEASES OF.

Acute Pancreatitis.—It is but rarely that this condition is recognized before operation, which is usually carried out on the diagnosis of perforation of a peptic ulcer. On opening the abdomen, blood-stained fluid escapes, and there is a characteristic slimy feel about the omentum, pointing unmistakably to fat necrosis.

Fat necrosis is not pathognomonic of acute pancreatitis; it simply denotes the escape of the pancreatic ferments, and may occur, as first pointed out by the writer, in perforation of a duodenal ulcer.

If the pancreas is tensely distended, it may be incised in a direction parallel to the duct. The gall-bladder and bile-ducts should be carefully investigated; they should be drained if stones are found. In rare cases an abscess may form as the result of acute inflammation; this should be drained through an incision in the costovertebral angle.

Chronic Pancreatitis.—This is usually secondary to disease in the gall-bladder. In these cases, removal of gall-stones and drainage of the gall-bladder is usually sufficient. Occasionally, on closure of the drainage opening, the symptoms, shivering and jaundice, recur, necessitating further operation.

There is a group of cases in which the symptoms are those of an obstructive jaundice with distended gall-bladder, difficult to diagnose from malignant disease even at operation. In this group, the gall-bladder should be united to the duodenum (cholecyst-duodenostomy), or failing this to the stomach (cholecyst-gastrostomy). The writer has seen no evil results from this latter procedure, which he has carried out on several occasions.

In the group in which the symptoms are those of interference with pancreatic secretion only, I do not think drainage of the gall-bladder is likely to benefit.

Pancreatic Calculi.—If situated in the head of the gland these should be removed by incision of the anterior wall of the second part of the duodenum, opening up the ampulla of Vater. If in the body of the gland, they can be removed by direct incision.

Pancreatic Cysts.—In a few cases it is possible to excise these; the majority must be drained. The incision should be made over the most prominent part of the swelling, which is usually reached between the stomach and transverse colon. After aspirating the cyst, the edges of the opening should be fixed to the abdominal wall, usually, from the situation of the incision, to the posterior sheath of the rectus, and drained by tube.

Tumours of Pancreas.—In the majority of cases these are carcinomatous. A few sarcomata have been successfully removed. At the present time, operative treatment of carcinoma is limited to cholecystenterostomy for the relief of the jaundice.

James Sherren.

PAPILLOMATA.—(See WARTS.)

PARALYSIS AGITANS.—This is an affection which severely taxes the resources of the physician. The disease pursues a very chronic course. The symptoms may remain stationary for long periods of time, but it is very doubtful whether an actual "cure" has ever been effected. While there is no conclusive evidence that any of the therapeutic measures hitherto employed have permanently arrested the disease, it is at the same time to be remembered that the very chronic course it pursues renders judgement as to the effects of remedies upon its progress extremely difficult.

Treatment consists in attention to the general hygiene, and the avoidance of influences which have been observed to exert a deleterious effect, together with the administration of drugs, and the adoption of other therapeutic measures which have been found by experience to benefit the individual symptoms, and may perhaps help in retarding the progress of the disease.

The patient should lead a quiet, restful life, free, as far as possible, from excitement and all cares and business worries. Fresh air seems undoubtedly beneficial; an outdoor life, with exercise graduated to meet the individual's capabilities, is therefore to be recommended. A carriage drive, it is worthy of note, will often assist materially in lessening the patient's discomfort for the time being.

Alcohol and stimulants, such as strong tea and coffee, are to be avoided. A glass of whisky and hot water at bedtime may, however, be permissible in cases of sleeplessness. A warm, but not very hot, bath sometimes has an appreciably soothing effect upon the subjective symptoms.

In the later stages, restlessness, and an inability to remain for any length of time in one position, are among the most troublesome manifestations of the disease. A hard bed, by enabling the patient to alter his position more easily,

will be found preferable to a feather mattress when these symptoms exist. Gentle massage often helps to allay discomfort in the affected limbs. Observers are almost all agreed as to the uselessness of electricity in this disease, although Oppenheim has seen some benefit from weak bipolar faradic baths.

Distinct benefit may accrue from exercises, as Friedlaender has pointed out. Thus, in early cases, where the tremors can be for a short time controlled, the patient should practise his power of voluntary control two or three times a day. Temporary lessening of the tremor, and, it may be, after a time a more permanent beneficial effect, are sometimes attained in this way. The same author strongly advocates the value of slow passive movements of extension at the various joints. The limb should be fixed, and while the patient does his best to relax his muscles, the operator carries out five to ten movements at each joint. Even in severe cases, improvement may be obtained by this procedure. Active movements of the extensor muscles against varying degrees of resistance, carried out systematically with the purpose of overcoming the flexor rigidity, will also be found of service. Again, the patient's attention should be directed to the necessity of constantly trying to correct the abnormal attitudes which the limbs, head, and trunk tend to assume. While walking, for instance, he should pause after each step and extend the trunk and vertebral column as the advancing foot is placed upon the ground, and should practise at the same time taking longer steps. Great improvement cannot be expected from these exercises, but the amount of benefit which may be derived thereby is ample justification for their systematic use.

Suspension, nerve stretching, and the "jolting chair" of Charcot, are methods of treatment which are no longer employed.

Many drugs have been credited with producing benefit in this disease, but few have justified their vaunted reputation.

Arsenic is a medicinal remedy which is generally regarded as of some service. Fowler's solution, 2 min. three times a day, the dose being gradually increased to 8 or 10 min., is the usual method of administration. If an arsenical erythema or gastro-intestinal symptoms appear, the dose should be reduced. Pigmentation of the skin may be produced when arsenic is given in large doses. Where it is deemed desirable to continue the administration of large doses, the possible development of an arsenical neuritis is to be kept in view.

Strychnine is another drug which appears in some cases to do good. It may be combined with arsenic, or it may be given as Easton's syrup, beginning with a dose of half a teaspoonful three times a day, and gradually increased.

The merits of hydrobromate of hyosine, originally recommended by Erb, in this disease, have been advocated by Williamson, who points out that this drug diminishes the tremor and general restlessness, while the patient often sleeps better during its administration. The writer's experience corroborates the efficacy of this remedy. Williamson advises that the drug be given in chloroform water, commencing with an initial dose of $\frac{1}{150}$ gr., which may be gradually increased up to $\frac{1}{100}$, or even *with due caution* to $\frac{1}{50}$ gr. two or three times a day. The same preparation of hyosine should be used, to ensure constancy.

R Hyoscinæ Hydrobromatis gr $\frac{1}{4}$ | Aquæ Chloroformi $\overline{3}$ vj
Two teaspoonfuls twice a day, the dose to be increased as directed
by the physician.

The first dose should be given after breakfast, the second shortly before the patient retires to rest. The action of the drug appears to wear off in a few days, but if it is discontinued and again renewed, the effect is usually as marked as at first. The dose should be reduced if dryness of the mouth supervenes.

Hyoscine sometimes produces gastric symptoms which interfere with its administration.

A patient, recently seen by the writer, who had suffered from pronounced tremor and had been taking hyoscine for years, when he wished to steady his hand in order to sign his name was in the habit of taking 10 gr. of veronal.

Sulphate of hyoseyamine ($\frac{1}{100}$ gr.) and sulphate of duboisine ($\frac{1}{5}$ gr.) are, it is affirmed, sometimes of benefit. For pains in the limbs which are giving rise to discomfort, phenacetin or some of the other analgesics may be employed. (See also CRAMP.)

Edwin Bramwell.

PARALYSIS, VOLKMANN'S ISCHÆMIC.—(See VOLKMANN'S ISCHÆMIC PARALYSIS.)

PARAMYOCLONUS MULTIPLEX.—(See MYOCLONUS.)

PARAPHIMOSIS.—This is a complication of phimosis, and denotes an inability to draw the prepuce forwards over the glans after it has been retracted. Balanitis is a frequent cause of the narrowing and rigidity of the preputial orifice. The condition is seen in childhood as well as in adult life. The tight ring formed by the preputial orifice may be immediately behind the corona, but is more commonly found a little further back, and is then separated from the corona by a roll of œdematous mucous membrane. If left untreated, ulceration of the tight ring of tissue takes place. The condition may be relieved, but sloughing of the mucosa, and even of the glans, may take place.

TREATMENT.—The glans must be reduced through the narrow preputial orifice. In cases seen early this can usually be accomplished by pulling the prepuce forward by grasping the penis between the first and second fingers of each hand, while the thumbs press on the glans, reducing the swelling and forcing it backwards. An anæsthetic may be necessary. In more severe cases, the collar of œdematous mucosa in front of the constriction may need puncturing in several places to reduce the swelling, while in others the constricting ring will require division on the dorsum of the penis before the prepuce can be unrolled and drawn forwards. Circumcision should be performed after the parts have been given a few days in which to recover, frequent syringing being made use of meanwhile.

H. A. T. Fairbank.

PARAPLEGIA.—(See also NEURITIS, POLIOMYELITIS, PALSIES OF CHILDHOOD.)

Paraplegia may be due to many causes, the nature of which, in conjunction with the special characters of the paralysis, will determine the treatment of the individual case.

The treatment of paralysis of the lower limbs consequent upon disease of the peripheral nerves, of acute anterior poliomyelitis, and of the spastic paraplegias of childhood (Little's disease), is dealt with in special articles.

A rapid survey of the paraplegias from a pathological standpoint is necessary as an introduction to our subject.

Conduction in the spinal cord may be interfered with or abrogated by lesions within its substance, such as acute myelitis, hæmorrhage, tumour, syringomyelia, and disseminated sclerosis.

Again, pressure upon the spinal cord may interrupt the transmission of impulses to and from the parts below the level at which the cord is pressed on. Among the lesions which may be instanced in this connection are malignant and simple tumours growing from the spinal membranes or from the bone, hydatids, pachymeningitis (whether syphilitic, tuberculous, or simple), tuberculous disease of the spine, and aneurysm of the abdominal aorta which has eroded the vertebral bodies and invaded the spinal canal.

Further, the paraplegia which results from direct violence in association with a fracture-dislocation of the spine may with advantage be separated from the pressure paraplegias just referred to.

Another group includes those cases in which the paraplegia is dependent on systemic disease affecting primarily the motor neurons, although, in addition, other tracts may be involved. Examples of this type are to be found in amyotrophic lateral sclerosis, the combined degenerations of the spinal cord, familial spastic paralysis, etc.

Lastly, there are the hysterical paraplegias. In this connection, cases in which a functional paralysis is superimposed upon a recovering organic paralysis are deserving of special mention, since their true nature is especially apt to escape detection.

The type of the paralysis may vary. Thus, a paraplegia is often referred to as spastic or flaccid, according to the presence of spasticity or flaccidity in the paralyzed limbs. Since the character of the paraplegia is important in relation to treatment, a few words in explanation of these terms are necessary.

The spinal centres for the movements of the lower limbs are situated in the lumbosacral region of the spinal cord (L2 to S2); hence any lesion which destroys this region will produce a flaccid paralysis of the lower extremities associated with wasting of the muscles, impairment or loss of their electrical excitability, and abolition of the reflexes in the region of the body supplied from the segments which are destroyed. On the other hand, if the lesion is situated at a higher level—in other words, if the pyramidal fibres and not the spinal centres are implicated—a condition of muscular spasticity, with increase of the deep reflexes, is met with. If, however, the lesion is so complete as to totally interrupt upward and downward conduction through the cord, notwithstanding that the lumbosacral region of the cord remains intact, a flaccid palsy, with wasting, impaired electrical excitability, and abolition of the deep reflexes results. For instance, in cases of complete localized destruction of the spinal cord due to a fracture-dislocation of the spine, this form of flaccid paraplegia is met with. Cases may be observed in which a tumour pressing on the cord at first produces a spastic paralysis, the spasticity gradually increasing until conduction in the cord becomes impossible, when a flaccid palsy takes the place of the previous spastic state.

At this juncture it will be convenient to refer to certain of the paraplegias, the causative treatment of which calls for special emphasis.

The Primary Treatment (Treatment directed against the Cause).—From the preceding remarks it will be seen that the treatment of paraplegia necessitates a recognition of its cause. This may at once be obvious; on the other hand, the solution of the diagnostic problem may be attended with the greatest difficulty, and is sometimes, especially in the early stages of a case, impossible. If the physician is unable to come to a positive conclusion as to the exact nature of the case, he must at least attempt to exclude those various forms of paraplegia which urgently demand a special line of treatment.

If the paraplegia is *hysterical*, and if, as the result of a confident opinion as to the absence of organic disease, no immediate improvement takes place, the patient should be promptly removed from her relatives and treated in isolation by psychotherapeutic methods, either in a hospital ward or nursing home. Decisive measures are to be adopted from the first if a good result is to be obtained, for dilatory temporizing diminishes the prospect of cure in these cases. Needless to say, the measures above advocated are only to be adopted when the physician is perfectly certain of his diagnosis.

When there is evidence of syphilis, a course of mercurial inunctions and potassium iodide internally should be immediately instituted. Details as to the method in which these drugs are to be administered will be found in the article on syphilis. Here, again, temporizing is inexcusable. Potassium iodide should be given in doses of 10 to 15 gr. three times a day in combination with mercury, and rapidly increased until 90 gr. are taken in the course of the twenty-four hours. If a gumma or gummatous meningitis is responsible for the symptoms, the beneficial effects of treatment will probably be evident in the course of a few days. Even should the symptoms entirely disappear, the possibility of their recurrence must be kept in view, and the remedies continued in smaller doses, with intermissions, over a considerable period. The amount of improvement which follows in a case of syphilitic paraplegia, even when the paralysis

is of considerable standing, is often most surprising if the remedies are continued over a long period. In some of these cases salvarsan gives excellent results. The drug should be given intravenously, in doses of 0.4 to 0.6 gram. This dose may be repeated three or four times, at intervals of a week.

Is the spinal cord pressed on by a *tumour*? If so, is the neoplasm a secondary deposit? is it a malignant tumour growing from the membranes or the bone? or is it a localized simple growth arising from the membranes? When the facts point towards the latter diagnosis, and if syphilis can be excluded, the question of operation must be carefully considered, and without delay, for it must be remembered that, as a consequence of pressure, a softening of the area of cord in immediate relation to the tumour may at any time take place, after which no relief of symptoms is to be anticipated as a sequel to removal of the tumour. In any case of progressive paraplegia, associated with severe pain in the back which corresponds to the upper level of the symptoms, with, it may be, root pains, and especially if there is a tendency to the Brown-Séquard syndrome, an abdominal aneurysm and syphilis having been as far as possible excluded, and there being no evidence of disease of the bone or of tumours elsewhere, an operation should be undertaken without delay, provided that there are no special contra-indications. The brilliant results which have been obtained in a large number of cases by the removal of a simple tumour pressing on the cord, afford ample justification for this procedure *in any case of progressive paraplegia in which there is a distinct possibility that the symptoms may depend upon a growth of this nature*. In some of these cases the operator may find localized tuberculous disease of the bone of which there was no previous indication, in others tuberculous granulation tissue or a pachymeningitis, or again, he may meet with an extensive and irremovable sarcoma; but the possible presence of these lesions constitutes no contra-indication to the surgical procedure. It is not proposed to consider here the segmental location of the tumour; on this point, and that of vertebrospinal topography, the reader must consult special neurological and surgical works; but it may be noted that the constant tendency is to locate the tumour rather too low than too high in the spinal canal.

Tuberculous disease of the spinal column, often apparent at the first glance, is in some cases extremely difficult or impossible to distinguish from the other forms of pressure paraplegia, and notably from tumour. The condition having been diagnosed, if there is no evidence pointing to a tuberculous abscess as the cause of pressure, absolute rest in bed is to be enjoined. Extension should be applied, with counter-extension to the head if the disease is situated in the cervical region. (See SPINE, CARIES OF.) If there is reason to suspect a tuberculous abscess as the cause of the paraplegia, it is probable that operation will prove the only effective mode of treatment. It is especially in the case of children that a favourable result is to be anticipated as a consequence of operation in these cases. Caries sicca (dry caries), a condition which occurs specially in adults and elderly people, is very occasionally benefited by operation.

The *traumatic paraplegia* associated with fracture-dislocation of the spine deserves notice, since operation is attended with some hope of relief, if it so happens that the cord is pressed on by a piece of bone which is removable. Operation is probably justifiable when, in a case of incomplete interruption, after six weeks there is no further improvement.

No treatment is known which has a direct influence on the paraplegias which result from systemic disease, syringomyelia, and disseminated sclerosis.

Symptomatic Treatment.—Under this heading it is proposed to describe the measures to be adopted in the symptomatic treatment of a case of paraplegia more or less irrespective of its origin.

In cases of *paraplegia of acute onset*, certain precautionary measures are at once necessary.

1. In the event of the patient being unable to pass urine, as is usually the case, the next point to determine is whether the bladder is distended. If there is distention of the bladder, the *urine should be at once drawn off* with the strictest aseptic precautions. A catheter is to be passed three times a day until the patient is able at will to pass water freely. Statements to the effect that urine is being passed are to be accepted with caution, since an overflow incontinence may delude the patient into believing that all is well.

2. The patient should at once be placed upon a *water bed*, with the special object of avoiding bedsores.

In order to prevent the development of bedsores, it is of primary importance that the patient should be kept absolutely dry and clean. If there is incontinence of urine, the patient should be provided with a receptacle for the urine. Care is to be taken in the case of male patients that a trophic ulcer does not form on the penis in consequence of pressure. The buttocks and back should be carefully washed with soap and water at least twice a day; methylated spirit is then to be rubbed into the skin, which may afterwards be dusted with some bland non-irritating powder. The heels may be allowed to lie in nests of cotton-wool as an additional precaution against bed sore formation. The danger of burns as a consequence of hot bottles coming in contact with the insensitive skin is to be borne in mind.

Whether the case be one of hæmorrhage or acute myelitis, on theoretical grounds it has been suggested that the patient should be placed in the *prone position* until the acute process has ceased to progress. It seems reasonable to suppose that in this position gravity may to some extent deplete the vessels in the neighbourhood of the lesion, a result which in the supine position is probably reversed. Two pillows placed beneath the abdomen will help to diminish any discomfort the patient may experience in assuming this unwonted posture. Absolute rest should be enjoined. If the patient finds this to be impossible in the prone position, it is probably well to let him lie upon his back.

Ice applied over the situation of the lesion is recommended by most authorities in cases of acute myelitis. A sponge-bag filled with ice will be found convenient for this purpose.

It is improbable that ergot is of any use in arresting the inflammatory process in a case of acute myelitis; if, however, hæmorrhage has been diagnosed, or even if its presence is suspected, full doses of this drug may be administered with possible advantage. When there is much pain, as there is very apt to be in cases of hæmorrhage, 10 gr. of phenacetin may be given. Should this prove ineffectual, $\frac{1}{4}$ gr. of morphia, injected subcutaneously, will probably bring relief.

Constipation, a constant accompaniment unless treated, is to be guarded against by a daily soap and water enema.

Small doses of iodide of potassium (5 to 10 gr.) may be administered internally, in the hope that they may aid in promoting absorption of the inflammatory products.

The nursing of these cases requires the greatest care, and, whenever practicable, the services of one, or better, two, trained nurses should be secured.

In cases of *chronic paraplegia*, or in those of sudden onset in which the acute stage has passed off, the patient should be given every encouragement to use his limbs, with due caution as to the avoidance of fatigue.

When the *paraplegia is of the flaccid variety*, a consequence of destruction of the lumbosacral cord or nerve roots of the cauda equina, the paralyzed muscles should be massaged every day. The application of faradism—or, if the muscles will react only to galvanism, the latter form of electricity—may be recommended

as soon as the acute process has passed off. Strychnine may be given hypodermically with advantage in the flaccid paraplegias, although contra-indicated where spasticity exists.

Cases of paraplegia dating from birth, in which difficulty in walking is due to muscular rigidity rather than to want of power, have recently been submitted to operation. Division of a number of posterior spinal roots has been followed, in several instances, by pronounced diminution in the muscular rigidity and corresponding improvement in locomotion.

In treating the flexor spasms, the jumping of the legs of which paraplegics so often complain—a specially annoying symptom, since it is apt to interfere with sleep—veronal in doses of 5 to 10 gr. may be of value. Extension applied at night-time, the necessary weight to be determined by experiment in the individual case, may also prove of service.

Pain in the back is sometimes relieved by the application of the Corrigan button over the spine in the region where it is experienced. In some cases of malignant disease of the vertebral column the pain is so severe that the condition well deserves the epithet "*dolorosa*" which has been applied to it. There is no object in withholding morphia in the treatment of those cases in which a fatal termination is to be looked for in the near future.

One of the most common causes of death in cases of paraplegia is the development of a cystitis, with a subsequent spread of the infection to the kidneys, producing a pyelonephritis. Should cystitis exist, the bladder should be washed out two or three times a day with weak boracic lotion, while suitable remedies, such as salol, hexamethylenamine, and acid phosphate of soda, may be given internally, as indicated by the condition of the urine. Other associated lesions and complications, such as anæmia, are to receive the necessary treatment which their presence demands. (See also *ELECTROTHERAPEUTICS*, and *SPINE*, *CARES OF*.)

Edwin Bramwell.

PAROSMIA.—The majority of patients who seek advice because of an unpleasant smell in the nose will be found to be suffering from some local disease. The most careful examination must be instituted to discover any cause, such as suppuration in the accessory sinuses (especially in the antrum), syphilitic ulceration, necrosis, or a foreign body. The mouth, throat, and even the lungs must be examined as a possible source of the trouble. The chief causes of true parosmia are hysteria, neurasthenia, influenza, and central nervous diseases. The treatment must be directed towards the removal of the cause, and combined with appropriate general measures. The prognosis in the majority of cases is good.

PAROXYSMAL RHINORRHOEA.—(See *HAY FEVER*.)

PAVOR NOCTURNUS.—(See *NIGHT TERRORS*.)

PEDICULOSIS CAPITIS.—It is not enough to bring about the destruction of the living pediculi. That is easy, and may be accomplished by the free application of any antiseptic, or by simple prolonged soaking in water. If the embryos in the nits are not also destroyed, any relief is only temporary. The best and surest method of cure is the application of common paraffin oil. It is not advisable to wash the head before beginning this treatment, as the removal of the natural grease from the scalp makes the application needlessly painful:

the pediculi are in the hair, not in the skin. Further, to avoid unnecessary pain, the skin at the nape of the neck, and behind the ears, should be liberally smeared with lard or zinc ointment. The hair is then soaked (at night) with the oil, and strips of rag, dipped in it, are plaited up with the hair into a chignon, over which a bathing-cap is applied. The soaking is repeated, morning and evening, on the next day. On the following morning the head is washed with soap and water. If these directions are faithfully carried out, one may feel confident of the destruction of all the embryos, and thus of complete cure. Oil of sassafras may be substituted for paraffin. The nits still remain adherent to the hairs in large numbers, acting as unpleasant reminders of the past. Many methods for their removal have been recommended; probably the best is the diligent use of the old-fashioned tooth-comb dipped in warm vinegar.

Norman Walker.

PEDICULOSIS CORPORIS.—The pediculus corporis, though usually found on the vestments, deposits its eggs on the fine downy hairs of the trunk, and it is therefore not sufficient to disinfect the clothes and bathe the patient. In addition to these most desirable procedures, some antiparasitic ointment, such as sulphur or stavesacre, must be thoroughly applied to the body surface for two or three days. Allan Jamieson recommends that elderly persons whose habits are such as to "predispose" to pediculosis should wear a little bag filled with sulphur, like a charm, round the neck. The vapour of the sulphur is repulsive to the pediculus.

Norman Walker.

PEDICULOSIS PUBIS.—The crab-louse does not restrict itself absolutely to the region which is suggested by its scientific name, but is found occasionally on the hairs of the axillæ, eyebrows, and eyelashes: in these latter situations, only in greatly neglected children. In the usual situation on the pubis, it is easily destroyed by the regular application of some antiseptic ointment. Blue ointment, the usual chemist's prescription, is not a desirable antiseptic to use, for two reasons: first, the readiness with which the mercury is absorbed into the system from this warm moist region, and second, the frequency with which a mercurial dermatitis is set up. This, in its turn, causes irritation; the unfortunate victim attributes this to the pediculi, and in his anxiety he applies more and more of the ointment, which has probably already destroyed the parasites, and now merely aggravates his sufferings. White precipitate ointment is as efficacious and less injurious; warm vinegar, with a little sublimate, is a favourite application in France; and in very severe cases the parts may be shaved.

Norman Walker.

PEMPHIGUS.—True pemphigus is a very grave disease, and fortunately, for treatment is far from satisfactory, a rare one. Arsenic is the most useful remedy, and should be given as freely as the patient's general condition permits. As soon as it has obtained control of the disease, the dose should be reduced till just enough is given to maintain the improvement. No other drug has so specific an influence as arsenic, but strychnine and other tonics are sometimes useful when, for one reason or another, one is compelled to suspend the administration of arsenic. The cacodylate or other organic compounds of arsenic may be tried, but their effects are just the same as those of arsenic, while they impart a very marked garlic odour to the breath. In one case under the writer's care the administration of soamin (one of the modern synthetic arsenical compounds) was followed by complete and permanent blindness. Similar disasters have been recorded in connection with other like preparations, and he has accordingly ceased to use any of them.

Local treatment consists in letting the contents out of the bullæ, and the

application of some simple antiseptic ointment ; but if it is feasible, the patient's chances of recovery are greatly aided by continuous immersion in a weak antiseptic bath, kept just above the normal body temperature. Cases of pemphigus should always be sent to, and always admitted to, a hospital. [*Norman Walker.*]

PERICARDITIS.—(See RHEUMATISM, ACUTE.)

PERICOLITIS.—(See DIVERTICULITIS OF COLON.)

PERIOSTITIS.—(See BONE, INFLAMMATIONS OF.)

PERIPHERAL NEURITIS.—(See NEURITIS ; PARAPLEGIA.)

PERITONITIS, TUBERCULOUS.—In this, as in all forms of tuberculosis, hygienic treatment is of the first importance. Whilst active symptoms (e.g., fever) are present, the patient must be confined to bed, but care should be taken to see that he gets as much fresh air as possible, and as soon as may be he should be taken out of doors. If the patient be a child, he can be wheeled about in an invalid perambulator, preferably by the seaside—Margate and Broadstairs being specially suitable localities.

The diet should be abundant, and should contain plenty of the more easily digested forms of fat, such as bacon, butter, and cream, besides minced meat, pounded chicken or fish, eggs, and abundance of good milk. Unless the latter can be guaranteed to be free from tubercle bacilli it is safer to boil it. Starchy foods should be given sparingly.

Locally, $\frac{1}{2}$ dr. of one of the following preparations should be rubbed into the abdomen night and morning : equal parts of iodoform ointment and olive oil, oleate of mercury ointment (10 per cent), linimentum hydrarg. (B.P.), blue ointment, or croton oil. The abdomen should also be covered with a firm flannel binder.

Internal medication must first be directed to the state of the bowels. If, as is so often the case in children, there be a tendency to diarrhœa with offensive motions, $\frac{2}{3}$ min. tinct. opii should be given for each year of the child's age, three times a day, along with full doses of bismuth or chalk. When the diarrhœa has been overcome, cod-liver oil or oil and malt may be given, and, if there be anæmia, 20 min. of glycerin. ferr. iodid. thrice daily. Small doses of arsenic are also useful. Guaiacol carbonate or creosote may be given (see PHTHISIS), or iodoform (though cautiously). The following is a convenient formula for the administration of the latter :—

R Iodoformi	gr ss	Emulsi Olei Morrhuæ	q.s. ad 3j
Tincturæ Lavandulæ Co.	℥viiss		

If pain be troublesome, Dover's powder (4 gr. thrice daily for a child of five) is the best analgesic.

Ascites need not be interfered with in acute cases unless it is causing distress. It is then most safely dealt with by incision.

If, after a persevering use of these measures for six weeks, no improvement is observed, the propriety of surgical interference should be considered ; but it must be pointed out that the results of medical treatment are, on the whole, so satisfactory that operation is less often resorted to in such cases now than formerly. The cases most favourable for operation are those in which there is considerable ascites. In such circumstances evacuation of the fluid by laparotomy, with or without irrigation of the peritoneum, is often followed by cure. Cases in which there are little free fluid and much matting do not give nearly such good results. It need hardly be pointed out that operation should not be recommended when there is evidence of tuberculosis elsewhere, e.g., in

the lungs; for in that case the abdominal affection is merely part of a general tuberculosis.

It should be added that the "specific" treatment of abdominal tuberculosis by means of tuberculin or bacillary emulsion is advocated by some, and may be tried cautiously. (See SPECIFIC THERAPY.)

Robert Hutchison.

PERNICIOUS (ADDISONIAN) ANÆMIA.—(See ANÆMIA.)

PERSPIRATION, EXCESSIVE.—(See HYPERIDROSIS.)

PERSPIRATION, OFFENSIVE (Bromidrosis).—Patients who suffer from this troublesome complaint should pay great attention to personal cleanliness; a daily bath should be taken and the linen frequently changed. Thymol soap should be used freely. The feet, axillæ, and other parts where perspiration is most profuse, should be bathed with a 1 per cent solution of formalin, after which an antiseptic dusting-powder may be applied. Pieces of lint dusted with boric acid should be placed between the toes and changed daily; the interior of the socks may also be dusted with boric acid or tannoform. A lotion of 30 min. of ammonium ichthyolate to an ounce of cold water may be sprayed over the surface of the body with advantage in severe cases.

When the feet alone are affected, pure formalin or a 2 per cent solution of chromic acid may be applied on a tampon of cotton-wool. The application is at first repeated daily, but afterwards at longer intervals. It should be noted that the solution stains the skin and nails yellow. The application of the x rays is also very effective, and gives permanent results (see HYPERIDROSIS).

As regards internal remedies, laxatives are often helpful, but those which contain sulphur should be avoided. Liq. ferri perchlor. (Edin. Pharmacop.) 1 dr., with calc. chlor. 5 gr., in half a tumblerful of water three times daily, has also been recommended. (See also HYPERIDROSIS; BREATH, OFFENSIVE; and RADIOTHERAPEUTICS.)

PES CAVUS.—(See TALIPES, ACQUIRED.)

PHARYNGITIS.

1. Acute Catarrhal or Simple Pharyngitis is generally due to an acute cold in the head, but often occurs alone in those of a gouty or rheumatic diathesis, without any implication of the nasal passages. Care must also be taken to eliminate the possibility of secondary syphilis.

TREATMENT.—When it occurs along with a cold in the head, besides treating the cold (see RHINITIS), the pharynx should be sprayed with an alkaline solution and painted with Mandl's throat paint, two or three times a day.

R Potassii Iodidi	gr viij-xv	Olei Ment hæ Piperitæ	Mij
Iodi	gr v-x	Glycerini	q.s. ad ʒj

2. Septic Pharyngitis is nearly always associated with acute disease of the tonsils or larynx, and is due to infection by a pyogenic organism.

TREATMENT.—The patient should be kept quiet in bed. The room may be warmed by means of a fire, but the windows must be open. Also oxygen may be given for five minutes every hour. As the infection is a mixed one, if the temperature runs high an injection may be given of polyvalent serum, or of antistreptococcic serum. Everything must be done to maintain the patient's strength, and if nourishment cannot be taken by the mouth, nutrient enemata must be given. A spray of cocaine (20 per cent) combined with epinephrin

(1-2000) will often enable the patient to swallow, and will also prevent spasm of the larynx. The measures already advocated (see LARYNGITIS) of alternately using hot and cold applications to the throat, and a mustard plaster, should also be tried. If the dyspnoea becomes urgent, laryngotomy or tracheotomy must be performed. The most useful drugs are perchloride of iron (20 to 30 min.) with glycerin (30 min.), combined with liquor strychninæ (1 per cent) (5 to 10 min.), and chlorate of potash (10 gr.).

There are two forms which occur independently of tonsillar disease, viz., tuberculous ulceration, and that which occurs in the course of typhoid fever.

Abscess in the pharynx may also occur, and be (a) Septic; (b) Tuberculous.

a. *Septic Abscess* occurs under the name of retropharyngeal abscess in young children between the ages of two months and two years. The child gets restless for no apparent reason, and then difficulty of swallowing sets in. The diagnosis is made easy by the peculiar way in which the child holds its head back, with the chin protruded forwards as far as possible, and the mouth wide open, so as to make the passage into the lungs as short and straight as possible. The breathing is of a snorting character, thus differing from the stridor of laryngeal obstruction. On examining the throat for the cause of the stertor, the soft palate is seen to be red and pushed forward, and the posterior wall of the pharynx generally bulges more to one side than the other.

TREATMENT.—The abscess should be opened without delay. The child should be placed on a table with the head hanging over the end, but supported by a nurse or assistant. The mouth should then be kept open with a gag, and the abscess incised with a guarded bistoury. A spray of sanitas or Condyl's fluid should afterwards be used until the wound is healed.

b. *Tuberculous Abscess* is due to caries of the cervical vertebræ. When dyspnoea occurs in a case of cervical caries, accompanied by difficulty of swallowing and retraction of the head, retropharyngeal abscess should always be looked for. In these cases the abscess should be opened externally from the neck behind the posterior border of the sternomastoid muscle, with aseptic precautions.

3. **Chronic Pharyngitis** may be divided into three chief groups: (a) General; (b) Granular; and (c) Pharyngitis sicca.

a. *General Pharyngitis* occurs in those who smoke or drink to excess, or use their voice much without knowing how to use it properly. It is also common in those of a gouty or rheumatic diathesis when they are exposed to damp or cold.

TREATMENT.—General treatment is necessary in all cases. If the nose be affected in any way it should be attended to, and smoking to excess or abuse of alcohol should be prohibited. In the cases due to gouty dyspepsia the diet should be regulated. If possible, the patient should take a "cure" at Aix-les-Bains, Harrogate, Matlock Bath, Mont Dore, or a similar watering-place. If unable to do so, he can carry out the "cure" at home by taking half a tumbler of Vichy water filled up with hot water before breakfast, instead of the morning cup of tea, and the same in the afternoon, substituting hot milk for the hot water, or by sipping two tumblers of hot water to one of which half a teaspoonful of Epsom salts has been added. If constipation be present, as it generally is, it must be treated.

The pharynx should be sprayed with the alkaline wash, or half a teaspoonful of common salt may be added to half a tumbler of warm water tinged a pale pink by a few drops of Condyl's fluid and used as a gargle. Carbolic acid lozenges (B.P.) (T.H.P.) may be used frequently. It is best to break one in half and take a half every two hours.

In the case of clergymen and others who are exposed to damp and cold, and are constantly getting attacks, especially if they have to use their voice, it is an excellent plan to grow a full beard and moustache. This provides the throat

with its natural protection ; if it be done, the all-round clerical collar should be as open as possible, so as not to press upon the larynx or the blood-vessels at the side of the neck.

b. Granular Pharyngitis, often called "clergyman's sore throat," is characterized by little swellings of the lymphoid tissue surrounding the mouths of the mucous follicles dotted over the posterior wall. Sometimes the follicles are filled with mucus, and have swollen veins running into them. It usually occurs in those who use their voice professionally, and at the same time wrongly, and the various stages of the causation have been succinctly described as "constriction, friction, congestion, inflammation, and disease."

TREATMENT.—The first requisite is for the patient to learn to use his voice in a proper manner ; otherwise, if the granulations be cauterized, others will appear as long as the cause continues. The writer has seen several throats which seemed to have had every bit of mucous membrane cauterized, with no good result, and as soon as the patient learned to produce his voice properly the granulations ceased to recur. Sometimes, however, only one or two granulations may be present, and give rise to a constant feeling of irritation and desire to cough. The application of the cautery to them generally removes all the symptoms for the time being. It is advisable, however, to paint the pharynx with Mandl's solution, or spray it with a solution of aceto-tartrate of alumina (1-500) or argyrol (30 gr. to the oz.), for some time afterwards.

c. Pharyngitis Sicca.—This condition is always dependent on disease of the nose or nasopharynx, and disappears if the latter can be put right. Stuart-Low recommends spraying the nose and pharynx, after cleansing them, with a solution of mucin. It certainly keeps the throat moist for some hours after using it.

George C. Cathcart.

PHARYNX, FOREIGN BODIES IN.—(See FOREIGN BODIES IN THE AIR-PASSAGES AND OESOPHAGUS.)

PHARYNX, MALIGNANT DISEASE OF.—(See MOUTH AND PHARYNX, MALIGNANT DISEASE OF.)

PHIMOSIS.—By phimosis is meant a condition in which the preputial orifice is too small, so that the prepuce cannot be fully retracted and the glans exposed. It may be congenital or acquired. When congenital it is associated with adhesions between the prepuce and the glans. When acquired, it is either *temporary*, in which case it is the result of inflammatory swelling of the prepuce, and may disappear when the inflammation subsides, or *permanent*, when it is the result of repeated attacks of balanitis, or of chronic inflammation associated with diabetes (Thomson Walker), or is due to the contraction of chancroids occurring at the preputial orifice. Both in children and adults a slight degree of congenital phimosis may be aggravated by the presence of septic sores and inflammatory induration about the preputial orifice.

In infants and children phimosis is usually treated by circumcision, though this is not always necessary in the mildest cases. When the prepuce is of normal length and its orifice only slightly contracted, it should be forcibly retracted and the adhesions broken through. This manœuvre should be repeated daily by the nurse, a little simple ointment being smeared over the glans.

The following are the indications for circumcision in children with phimosis :—
(1) Moderate or severe contraction of the orifice ; (2) A long prepuce, whether the contraction of the orifice is considerable or not ; (3) When the daily retraction of the foreskin is not being successfully carried out ; (4) When the condition has given rise to masturbation, or other signs of irritation.

In adults, every case of phimosis, whether congenital or acquired, with the possible exception of some cases of the temporary inflammatory variety, should be submitted to operation. In acquired phimosis associated with diabetes, only the most severe cases should be operated upon, and then only with elaborate precautions against sepsis, and under local anæsthesia (Walker). It is unnecessary to enumerate here the various troubles of an inflammatory and even of a malignant nature which are aggravated or even indirectly caused by phimosis in the adult, and which may call for the immediate relief of the deformity.

Two operations are available, viz., slitting up of the prepuce on the dorsum, and circumcision. In the presence of acute inflammation, particularly when the prepuce itself is much involved, the former operation is to be preferred, and should be performed without delay. The prepuce should be slit up as far as the corona, and the corners of the two flaps thus formed trimmed off. A director should be used to ensure separation of the prepuce from the dorsum of the glans before the former is slit up. In all other cases circumcision should be performed.

The Operation of Circumcision.—A general anæsthetic should be administered to all children, and most adults, though in the latter novocain or eucaine may be used in some cases. The parts having been cleaned up in the usual

way, the penis is passed through a hole cut in the centre of a piece of sterilized lint. The extremity of the prepuce is seized in a pair of toothed catch forceps and gently drawn forwards. The prepuce is then grasped by a pair of long-bladed dressing forceps placed obliquely, from above downwards and forwards, opposite the anterior part of the glans, which is allowed to slip back as the forceps are closed. The prepuce is then cut away in front of the forceps with a knife or scissors.

Fig. 61.—Circumcision.

The late Mr. Davies Colley directed that "the incision should begin upon the dorsum, at a point corresponding to that part of the glans which is half way between the meatus and corona," and should leave "a sharp point in the middle of the under surface" to cover the raw area which would otherwise be left uncovered opposite the frænum (Fig 61). The mucous membrane is now slit up on the dorsum as far as the corona with a pair of scissors, a director being first used if any difficulty is experienced in breaking down adhesions. The two flaps of mucosa are then peeled off the glans till the whole of the corona is exposed, and all smegma cleaned away. The redundant mucosa is now cut away with scissors, leaving an eighth of an inch, or a trifle more, all round, or just enough to carry the sutures and to cover the sensitive coronal papillæ.

Kirmisson suggests the application of artery clips to the prepuce to mark the line at which the section is to be made.

The frænum itself must not be damaged. To prevent the œdema which so often occurs in the region of the frænum, a narrow strip of the loose areolar tissue lying between the mucosa and the skin should be pulled out and excised from the ventral side of the glans. It is important that all vessels which are bleeding, or are likely to bleed when reaction sets in as the child recovers

from the anæsthetic, should be secured. This can usually be done by means of the sutures, but if any vessels continue to bleed they must be ligatured. A few interrupted sutures of silk or horsehair are inserted in all cases, even in infants. For the latter, three are quite sufficient, one being placed at the frænum and one on either side.

In young children the dressing should be a piece of gauze, soaked in lead lotion, and wound round the penis. This can be soaked off in a bath, and renewed by the nurse once a day till healing has taken place. In adults the same dressing may be used, or the penis may be simply wrapped in plain dry gauze; in either case the dressing need not be disturbed till the fourth day, when it is soaked off, some of the stitches are removed, and a fresh, dry dressing is put on. In adults the penis should be slung up to the abdominal wall with a handkerchief or triangular bandage, to prevent œdema. The patient should remain in bed for a couple of days, and should be on his feet as little as possible till the end of a week, when all the stitches should be out and the wound healed. Jacobson recommends a dose of bromide at night to prevent erection of the organ.

It is important that the operator should remember (1) To remove plenty of mucous membrane: if this is not done relapse may follow, as the deformity is caused by contraction of the mucosa, not of the skin; (2) Not to remove too much skin: he must leave enough to cover the corona; (3) Not to damage glans or frænum, though he should remove as much tissue as possible near the latter.

There is one more important point which should always be remembered while circumcising a child. The meatus should always be examined, as it is often too small, and is more often the cause of difficulty in micturition than is phimosis. Moreover, after circumcision, the glans becomes dry by exposure, and exhibits a tendency to the formation of scabs about the meatus, as well as further back where adhesions have been torn, so that the orifice is still further contracted. If the meatus is small it must be enlarged downwards, and a horsehair or fine gut suture inserted at the bottom of the cleft thus made, and left in for ten days or a fortnight, when healing will have occurred. The edges of the enlarged meatus should be separated daily, and a little ointment applied.

H. A. T. Fairbank.

PHLEBITIS.—Treatment depends upon the cause and extent of the phlebitis. An inflammation due to causes not actively septic, and localized in a small vein, runs a favourable course if the part be protected from injury and movement. The single risk is that of embolism through the detachment of clot from the inflamed and thrombosed vein, and this is to be minimized by securing that the clot shall be left undisturbed till it has either been absorbed, or has formed strong attachments to the vessel wall. This takes ten days.

The most common example occurs in connection with varicose veins of the legs, and in such cases elevation of the limb, rest in the horizontal position in splints for two weeks after the active mischief has ceased, and hot applications, are suitable treatment.

Where deeper veins are involved—for instance, the common femoral—the cause is more serious, and the extent of the clotting less likely to be limited. Preventive treatment therefore occupies a position of first importance. In all cases likely to develop this complication—and it is specially common in patients who have lost much blood and have undergone some pelvic traumatism such as fractured pelvis, difficult parturition, or operation for pelvic disease, and still more so if septic infection has been superadded—the lower limbs should be rubbed

upwards three or four times daily in order to assist the venous circulation, and this should be commenced not later than a week after confinement to bed. At the same time daily exercise of the legs should be practised, the movements being similar to those used to propel a bicycle. These simple measures, which I have now advocated and employed for some years, rarely fail to prevent phlegmasia alba dolens, the classical name for phlebitis and thrombosis of the femoral vein.

The treatment of the developed condition is, to say the least, unsatisfactory. The pain may be relieved by elevation of the limb, complete rest of body and limb, and the use of hot fomentations containing opium or belladonna. Careful nursing and fever diet are necessary during the first two weeks. If all tenderness has then disappeared, and there are no signs of further extension of the inflammation and clotting, gentle massage may be commenced, with the object of reducing swelling and assisting the anastomotic circulation in the limb. At a later stage more vigorous massage is employed, and when the patient gets up, as he may be allowed to do in favourable cases after the sixth week, an elastic bandage aids in the reduction of that swelling of the limb which constitutes the most troublesome and rebellious of the inflammatory results.

In the most acutely septic cases, recognized always by their recurring rigors, the only treatment likely to be successful is arrest of the circulation through the infected vein by means of operation.

The most successful application of this method of treatment has been in septic phlebitis and thrombosis of the lateral sinus secondary to suppuration in the middle ear. In such cases operation has been the means of saving many lives.

A more recent application of operative methods for arrest of the circulation in infected veins deserves more recognition than it has yet received.

As a consequence of uterine sepsis, generally puerperal, thrombophlebitis of the pelvic veins may occur. Recurring rigors in a predisposed woman are strong evidence, however good the general condition of the patient between the rigors may be, that this is the cause of her illness, that surgical measures alone are likely to be useful, and that operation to obliterate or excise the infected veins should be considered without delay.

A similar condition occurs in connection with rare cases of acute appendicitis. Thrombophlebitis of the appendicular veins follows the attack or the operation, and may steadily progress to infection of the liver through the portal circulation. The first evidence is a rigor; this is followed by repeated, usually daily, rigors, and the patient, though often at first in good condition, rarely escapes death. Excision of the ileocolic vessels and the bowel which they supply (six inches of ileum, cæcum, and ascending colon), followed by anastomosis between the ileum and transverse colon, is now so safe an operation, and offers in an early stage so good a chance of arresting the venous infection, that on the first available opportunity I intend to have the courage of my convictions and perform it.

Phlebitis of the facial veins occurs frequently from infections of the face, and thrombosis of the cerebral sinuses may follow spread of the sepsis. All superficial septic foci on the face should be isolated by a circular incision, and if this demonstrates thrombosis, the infected veins should be opened, the thrombus followed up and removed, and the resulting wound should be packed open with sterile or iodoform gauze.

Rutherford Morison.

PHLEBOTOMUS FEVER.—The treatment for this short fever is entirely symptomatic. The debility which sometimes follows requires change to a cooler and more bracing climate.

C. W. Daniels.

PHOSPHATURIA.—An unnatural deposition of phosphates in the urine is seen under a variety of conditions, the most common being one where, owing to an alteration in the inter-relationship of its normal saline constituents, and a consequent diminution in the acidity of the urine, phosphate of lime in an amorphous form is present in the urine as passed, giving it a milky appearance. This condition is seen frequently in health, to a slight degree, in the urine passed immediately after meals, but it occurs not uncommonly to a greater extent in young men in association with gastric disturbance. Such patients pass a more or less milky urine throughout the day, although that passed the first thing in the morning may be free from deposit. They generally suffer from some form of indigestion, are not uncommonly thin, and their general nutrition is bad; they frequently present marked neurotic or neurasthenic symptoms. The milky appearance of the urine not uncommonly gives rise to alarm, owing to its abnormal appearance. There is no evidence that in such cases there is any unnatural amount of phosphates excreted, the whole condition being merely dependent on the alteration of the relative amounts of soluble and insoluble phosphates in the urine. The condition can usually be treated by simple measures directed to increase the acidity of the urine, and this can be effected by alterations in the diet, e.g., the diminution of vegetables, and by the prescribing of acids and the treatment of the indigestion, and by encouraging the ingestion of considerable quantities of fluid.

Where the deposition of phosphates is associated with decomposition of the urine and the development of ammoniacal fermentation, the conditions are totally different. In such instances treatment must be directed to checking fermentation, either by local treatment of the cystitis, or by the administration of urinary antiseptics such as hexamethylenamine, and by measures directed to increase the acidity of the urine. This can often be brought about by giving acid phosphate of soda, and in this way the urinary fermentation can be greatly checked. In many cases of bladder and prostatic disease, where cystitis with ammoniacal fermentation is present, the administration of acid phosphate of soda is advisable for some time prior to operative procedures being undertaken, since by this means the local conditions can be rendered much more favourable to the success of such treatment. The acid phosphate of soda should be given in full doses.

In addition to these more or less common forms of so-called phosphaturia, there is another condition of genuine phosphaturia, in which the actual amount of phosphates excreted is increased. It is a condition which has sometimes been spoken of as phosphatic diabetes, and which has been described by some as not only existing in diabetes, but as also occurring prior to the onset of glycosuria. In phosphatic diabetes unaccompanied by glycosuria, the nutrition would seem to be considerably affected, and much wasting may be present; the only treatment available is that directed to improving the general nutrition. In true diabetes, the excess of phosphates in the urine is probably largely dependent on the increased appetite. (See also CALCULUS.) *J. Rose Bradford.*

PHOTOTHERAPY.—The use of x rays as a therapeutic measure is dealt with in another section, and under the heading phototherapy we have to consider only two types of *Light Treatment*, those by the arc lamp and by the incandescent—with a brief reference to the Finsen rays.

The Electrical Arc Lamp is one of the earliest forms employed. When iron-cored electrodes are used for its generation, it has the advantage of giving out rays very rich in the chemical factor belonging to the ultra-violet end of the spectrum. A practical disadvantage of this light is that it has to be always in the horizontal or semi-horizontal position, and not suspended over the patient,

owing to the danger of burning particles of carbon falling on him from the electrodes as they consume. Also, a very heavy current is used up in proportion to the amount of radiant light and heat given off, much heavier than when a high-power incandescent lamp is used, such as the leucodescent. The arc lamp, moreover, is unsuitable for use in an enclosed chamber such as the electric-light bath, because of the gases, composed largely of ozone and nitrous fumes, thrown off. Ultra-violet rays, moreover, produce a very high degree of hyperæmia of the skin, with resultant tanning, if used for any length of time. While the hyperæmia is to be desired in many cases, the tanning interferes with any subsequent application of a radiant energy to the deeper tissues.

Duration.—Fifteen to twenty minutes, according to nature of case and the toleration of the skin of patient.

Of Incandescent Lamps, the special form known as the *leucodescent** is the most efficacious and powerful. It consists of a high-power incandescent electric lamp—from 300 to 500 C.P.—placed within a cylindro-conical metal hood. This hood is lined with a highly polished nickel-plated surface, known as the reflector. The back or top of the dome-like hood is formed by a corrugated aluminium plate called the condenser. It is made of aluminium, owing to that metal's freedom from tarnishing. It is important to keep the nickel-plated reflector bright by means of silver polish and a small piece of chamois leather. The lamp differs in construction from the ordinary types employed for domestic purposes in some details. It is held within the hood by means of two binding posts connected by suitable wiring with the street current, which is conveyed to the filament in the bulb. The operator must therefore not attempt to take the lamp out by means of the usual twist to one side or another when a bayonet catch is used. To remove the lamp, first see that the switch reads "off," and then take out the screws at the top of the porcelain cap, carefully supporting the lamp with one hand inside the hood. Detach the cable ends from the porcelain disc inside the cap, and remove the lamp from the reflector. Then, detaching the lamp connections from the under side of the disc, pull the lamp out of the holder.

One of the great advantages of the leucodescent lamp is its ready adaptability to any room or surgery where the electric current is available. The whole apparatus swings from a wall bracket, and is balanced on it by a weight equipoise and two easily running pulleys. The cord on which it is suspended only requires to be connected up with a wall plug, and then the lamp can be moved up or down, or from side to side, with the greatest possible ease and with a large range of movement. In this respect it compares very favourably with the arc lamp, which has to be supported on a stool covered with asbestos sheeting, and which is capable of very little movement.

Attached to one side of the hood of the leucodescent is a wooden handle for manipulating it, and on the opposite side is a window of inspection for observing the effect on the part being treated. According to whether the affection is *acute* or *chronic* there are two modes of applying the treatment by this apparatus:

1. The light may be gradually focused so that the application can be tolerated for a considerable time at each application. The lamp is kept at a good distance from the part under treatment, and the heating effect is controlled by the operator brushing his hand from time to time over the part. A good plan is to keep the lamp swinging slowly to and from the part being treated.

Duration.—Twelve to fifteen minutes each part.

2. In acute affections it is better to apply the rays strongly for a brief period.

* Particulars from A. E. Dean, 86, Hatton Garden, E.C., for Spear-Marshall Co.

AFFECTIONS FOR WHICH THE LEUCODESCENT LAMP IS SUITED :—

In *localized inflammatory conditions due to pyogenic organisms*, such as boils, abscesses, and acne pustules on the back, etc. A prolonged application destroys or lessens the vitality of the organisms and relieves the pain in a very remarkable manner. Subsequently a small incision may be made and the pus evacuated. The pain of the incision is lessened by the exposure to the rays. If the suppuration be deep, an application of half an hour or more may be necessary.

Muscular rheumatism, lumbago, etc.—Prompt relief is afforded in this class of affection by a few applications. *Pleurodynia*, or intercostal neuralgia, is similarly benefited. The patient is laid on the sound side, and brief, strong applications of half to one minute are made; then the lamp is moved further away for a pause, and the application repeated in a little while until some relief is afforded.

Neuritis.—This affection of course depends on a vast variety of causes, from injury to various toxæmiæ, such as gout, rheumatism, malaria, alcohol, lead, arsenic, syphilis, diphtheria, etc. Very often, therefore, a prolonged course of constitutional, as well as local, treatment is needed; but in any case the severe pain, which is so common a symptom, is markedly relieved by an application of the lamp. Similarly, in *neuralgia* it may be used with benefit, and the depressing and deleterious effects of coal-tar-product tablets avoided. Such treatment is to be preferred in every way, for the patient does not go off and purchase a bottle of tablets and *feed* on them for weeks while the pain troubles him, but returns to his doctor for an application when the pain is severe, and the latter is thus enabled to keep in touch with him and shorten the cure.

One of the most common affections calling for this treatment is *sciatica*. The application must be made along the outer aspect of the hip and thigh, and close over the great trochanter, for a few minutes at a time. In this way the congestion of the nerve is lessened and relief afforded, though perseverance may be needed in this as in all forms of treatment for so obstinate an affection.

In most of the above affections the effect of the lamp is greatly enhanced by applying the static wave to the part immediately after, with a lead foil electrode.

The Dowsing Incandescent Lamp is a small portable lamp for the local application of radiant heat, placed on the market by the Dowsing Co. It is much less powerful than the leucodescent as a therapeutic agent, but is very useful for treating restricted areas, such as a shoulder-joint or an elbow, and is very easy to manipulate.

The Finsen Rays.—The Finsen light was first applied by the well-known Danish inventor of this name, for the treatment of lupus. The principle was to focus sunlight through water lenses pressed over the skin so as to render it anæmic and permit the rays to penetrate. Partly because sunlight is less rich in ultra-violet rays than the electric arc lamp, and partly because of its inconstant supply, large electric lamps of the arc type were devised by Finsen for the treatment, the light being focused by means of telescopes, fitted with quartz lenses cooled by water. Quartz allows almost free passage to ultra-violet rays, much more so than glass. The lamps are very powerful, and require a heavy current of about 80 ampères. Smaller and more portable types of lamps of the Finsen description have been made, viz., the Finsen-Reyn and the Lortet-Genoud (full particulars from the Sanitas Electrical Co., New Cavendish Street, W.). They are brought close to the patient and are available for only one person at a time. With the large Finsen fitted with several telescopes, as many as four patients can be treated at once. The Finsen-Reyn lamp requires about 20 ampères of current, and is the best modification.

The Finsen light in no way rivals x rays for any other affection than lupus. For this affection it has at least the advantage of complete safety. It is, however, very slow in its cure, and taxes both the patient's and the physician's time and patience. Also it is difficult to penetrate the deeper tissues by means of its use.

A very complete and elaborate Finsen outfit was installed at the London Hospital some years back, and many cures have been effected by it. For rodent ulcer and malignant disease generally, Röntgen treatment is much more efficacious and to be preferred.

T. D. Luke.

PHTHISIS.—(See PULMONARY TUBERCULOSIS.)

PHTHISIS, LARYNGEAL.—(See LARYNX, TUBERCULOSIS OF.)

PILES.—(See HÆMORRHOIDS.)

PITYRIASIS ROSEA.—This disease usually disappears spontaneously in from six to eight weeks, but its departure can be greatly hastened by treatment. Every night the patient should take a bath to which sufficient permanganate of potash is added to make the water claret-coloured. After drying, a 5 per cent salicylic ointment should be well rubbed in. In favourable cases the eruption is removed in less than a week; in others it may persist for a fortnight.

Norman Walker.

PITYRIASIS VERSICOLOR.—The treatment of this disease is really only difficult because the fungus is so easily destroyed that the patient is usually satisfied with a large measure of apparent improvement, and leaves off treatment prematurely. If even the smallest portion of fungus be left, it is quite obvious that the disease will "return." It is therefore necessary to keep up the treatment for a considerable time after all traceable evidence has disappeared. Almost any antiseptic will destroy the fungus, but it is better to use those which at the same time produce an exfoliation of the cuticle, such as tar, resorcin, and salicylic acid. While not denying altogether to hyposulphite of soda some antiseptic powers, the writer is of opinion that it owes its reputation in this disease largely to its bleaching properties.

Norman Walker.

PLAGUE.—*Symptomatic treatment* is that usually adopted. As early as possible in the disease, calomel (3 to 5 gr.) should be given, and be followed by a saline purgative. Diarrhoea, if it occur, is best treated by antiseptics such as salol; or bromide and morphia may be given. Stimulants must be used early, on any sign of cardiac failure. If collapse occur, strychnine hypodermically gives the best results. In apparent convalescence, the possibility of sudden cardiac failure must be remembered.

Hypodermic injections of morphia may be required to produce sleep and relieve pain. The buboes may be fomented or treated with glycerin and belladonna. When pus forms, they should be incised, but there is no advantage in incisions in the early stages. All dressings and discharges may be carriers of infection, and must be thoroughly sterilized or destroyed.

Serum Therapy.—Numerous attempts at treatment by the injection of sera have been made, but none can be said to be of proved value. Yersin's and Lustig's sera in large doses are still advocated by some observers. Injections of various antiseptic solutions into the buboes have not led to any beneficial result.

In the pneumonic form, stimulating expectorants, inhalations of oxygen, and antiseptic sprays have been used, but are of doubtful value. (See also SPECIFIC THERAPY.)

C. W. Daniels.

PLANTAR ABSCESS.—(See ABSCESS.)

PLEURISY.—(See also RHEUMATISM, ACUTE.) Putting aside questions of etiology, and looking at this affection mainly from the point of view of treatment, pleurisies become naturally divided into acute and chronic, dry or with effusion. The acute stage is much the same for the cases which remain dry and for those in which fluid eventually forms. We will, therefore, consider the treatment of: (1) *Acute Pleurisy*; (2) *Chronic Dry Pleurisy*; (3) *Pleurisy with Effusion*.

1. Acute Pleurisy.—Here we have no effusion, and our indications are to relieve pain, reduce fever, and prevent, as far as possible, extension and implication of lung. At the same time we must carefully watch for indications which would point to the presence of trouble in the lung, pericardium, or any other organ of which the pleura is only a part, and also for the supervention of effusion, with which we may subsequently have to deal.

The patient should be kept warm and at rest in bed. Leeching, wet or dry cupping, blistering, or repeated hot stupes or poultices are the best local measures. The first two (leeches and cupping) are the most efficacious for the relief of pain and checking extension, and should be used in all severely acute cases. Bleeding may be encouraged by subsequent poulticing. The patient is easier the more the respiratory movements can be restrained; firm bandaging or strapping of the chest often helps in this way, while, for a similar reason, it is well to check a troublesome cough with some simple linctus. There is generally some fever, and it is well to open the bowels with a pill or calomel and saline, followed by a diaphoretic mixture. If the attack occurs as part of acute or subacute rheumatism, salicin, salicylate of soda, acetyl-salicylic acid, or some other anti-rheumatic treatment, is often rapidly effectual in giving relief. The presence of Bright's disease must not be overlooked, as influencing the use of opium and blisters, and as also affecting the gravity with which we regard the case. Further, it is obvious that the treatment must be influenced to a certain extent by whether the attack is simple, or only part of some grave malady in the course of which it occurs.

2. Chronic Dry Pleurisy.—This is generally rheumatic, frequently recurrent, and the danger of its prolongation is great thickening of the pleura, with possible fibrotic extension into the lung itself, which may eventually culminate in a more or less contracted fibroid condition (cirrhosis). It may arise as an acute pleurisy, when the treatment already discussed for that condition will be necessary; but more generally it runs a chronic course, with slight subacute exacerbations. The chief indication is to keep the patient at rest, limiting especially the respiratory movements of the affected side, for by these movements recovery is delayed, involving increased thickness of pleura and more permanent damage to the lung. The patients are frequently not at all ill, and it is, therefore, difficult to persuade them of this necessity, but it is a point which must be emphasized. They should be kept at rest, the chest bandaged or strapped, and, until the attack has passed off, any exertion or further exposure, which may cause a relapse, must be forbidden. The salicylates are not so effective in this form, but iodide of potash and belladonna are often useful. After or between attacks it is important to see to the proper expansion of the lung by appropriate gymnastics and deep-breathing exercises.

3. Pleurisy with Effusion.—Pleural effusions have been divided pathologically into: (1) Septic; (2) Idiopathic; and (3) Mechanical. For purposes of treatment they are perhaps better divided into: (1) The small or stationary; (2) The large or increasing. (Only serous effusions will be dealt with here; for purulent effusions see EMPYEMA.)

Small or large effusions may arise acutely, and the appropriate treatment for acute pleurisy may have been employed. Many, however, arise without

any acute stage, often the only complaint being increasing dyspnoea. Beyond the treatment already discussed for pleurisy, all we have to consider is the question of tapping. Many authorities advise early and repeated tapplings, whatever the cause of the pleurisy or the amount of the fluid. We believe, however, that many small effusions accompanying febrile disorders or following simple lung affections (such as bronchitis and pneumonia) become rapidly reabsorbed, without causing any inconvenience or leaving any more mischief behind than if they had been tapped. Let us consider the possible results of leaving fluid untapped, or of taking it away, and then try to deduce guiding rules in this matter.

DANGERS ATTENDING THORACENTESIS.

- i. Syncope, from too rapid emptying, and consequent sudden shifting of important organs (heart, etc.).
- ii. Rupture of lung, which may be softened by inflammatory changes or partly tied down, so that only part of it can dilate.
- iii. Conversion of a serous into a purulent effusion.
- iv. Repugnance of patient and friends to the operation, which may have to be frequently repeated.
- v. "Albuminous Expectoration" (rare), from the sudden release of previously compressed vessels, allowing copious exudation into tubes and alveoli.

DANGERS ATTENDING AN UNTAPPED PLEURAL EFFUSION.

- i. Permanent damage to lung, which, if long collapsed, will undergo fibroid changes; also thickening of pleura, which prevents complete expansion subsequently.
- ii. Sudden attacks of syncope, which are frequently fatal. (These occur chiefly with large effusions. N.B.—It is very difficult to tell whether an effusion is large or small.)
- iii. Protraction of the case to the detriment of the general health.

We would suggest the following rules for guidance:—

a. When an effusion is obviously small in amount; is causing no inconvenience to circulation or respiration; when it has followed some definite simple affection of the lung, such as bronchitis or pneumonia; then, perhaps, especially in children (who so frequently rapidly reabsorb pleural fluid), there is no harm in allowing a week or two to pass, to give time for reabsorption.

b. When, in the course of pneumonia, an effusion forms on the affected side, unless our hands are forced by urgent symptoms, we should give the lung time to resolve before tapping, and in any case only a small amount of fluid should be withdrawn. We have seen pneumothorax result from neglect of this precaution, where the lung, softened by the pneumonia, ruptured in trying to dilate as the fluid was withdrawn.

c. On the other hand, when the effusion is large, or increasing; when it is of long standing or recurrent; whenever it is attended by urgent symptoms; when it has come on insidiously (that is, from some cause not likely to be shortly removed); and when, as in the above-mentioned exceptions, time has been given and no progress made, then undoubtedly the best and quickest results are given by tapping, and, if necessary, doing so repeatedly.

Thoracentesis.—The operation, small as it may seem to the surgeon, is not considered so by the patient or his friends, and it is well to remember that it can be ill or well done. The chief points to be remembered are these:—

- i. The patient should be in the lying or half-lying position.
- ii. The operation must be carried out with the strictest antiseptic precautions; the diagnosis having been verified by hypodermic needle.
- iii. The trocar and cannula used should be of medium size; if too large, there is danger of withdrawing the fluid too rapidly; if too small, it is very apt to become choked by lymph. Further, the larger the instrument, the greater the force needed to puncture and the greater the pain inflicted. Whether the ordinary aspirator (Potain), or the large, exhausting syringe (Dieulafoy) be used,

or the fluid allowed to trickle out under its own pressure, care should be taken that the withdrawal is *slow*. If coming too fast, it can be checked easily by pinching the rubber tube.

iv. The point at which the puncture should be made must vary according as the fluid is free, or located in some particular part of the pleural cavity. When the fluid is in the general cavity, a point should be chosen a little in front of, or behind, the posterior axillary border, at the level of the angle of the scapula.

v. In introducing the needle, care must be taken to keep close to the upper border of a rib (lower border of the space), to avoid injuring intercostal vessels.

vi. A general anæsthetic is strongly contra-indicated; a local one may, occasionally, be needed. For this purpose a few minims of 5 per cent solution of eucaine may be used.

vii. Have brandy and ether handy in case of necessity.

viii. It is not well to take away all the fluid that will come; 20–50 oz. is generally quite sufficient at one time. Frequently the remaining fluid will be rapidly absorbed when only a small quantity has been removed.

ix. The necessary amount having been withdrawn, remove the instrument, and seal the puncture with a piece of lint soaked in collodion.

The dangers of tapping: (a) If sudden faintness come on, withdraw the instrument, or check the flow of fluid by pressure on the tube, and apply restoratives. (b) If troublesome cough occur, the withdrawal of fluid should be discontinued. (c) If “albuminous expectoration” result, it is stated to be increased by the attendant cough, and this should be checked by morphia. *Too rapid removal* may cause both (a), (b), and (c). (d) If a serous effusion should become *purulent*, treat the case as an empyema (free drainage) without delay.

After the removal of fluid, our object is to get the lung to expand. We should, therefore, not bandage nor strap the chest, as is sometimes recommended, but, on the other hand, after a day, get the patient to use Wolff’s bottles (blowing water from one to the other), so as to help in expanding collapsed air vesicles. It is well not to delay this, and in our experience reaccumulation is less frequent in cases where this method is employed early.

Injections of Epinephrin.—These have been employed with the idea of contracting the vessels of the pleura and so preventing recurrence of the effusion. We have seen very good results, in cases where the fluid has recurred frequently, from injecting 10 to 15 min. of 1–1000 epinephrin chloride solution into the pleural cavity after part of the fluid has been withdrawn.

The after-treatment of cases of pleural effusion is perhaps more important than their immediate management. If the effusion occur in the course of morbus cordis or Bright’s disease, the proper treatment of these conditions must be undertaken. If the effusion be primary, the origin is nearly always tubercle. Attempts should be made to arrive at a definite diagnosis in such cases by carefully examining the lungs for any evidence of phthisis, and by submitting some of the fluid to expert examination for tubercle bacilli. When this cannot be done, we should not be far from the mark if we regard all cases of primary, idiopathic, sero-fibrinous, pleural effusion as tuberculous. It is only necessary to point out that, for all such, the proper treatment is that which is now well known as “sanatorium” or “open-air” treatment. Cases of phthisis, starting with pleural effusion, are, as a rule, very hopeful ones, and no pains should be spared to persuade them to undergo a course of after-treatment as suggested above.

W. J. Hadley.

PLEURODYNIA.—(See RHEUMATISM.)

PLUMBISM.

I. CURATIVE TREATMENT.—This may be summed up in the employment of means to relieve symptoms, promote elimination of the metal, and restore function.

In the milder forms, with recurring attacks of colic and constipation, it is desirable that the bowels should be moved as early as possible by means of olive oil and warm water enemata, and by the internal administration of magnesium sulphate along with belladonna and carminatives :—

R Magnesii Sulphatis	℥vj	Tincturæ Zingiberis	℥iv
Tincturæ Belladonnæ	℥iij	Aquæ Destillatæ	q.s. ad ℥ viij
Tincturæ Cardamomi Co.	℥iv		

A tablespoonful in water every three hours until the bowels have been moved.

There is the opinion that sulphate of magnesia acts in these cases by precipitating lead in the bowel in the form of a rather insoluble sulphate. There is no proof that lead sulphate is less soluble in the alimentary canal than the carbonate. Opinions are divided upon this point; besides, *all* lead compounds are more or less poisonous. Workers in lead sulphate show signs of a well-marked saturnine cachexia, but in them the symptoms are developed slowly.

When colic is extremely severe, and the patient is being worn out from want of food and sleep, a hypodermic injection of morphia may be required. Should there be vomiting, an effervescing mixture of soda and bismuth may be tried, e.g. :—

R Sodii Bicarbonatis	℥ij	Tincturæ Zingiberis	℥j
Liq. Bismuthi et Ammon. Citratis		Spiritus Chloroformi	℥xl
(B.P.)	℥iv	Aquæ Destillatæ	q.s. ad ℥ viij
Spiritus Ammoniæ Aromatici	℥ij		
R Acidi Tartarici	℥iiss	Aquæ Destillatæ	℥iv

One tablespoonful of No. 2 to be added to two tablespoonfuls of No. 1 and drunk during effervescence four times a day.

Warmth applied to the abdomen, and, in severe cases, a hot bath, will often give relief. If the colic persists after the bowels have been opened, nothing acts so well as sulphite of soda, in doses of $\frac{1}{4}$ or $\frac{1}{2}$ gr. every three hours :—

R Sodii Sulphitis	gr. $\frac{1}{4}$	Aquæ	q.s. ad ℥j
Tincturæ Cardamomi Co.	℥xv		

Every three hours.

Calcium permanganate $\frac{1}{4}$ gr. in paraffin capsule thrice daily often gives rapid relief to lead colic. It is well worthy of a trial. Potassium iodide favours the elimination of lead from the system, but, if given too early or in too large doses, a patient may thereby be re-poisoned by lead which has been dissolved out of his own tissues. This drug should therefore be avoided in the severe and acute forms of plumbism, but in the milder cases of colic and constipation, after the bowels have been freely moved by sulphate of magnesia, a few grains of potassium iodide may be safely added to the aperient. Iodide of potassium has in a few instances caused albuminuria, which ceased on discontinuing the drug.

In Lead Palsy the object of treatment is to eliminate lead from the system and restore function. Iodide of potassium will accomplish the former; but to restore function, hypodermic injections of strychnine may be resorted to, with massage and electricity. Opinions differ as to whether the hands, when affected by wrist-drop, should be allowed to hang by the sides, or be supported on splints. The latter plan has much to commend it, in that it takes the weight off the affected muscles, and reduces the synergic action of those which are still healthy.

In the use of electricity in these cases, it must be remembered that the therapeutic effect is *not* to be measured by the amount of contraction produced in

the muscles ; there are invisible nutritive and vasomotor effects which are of great service. Indeed, over-stimulation of the muscles may induce fatigue, and do harm. Induction coil or sinusoidal currents may be used, with or without a water bath, to produce functional stimulation of the paralyzed muscles. Electric baths aid in the elimination of lead, and are therefore to be recommended. (See also NEURITIS, and ELECTROTHERAPEUTICS.)

2. PROPHYLACTIC TREATMENT.—For lead workers, personal cleanliness is of the first importance. The hands should always be washed before eating ; baths should be provided at all workshops where lead or its compounds are manipulated, and the workpeople urged to take a warm bath at least once a week. Aperients should be taken regularly. The acid lemonade on draught in lead works has only a questionable value ; sulphur lozenges taken twice a week do more good. In some of the white lead factories these have been superseded by a chocolate lozenge containing 5 gr. of hyposulphite of soda. Frequently workmen take 2 or 3 of these per day. While the lozenges are followed in some of the men by a mild aperient result, upon all the workmen they exercise a distinctly preventive influence. The day's work should not be begun without a meal ; milk is of special value as a preventive. Finally, it should be remembered that once a patient has had lead colic he becomes more susceptible to the metal, and ought therefore to exercise greater care at the factory, and change his occupation if the attacks are recurrent. In obscure cases of plumbism the drinking water should be analyzed for lead : 1 mgram of lead per litre of water is dangerous.

Electrolysis.—By means of the double electrical bath, encouraging results have been obtained in the treatment of workpeople employed in lead factories. In response to my suggestion that lead might be removable from the body of a lead-poisoned person, Mr. T. Maltby Clague, of Newcastle-upon-Tyne, devised a double electrical bath. It is a simple procedure. The whole body is not immersed. The workman seated on a stool, in a room in the factory set aside for the purpose, places his feet in a bath of warm water, while his arms are immersed in another bath. The positive pole of a battery is dropped into the foot-bath and the negative is placed in the arm-bath. A current of low voltage, usually 16 volts, with a milliampèrage gradually raised to 30 and 40, is allowed to pass for half an hour, or a little longer. To diminish the resistance a little salt is added to the foot-bath. No pain is experienced. The bath is taken every day or every second day. On the negative electrode lead is frequently found, the blue line on the gums rapidly disappears, as also the anæmia, and a feeling of fitness and well-being is experienced by the patient. Since the warm bath once a week is one of the requirements of lead workers by the Home Office, the double electrical bath not only supersedes this, but is preventive and curative as well.

Thomas Oliver.

PNEUMONIA.—(See also BRONCHOPNEUMONIA.) There is no disease which has given rise to so much difference of opinion as regards treatment, nor for which so many so-called specific remedies have been vaunted, as this. One might divide the various schools of treatment thus :—

1. Those who leave everything to nature, believing all interference useless or even harmful.

2. Those who treat every case on the same plan, or with the same remedies (specific treatment), many of whom push their hobby to an almost dangerous extent.

3. Those who wait till the patient shows some definite symptom, which they then endeavour to relieve (the symptomatic or expectant treatment).

4. Those who advocate very active treatment, believing that early measures

are most important, and that it is bad policy to wait until the patient is so ill that something *must* be done, by which time the possibility of giving relief, or of averting a calamity, may have passed.

In criticism we would say that we deplore the hopelessness of doing nothing. Although we are ready to admit that some cases get well without treatment, whilst others die in spite of everything, there is yet another class of cases which would not recover without help, and in which appropriate treatment saves life.

"Specific treatment" comprises many measures which are often most beneficial; but no two cases of pneumonia are alike, and even the same case will vary greatly at different times, so that quite different methods may be necessary. It is in blindly following the same line of treatment in every case, and in every stage, that these methods fail.

With regard to pure "expectancy," we feel that valuable time and opportunities are lost, especially in the early stages when there are usually no urgent symptoms to treat, and that by this method we lose sight of the case as a whole, regarding it rather as a collection of symptoms. Therefore:

1. It is bad policy to do nothing in every case;
2. It is often dangerous to wait for symptoms which necessitate active interference;
3. It can hardly be expected that specific plans and remedies can meet the requirements of every case alike.

When death occurs in pneumonia, it is due to toxæmia, heart failure, or the supervention of some complication. A rational treatment should, therefore, be framed on these lines:—(1) *To lessen Toxæmia* by every means in our power; (2) *To Limit Extension of Pulmonary Lesion* (because it causes heart failure); (3) *To prevent or Treat Cardiac Failure*; (4) *To Prevent or Treat Complications*.

1. **To Lessen Toxæmia.**—Most authorities agree that toxæmia is, directly or indirectly, the cause of the majority of deaths occurring in cases of pneumonia. The means we have at our disposal are:—

a. *Bleeding.*—By withdrawing a certain amount of blood, we not only relieve the right heart, but also lessen the total amount of poison circulating.

b. *Diaphoresis.*—By hot baths, hot packs, and best, by the hot foot-bath given in bed, and kept up by adding more hot water, and a little mustard, for half to three-quarters of an hour, till there is profuse sweating, which can be increased by giving copious drinks of water in the meantime.

c. *Catharsis.*—Calomel and saline are unequalled for this purpose. It must be remembered that, in order to get the best effects, free evacuation must be kept up (two or three times daily) for two or three days.

d. *Diuresis.*—The citrates are most useful in this respect, as also large quantities of bland drinks. We do not want to employ powerful remedies, because the kidneys are already congested from the fever and toxæmia (witness the almost constant albuminuria).

e. *The Cleansing of the Mouth.*—This is most important, so as to prevent auto-infection by the constant swallowing of bacteria, with which the mouth swarms.

Other methods of lessening toxæmia may be mentioned, as saline infusion, and the free use of oxygen for inhalation (which has a powerful effect in destroying the circulating toxins); but these methods are more useful in relieving the over-taxed heart, and should be included under treatment for cardiac failure. This is true of bleeding also.

All these measures are of a depletory nature: it must be remembered that bleeding is certainly not recommended as a routine treatment, but only in exceptionally acute, sthenic cases, when seen very early. So, too, diaphoresis, catharsis, and diuresis are applicable only in the early stages of the disease, while the powers of the patient are as yet unimpaired, and when, by promptly

and effectively promoting the increased excretion of toxins, the exhaustion, heart failure, etc., which the toxæmia so frequently causes may possibly be prevented.

Emphatically it is in the earliest stages that these measures are called for. The "expectant" treatment waits, and these golden opportunities (which never recur in cases of pneumonia) of lessening toxæmia, at a time when the measures recommended involve no risk to the individual, are lost. They should be regarded as most important preventive treatment, which may frequently prevent subsequent evils.

2. To Limit Extension of Pulmonary Lesion.—The importance of this lies in the fact that the wider the area affected the greater the work thrown on the right ventricle, from the consequent blocking of the pulmonary capillaries. As means, we have (locally) leeching, wet and dry cupping, and blisters, whilst certain drugs are sometimes useful in lessening the amount of fibrin in the blood (which is increased in pneumonia). By active treatment on these lines we may succeed in limiting extension if we get our cases early enough. Although we may not get them before there is a patch of consolidation, yet we should always be on the look-out for signs of extension to another part, or to the opposite lung, and apply vigorous measures at the earliest moment, while yet there may be only a few crepitations (congestion). The drugs useful for the same purpose are iodide of potash, the alkaline carbonates, and citric acid. Citric acid, by taking up calcium, tends to prevent coagulation, whilst the alkalies and iodide of potash promote fluidity of blood. The same result is aimed at by lowering the diet and giving fluids copiously. It may be said of these measures, one does not believe in starving patients, nor in drenching them with enormous doses of iodide of potash (300 gr. daily have been given); but in sthenic cases, running an acute course, low diet and iodide of potash are certainly useful; citric acid, although theoretically active, seems practically of little use. Local methods should be applied wherever fresh signs of disease can be found. Of these one prefers leeching to any other, and it must be remembered that they are all absolutely efficacious in removing pain (a great gain where rest is so important), whether we succeed in limiting the spread of consolidation or not.

3. To Prevent or Treat Cardiac Failure.—To prevent cardiac failure it is necessary to understand clearly what may cause it.

a. Toxæmia and Fever.—In this connection toxæmia is the most important. The means of lessening it have already been discussed. Fever generally goes hand in hand with toxæmia, and it is doubtful if it is well to use measures solely against the fever, such as powerful antipyretics, ice-packs, etc., because of their depressing influence on the patient.

b. Increased Resistance to the Pulmonary Circulation due to the Consolidation.—This has also been dealt with.

c. Abdominal Distention, so common in pneumonia, is less so where the bowels have been kept freely open in the early stage, as recommended. Care must be taken with the diet, as excess of milk, carbonates, and aerated waters seem to increase this tendency. Distention is most distressing to cardiac action, and if, in spite of all preventive care, it should occur, appropriate treatment must be applied. Calomel and salines should be used, and a simple enema given. If still troublesome, the long tube should be passed for its relief (for it is frequently colonic), and an enema of turpentine or asafætida given.

d. Constant Pain, best relieved by local measures, such as leeching, cupping, and blisters, as already mentioned.

e. Restlessness, Sleeplessness, and Delirium form the most difficult problems in the treatment of pneumonia. Again, prevention is better than cure. Early in the case avoid all necessary moving and disturbance, and during the first

few days, provided there is no distress of breathing, no cyanosis, and the kidneys are healthy, it is well to make sure that the patient shall sleep. This can generally be secured by an evening Dover's powder. Afterwards it is a much more serious matter. Each case must be carefully weighed on its merits. There are patients in whom continued restlessness and sleeplessness wear the heart out, sedatives being withheld : while in others the sedative has caused the patient to sink into a choked and cyanotic condition. On the one hand we fear to deaden the activity of the respiratory centre, tie up secretion, and check cough ; on the other we know the almost inevitable result of continued sleeplessness and exhaustion. If we feel that cardiac failure and exhaustion are threatening, and that nothing but sleep is likely to prevent them, having eliminated faulty kidneys, in the absence of cyanosis, and with no very copious bronchitis, sedatives should be used. We see much harm from the reckless use of them, but it is wrong to say that they should *never* be given. When their use has been decided upon, paraldehyde is, perhaps, the best, because the safest ; to avoid its objectionable taste, it can be given per rectum in 1- to 3-dr. doses. Chloral and bromide, and chloral formamide are more frequently used ; others prefer opium or morphia. Delirium must be treated on similar lines and with the same precautions. It must be remembered that delirium is, not infrequently, entirely due to want of sleep, or to exhaustion, and that it will often pass away completely if sleep be obtained, or food or stimulants given.

If in spite of our care the heart begins to fail, as will be evidenced by increasing difficulty of breathing, distant or absent heart sounds, increased rapidity of pulse, which is easily compressible or dicrotic, and perhaps irregular, what means have we for stimulation ? In this connection we must consider the relative merits and uses of strychnine, digitalis, alcohol, oxygen, and hypodermoclysis.

Strychnine should be given early, before the heart shows any sign of failure, because :—

- i. It keeps the respiratory centre awake.
- ii. It is a tonic to the general nervous system (as well as to the heart).
- iii. It is potent to prevent abdominal distention.
- iv. It is a profound and prolonged cardiac stimulant.
- v. It does not tend to poison the patient.

Digitalis has been used as a specific, given early, with the idea of preventing cardiac failure and of driving the blood through the lungs, so as to overcome the inflammatory stasis. We do not advocate its use for such a purpose, but as a powerful cardiac stimulant it is almost unequalled. Unfortunately it is prone to upset the stomach, and not infrequently does harm in this way. It must be remembered that, with regard to this drug, as well as strychnine, it is frequently useless when given by the mouth. One has often seen cases, past absorbing these remedies by the stomach, immediately respond to them when given hypodermically, and in all cases where the patients are very ill, and the tongue perhaps, dry and brown, hypodermic medication is indicated.

Alcohol.—Whilst much harm is done by the reckless use of alcohol, and also whilst acknowledging the fatality of the disease amongst chronic alcoholics, one still feels, occasionally, the necessity for its employment. The pernicious habit of putting every pneumonic patient on anything up to a bottle of brandy a day is responsible for a good many cases of delayed resolution, or even permanent damage to the lungs ; whilst it seems, in many cases, to increase the toxæmia, to develop uræmic symptoms, or to cause great restlessness, excitement, or even delirium, at the same time doing away with the desire for more useful nourishment, and causing stomach distention. Therefore, one deprecates its abuse, or even its routine employment, especially early in the case. Further, it may be urged that alcohol throws more work on the kidneys, which, as we know, are

frequently already allowing albumin to pass. These are the dangers and difficulties surrounding the use of alcohol; personally, we prefer strychnine and digitalis for cardiac stimulation before resorting to it. A further use of alcohol must be mentioned, and that is its use as a soporific. Where rest and sleep are so important, and where one finds, as sometimes is the case, that nothing calms the restlessness so well as some form of alcohol, we feel bound to use it for this purpose.

Oxygen, one believes, is frequently left till too late. Its beneficial action against toxæmia has already been mentioned, whilst its great stimulating effect on the heart through the blood is undoubted. It should be used freely. It is best given without a mask, just through a plain tube, and should always be washed and warmed by being passed through a bottle of warm water. Stimulants, such as ether and alcohol, are sometimes used instead of water for the oxygen to pass through, so as to get the combined beneficial effects of the oxygen and stimulant used.

Many other drugs have been used for stimulating the failing heart in cases of pneumonia, such as strophanthus, musk, nitroglycerin, camphor, etc., etc., but it would not seem that they have any claim to superiority over those already discussed. Finally, the question of injection of saline solution may suggest itself. This measure is undoubtedly very powerful in stimulating the heart. Normal saline solution (1 dr. to a pint) may thus be injected into the rectum, or beneath the skin (hypodermoclysis), or directly into a vein, being most powerful when used intravenously. From one to four pints, carefully sterilized, and at a temperature of 100° F., may be used in this way.

4. To Prevent and Treat Complications.—It is not within the scope of this article to discuss these, as it would involve the consideration of pericarditis, pleural effusion, empyema, abscess and gangrene of lung, meningitis, arthritis, phlebitis, and other affections, which may be referred to. But one wishes to emphasize the point that, because a serious complication of the pneumonia may occur, it is not therefore necessary to abandon hope and discontinue treatment. We see cases complicated with pericarditis, meningitis, empyema, or even abscess of the lung, not infrequently get well. Each complication will call for its particular treatment; but do not in the meantime lose sight of the fact that the case is one of pneumonia.

Serum Therapy.—It is too early to speak definitely with regard to this method. We know: (1) That a certain amount of immunity can be conferred in the case of animals, and from the use of serum in the South African War it would seem that a slight immunity can also be conferred on man, but that it is short in duration (that is, prevention). (2) That its use in patients suffering from the disease is rendered difficult by the fact that each individual breeds his own particular strain of pneumococcus. Bearing in mind this fact, viz., that A's pneumococcus does not protect B, and that it therefore becomes necessary to cultivate an individual's own organism for his own cure (a process which takes several days), it is obvious that this form of treatment will become more useful in lingering cases, or for some of the more chronic complications, such as empyema, delayed resolution, or arthritis; and that there would be no time to call in its aid in the ordinary case, swiftly culminating in death or resolution. Thus we have seen cases of pneumococcal empyema and arthritis treated most successfully by this method. (See also SPECIFIC THERAPY.)

Preventive Treatment.—It is only necessary to mention this to remind practitioners of its importance. We recognize that, at any rate in certain circumstances, pneumonia is an infective disease. It is therefore obvious that care should be taken, in every case, to destroy all emanations from the patient—especially the sputa, which should be burned. Elaborate precautions as to

isolation may not be necessary, but undoubtedly the spread from case to case does occur, sometimes assuming epidemic proportions.

DIGITALIS AND STRYCHNINE FOR CARDIAC FAILURE IN PNEUMONIA.

PNEUMOTHORAX.—The immediate results of the formation of a pneumothorax may be either profound shock, or a disturbance so slight as not to be noticeable, with many intermediate degrees. Pneumothorax is often not recognized during life, even by experts, when it is superadded to advanced pulmonary disease. If it occurs in a patient whose lungs are not widely damaged, the shock is marked. Three points in treatment deserve attention :—

1. *Stimulants.*—These should be freely given, both alcohol and ammonia and ether. They help the heart to tide over the extra strain suddenly thrown on the right ventricle, and the dilatation consequent on the one lung being put out of action. The heart is further hampered by its displacement, which sometimes is great. According to the condition of the pulse, digitalis and strychnine may both be given, but it is not wise to contract the arteries overmuch.

2. *Morphia.*—This is the best form in which to give opium. It may be used either hypodermically or by the mouth. It helps to relieve the patient's anxiety, and there is not, to any considerable extent, danger of its interference with the respiratory centre, which is usually in good condition in those cases where pneumothorax produces its most alarming symptoms, i.e., in relatively early lung disease.

3. If there are considerable cardiac displacement and cyanosis, and the signs point to great air-pressure in the damaged pleural cavity, it is well to allow some of the air in the pleura to escape ; this may be done by a fine trocar and cannula. There are three objections to this proceeding, none of which is really important :—

a. The air will collect again most probably ; this is no reason for not giving the patient temporary relief.

b. The opening in the visceral pleura, which may be on the point of closing, is likely to be reopened. There is no chance whatever of any firm closing of the pneumothorax orifice within the first few days after its rupture. It is at this time that the air-pressure is great, and that puncture may be advisable.

c. Subcutaneous emphysema may be produced. It may ; but it very rarely occurs, and the risk is worth taking.

Besides these three methods of procedure, it is sometimes advisable to have recourse to *bleeding*. This is not often to be recommended. If there be extreme cyanosis, with a bounding heart and thready pulse, all pointing to an over-burdened right heart and blocking of blood on the venous side, the letting of fifteen to twenty ounces of blood produces great relief.

Dry cupping, or the application of a few leeches, is helpful both in relieving pain and in aiding to some extent the right ventricle.

Strapping the side, which has been widely recommended and used, is not, in my experience, of any value. It has the obvious disadvantages of making the patient uncomfortable, and examination difficult. If, however, it is found that pressure applied to the damaged side of the chest relieves the patient, it should be tried.

After the first shock is over, the character of the case changes considerably. Fluid practically invariably collects, and partially or entirely fills the pleura. The fluid may be clear or purulent, generally becoming purulent ultimately. The pus may be sweet or fetid.

Cases where the Pleura becomes entirely filled with Fluid.

1. If the fluid be clear, or very thin pus, the temperature normal, and there be no marked distress of respiration, it is well to let it remain untouched for three or four weeks, by which time the opening in the visceral pleura may be firmly closed. Sometimes the fluid then becomes absorbed. If it does not, the case should be treated as an empyema, and drained in the usual way.

2. If the fluid be purulent, temperature raised, and the patient show all the signs of pus absorption, there is no use in delay, and he should be operated on at once. This is obviously all the more necessary when the pus is fetid.

Cases where the Pleura does not become filled with Fluid, purulent or otherwise.

These form the bulk of the chronic cases which give the classical signs of pneumothorax. Many patients remain some time in this condition, without much suffering. Their temperature is normal, or nearly so; there is no pressure of pus in the pleura. If, then, the opposite lung works well, there is no need to interfere.

If the condition change, temperature rise, and pus absorption begin, then operation should be advised.

Many of the patients do badly after operation; but that is caused by the normal progress of the disease: there is, in my opinion, no evidence to support the rather widely held doctrine that operation hastens the end in these cases.

Cecil Wall.

POISONING.—The most convenient emetics to use in cases of poisoning are :—

Mustard, a tablespoonful in $\frac{1}{2}$ pint of warm water.

Sulphate of Zinc, 30 gr. dissolved in water.

Powdered Ipecacuanha, 30 gr. in water.

Apomorphine, $\frac{1}{10}$ to $\frac{1}{4}$ gr., hypodermically.

Sulphate of Copper, 5 to 10 gr. in water.

The following are brief directions for the treatment of different forms of poisoning :—

Acetanilide or Antifebrin.—Emetic or stomach tube. Subcutaneous injection of strychnine $\frac{1}{15}$ gr.; warmth. If cyanosis—oxygen, alcohol.

Acid, Arsenious.—(See ARSENIC.)

Acid, Carbolic.—Stomach tube, or apomorphine hypodermically; sodium sulphate, 1 oz., or magnesium sulphate, $\frac{1}{2}$ oz. in 3 oz. of water; saccharated lime-water 1 oz. in 3 oz. of water.

Later: demulcent drinks; olive oil; brandy subcutaneously or by enema; warmth.

Acid, Chromic.—

Immediate treatment: stomach tube with extreme care; chalk mixture 5 oz., or chalk, $\frac{1}{2}$ oz. in half a pint of milk.

Later: olive oil; or milk, or gruel, or white of egg and water.

Acid, Hydrochloric (Spirits of Salts).—

Immediate treatment: introduce water, and use stomach tube with care; sodium bicarbonate, 2 dr. in 5 oz. of water; or soap and water; or chalk or calcined magnesia, $\frac{1}{2}$ oz., in $\frac{1}{2}$ pint of water or milk; or liquor ammoniæ or sal volatile, freely diluted; or white of egg and water; milk; gruel; arrowroot; or linseed tea.

Later: morphine for pain, and ice for thirst.

Acid, Hydrocyanic.—

Immediate treatment : dash cold water over head and chest ; emetic ; inhalation of ammonia ; brandy, by mouth or rectum ; artificial respiration ; faradic current ; hypodermic injection of liquor atropinæ sulphatis (1 per cent), 2 min.

Acid, Nitric.—

Immediate treatment : soap and water, calcined magnesia, chalk, whiting, or carbonate of soda with water.

Later : demulcents—olive oil, white of egg, morphine hypodermically.

Acid, Oxalic.—Stomach tube with care ; chalk, $\frac{1}{2}$ oz. in 5 oz. of water ; or saccharated lime-water, 4 dr. in 2 oz. of water, repeated every half hour for eight doses ; stimulants hypodermically ; gruel or linseed tea.**Acid, Sulphuric.**—

Immediate treatment : soap and water, calcined magnesia, chalk, whiting, or carbonate of soda with water.

Later : demulcents—olive oil, white of egg ; morphine hypodermically.

Aconite.—

Immediate treatment : emetic, or stomach tube ; subcutaneous injection of tincture digitalis 25 min., or digitalin $\frac{1}{100}$ gr.*

Later : brandy, warmth, friction, artificial respiration.

Alcohol.—

Immediate treatment : stomach tube, cold effusions to head.

Later : hot strong coffee ; warmth.—(See also COMA.)

Almonds, Bitter, Essential Oil of.—(See ACID, HYDROCYANIC.)**Ammonia.**—(See CAUSTIC POTASH AND SODA.)**Aniline.**—Stimulants ; artificial respiration ; bleeding and intravenous injection of warm saline solution (1 dr. of common salt to 1 pint of warm water).**Antimony.**—Stomach tube or emetic, if required ; glycerin of tannic acid, 2 fluid dr. in 5 oz. of water ; or tannic acid, 30 gr. in 5 oz. of water, to be repeated if vomited ; strong tea or coffee, $\frac{1}{2}$ pint ; milk ; stimulants ; hot bottles and blankets ; friction.

Later : morphine.

Antipyrin.—(See PHENAZONE.)**Aqua Fortis.**—(See ACID, NITRIC.)**Arsenic.**—

Immediate treatment : emetic or stomach tube ; ferric hydrate (prepared by mixing liq. ferri perchlor. $\frac{1}{2}$ oz. in $\frac{1}{2}$ tumblerful of water with equal quantity of saturated solution of washing soda ; collect precipitate on a handkerchief and mix with $\frac{1}{2}$ tumblerful of hot water), repeat frequently. (Liquor ammoniæ may be used instead of washing soda.)

Atropine.—Stomach tube or emetic ; brandy ; 1 pint of strong, hot coffee ; morphine hypodermically, $\frac{1}{2}$ gr. to be repeated in two hours ; or hypodermic injection of pilocarpine ($\frac{1}{2}$ gr. of pilocarpine nitrate), to be repeated in fifteen minutes, if pulse improves ; flicking ; pinching ; warm and cold douche ; faradism ; hot bottles and blankets ; artificial respiration ; friction.**Barbitone.**—Stomach tube or emetics ; castor oil or enemata ; introduce tannin solutions into the stomach (e.g., tinct. catechu, 1 dr.) ; hot coffee and camphor injections as stimulants ; digitalin* and strychnine for collapse ; oxygen for cyanosis.**Barium, Salts of.**—Stomach tube or emetic ; sodium sulphate, 1 oz., or magnesium sulphate, $\frac{1}{2}$ oz., in 5 oz. of water ; or alum, 1 dr. in 5 oz. of water ; stimulants ; hot bottles and blankets.

Later : morphine.

Battle's Vermin Killer.—(See STRYCHNINE.)**Belladonna.**—(See ATROPINE.)**Benzol.**—

Immediate treatment : emetic, stomach tube.

Later : brandy ; inhalation of ammonia ; subcutaneous injection of liquor atropinæ sulphatis (1 per cent), 2 min.

Bichromate of Potash.—Stomach tube or emetic ; chalk mixture, 8 oz. ; or $\frac{1}{2}$ oz. of chalk in $\frac{1}{2}$ pint of milk ; warm bottles and blankets.**Burnett's Disinfecting Fluid.**—(See ZINC, SALTS OF, and ACID, HYDROCHLORIC.)**Calabar Bean.**—(See PHYSOSTIGMINE.)**Camphor.**—

Immediate treatment : emetic and stomach tube.

Later : inhalation of ammonia ; subcutaneous injection of brandy ; hot fomentations.

Cannabis Indica.—Emetic, stomach tube ; apomorphine hypodermically ; stimulants.

* The preparation referred to is the English one, known also as digitalin verum. If German digitalin is dispensed, the dose must be increased accordingly.

Cantharides.—

Immediate treatment : stomach tube or emetic.

Later : demulcents ; opium ; morphine.

Carbolic Acid.—(See ACID, CARBOLIC.)

Carbonic Acid.—Fresh air ; artificial respiration ; inhalation of vapour of liquor ammonia ; stimulants ; hot bottles and blankets ; inhalations of oxygen ; bleeding ; faradism ; cold douche.—(See also DROWNED, TREATMENT OF THE APPARENTLY.)

Carbonic Oxide.—Fresh air ; artificial respiration ; bleeding and intravenous injection of warm saline solution (1 dr. of common salt to 1 pint of warm water) ; inhalation of oxygen ; stimulants ; hot bottles and blankets ; friction ; faradism.

Caustic Potash and Soda.—Stomach tube, with care ; vinegar or diluted acetic acid, or lemon juice ; olive oil.

Cesspool Gas.—(See SEWER GAS.)

Chloral Hydrate.—

Immediate treatment : prevent sleep by wet towel to face, head, and neck ; emetic and stomach tube ; hot blankets ; hot bottle to feet.

Later : hot strong coffee ; artificial respiration ; faradic current ; subcutaneous injection of liquor strychninæ hydrochloratis (1 per cent), 4 min. ; nitrite of amyl ; oxygen.

Chlorine, Inhaled.—Inhalations of ammonia or sulphuretted hydrogen.

Chlorine, Swallowed.—Albumin and mucilaginous drinks.

Chloroform, Inhaled.—Insert finger into mouth and pharynx to make sure that there is no obstruction, e.g., by artificial teeth ; extend the head, and push the jaw forward ; pull tongue out by forceps ; loosen clothes ; fresh air ; artificial respiration ; raise foot of table that the head may be lower than the rest of the body ; flapping with wet towels ; inhalation of capsule of amyl nitrite ; faradism (poles at pit of stomach and over larynx) ; strychnine ; ether ; alcohol, hypodermically ; brandy enema.

Chloroform, Swallowed.—Stomach tube or emetic ; olive oil ; stimulants hypodermically or per rectum ; flapping with wet towels ; faradism ; 1 pint of strong, hot coffee ; capsule of amyl nitrite for inhalation.

Chlorodyne.—(See OPIUM.)

Coal Gas.—Fresh air ; artificial respiration ; stimulants ; hot, strong coffee ; oxygen inhalation ; ammonia inhalation ; transfusion.

Cocaine.—Emetic, if swallowed ; stimulants ; inhalations of amyl nitrite.

Colchicum.—Emetic ; olive oil or any demulcent ; stimulants.

Conium (Hemlock).—Emetics ; stimulants ; strychnine hypodermically ; artificial respiration.

Copper, Salts of.—

Immediate treatment : white of egg and warm water ; milk ; emetic ; and stomach tube if vomiting has not occurred.

Later : demulcents ; morphine or laudanum, and hot fomentations if much pain.

Corrosive Sublimate.—Stomach tube, with great care ; flour and water ; or arrowroot and water ; or white of egg and water (1 egg = 4 gr. of corrosive sublimate) ; stimulants ; hot bottles and blankets.

Later : morphine.

Creosote.—(See ACID, CARBOLIC.)

Croton Oil.—Stomach tube or emetic ; stimulants ; $\frac{1}{2}$ gr. of morphine hypodermically ; or tincture of opium, 20 min. by mouth, by rectum, or by suppository ; morphia ; hot bottles and blankets ; friction ; poultices or hot fomentations to abdomen.

Cyanide of Potassium.—Stomach tube or emetic ; ferrous sulphate, 5 gr. in 5 oz. of water ; stimulants hypodermically ; faradism ; inhalation of vapour of liquid ammonia ; artificial respiration ; fresh air ; solution of atropine sulphate (1 per cent), 2 min. hypodermically (= $\frac{1}{10}$ gr. of atropine sulphate) ; or tincture of belladonna, 20 min. by mouth or rectum ; alternate warm and cold douches ; friction.

Dalby's Carminative.—(See OPIUM.)

Deadly Nightshade.—(See ATROPINE.)

Digitalis (Foxglove).—Emetics ; tannin, 30 gr. in water ; stimulants ; recumbent position ; tincture of aconite internally.

Elaterium.—Emetics ; stomach tube ; demulcent drinks ; opium.

Emerald Green.—(See ARSENIC.)

Eserine.—(See PHYSOSTIGMINE.)

Ether.—(See CHLOROFORM.)

Fly Papers.—(See ARSENIC.)

Formalin.—Small doses of ammonia largely diluted with water ; or large quantities of liq. ammon. acetatis every half hour.

Foxglove.—(See DIGITALIS.)

Fungi.—Emetics ; hypodermic injection of liquor atropinæ sulphatis (1 per cent), 2 min. ; stimulants.

Gelsemium.—Stomach tube; emetics; potassium bicarbonate and tannin; warmth, stimulants; artificial respiration; solution of atropine (1 per cent), 3 min. hypodermically.

Gibson's Vermin Killer.—(See STRYCHNINE.)

Godfrey's Cordial.—(See OPIUM.)

Henbane (Hyoscyamus and Hyoscyne).—(See ATROPINE.)

Iodine.—

Immediate treatment: emetic and stomach tube.

Later: starch and water; demulcents; nitrite of amyl; morphine and fomentations for pain.

Iodoform.—Emetics; stomach tube; bicarbonate of soda in large diluted doses; stimulants; hot pack; subcutaneous injection of saline solution.

Laburnum.—Stomach tube; stimulants; hypodermic injection of ammonia; counter-irritation; friction; cold douche.

Lead, and its Compounds.—

Immediate treatment: stomach tube or emetic; magnesium sulphate, $\frac{1}{2}$ oz., or sodium sulphate, 1 oz., in 5 oz. of water; or diluted sulphuric acid, 40 min. in half pint of water; milk; or white of egg and water; poultices to abdomen; morphine.

Later: potassium iodide.

Lime.—Carbonic acid; any aerated water; weak acetic acid or vinegar; oil or demulcent drinks.

Lobelia.—Stomach tube or emetic, if required; recumbent position; glycerin of tannic acid, 2 dr. in 5 oz. of water; or tannic acid, 30 gr. in 5 oz. of water; or 1 pint of strong tea; stimulants; hot bottles and blankets; friction; tincture of nux vomica, 35 min. by mouth or rectum; or solution of strychnine hydrochloride (1 per cent), 5 min. hypodermically ($= \frac{1}{10}$ gr. strychnine hydrochloride).

Mercury, Salts of.—(See CORROSIVE SUBLIMATE.)

Morphine.—(See OPIUM.)

Mother's Friend.—(See OPIUM.)

Muriatic Acid.—(See ACID, HYDROCHLORIC.)

Muscarin.—(See FUNGI.)

Mushrooms.—(See FUNGI.)

Mussel Poisoning.—Emetic; stimulants; solution of atropine (1 per cent), 2 min. hypodermically; castor oil, 2 oz. with 7 min. tincture of opium.

Nepenthe.—(See OPIUM.)

Nicotine.—

Immediate treatment: stomach tube or emetic; stimulants; warmth; artificial respiration; strychnine hypodermically.

Later: stimulants.

Nitric Acid.—(See ACID, NITRIC.)

Nitro-Benzene (or Nitro-Benzol).—Stomach tube or emetic; stimulants; solution of atropine sulphate (1 per cent), 2 min. hypodermically ($= \frac{1}{10}$ gr. of atropine sulphate); artificial respiration; faradism.

Nitroglycerin.—

Immediate treatment: recumbent posture; cold affusion.

Later: hypodermic injection of ergot, 3 min., or solution of atropine sulphate (1 per cent), 2 min. hypodermically.

Nitrous Oxide Gas.—Insert finger into mouth and pharynx to make sure that they are free from obstruction, e.g., by artificial teeth, gag, etc.; extend the head, and push the jaw forward; pull tongue out by forceps; fresh air; loosen clothes; if patient is upright, place in recumbent position; artificial respiration; flapping with wet towels; inhalation of oxygen.

Nux Vomica.—(See STRYCHNINE.)

Opium (or Morphine).—Apomorphine hypodermically. Stomach tube or emetic; wash out stomach with solution of potassium permanganate, diluted with 5 times the quantity of warm water, leaving about 5 oz. of the diluted solution in the stomach; strong hot coffee, 1 pint by rectum; ether, 60 min. hypodermically; liquor ammonia or smelling salts to nostrils; faradism; make patient walk about; solution of atropine sulphate (1 per cent), 3 min. hypodermically ($= \frac{1}{10}$ gr. of atropine sulphate), to be repeated in half an hour; or tincture of belladonna, 20 min. by mouth or rectum; artificial respiration.

Oxalic Acid.—(See ACID, OXALIC.)

Paraffin Oil.—Emetics; stimulants; hot bottles and blankets; friction.

Paraldehyde.—(See CHLORAL.)

Petroleum.—Emetics; stimulants; friction; hot bottles and blankets.

Phenazone (Antipyrin).—Stomach pump; brandy; subcutaneous injection of strychnine, $\frac{1}{10}$ gr.; warmth. If cyanosis—oxygen.

Phenol.—(See ACID, CARBOLIC.)

Phyostigmine.—Emetics; 30 gr. tannin in water; 2 min. solution of atropine sulphate (1 per cent) hypodermically; or tincture of belladonna, 20 min. by mouth every

- fifteen minutes until pupils dilate; chloral hydrate; stimulants; artificial respiration; solution of strychnine (1 per cent), 5 min. hypodermically.
- Phosphorus.**—Stomach tube or emetic; oil of turpentine, 20 min., repeated every half hour for six doses; or solution of hydrogen peroxide 30 min. repeated; purgative of $\frac{1}{2}$ oz. of magnesium sulphate; linseed tea. Avoid oils and fats.
- Pilocarpine.**—Stomach tube or emetic; tannin; hypodermic injection of atropine, $\frac{1}{16}$ to $\frac{1}{8}$ gr. doses.
- Potash, Caustic.**—(See CAUSTIC POTASH.)
- Potassium Chlorate.**—Stomach tube or emetics; demulcent drinks; purgatives; warmth; hot pack.
- Rat Pastes.**—(See ARSENIC, and PHOSPHORUS.)
- Salts of Lemon.**—(See ACID, OXALIC.)
- Salts of Sorrel.**—(See ACID, OXALIC.)
- Santonin.**—
Immediate treatment: stomach tube or emetic; stimulants. If convulsions, chloral and bromide of potassium.
Later: stimulants.
- Savin.**—
Immediate treatment: emetic.
Later: demulcents; castor oil; opium or morphine.
- Sewer Gas.**—Fresh air; artificial respiration; stimulants; strong, hot coffee, 1 pint by mouth or rectum; hot bottles and blankets; faradism.
- Silver, Salts of.**—Common salt, $\frac{1}{2}$ oz. in a pint of water; stomach tube; white of egg and water; milk.
- Simpson's Rat Paste.**—Contains 40 per cent of arsenious acid. For treatment see ARSENIC.
- Snake Bites.**—Proximal ligature; remove ligature at intervals for a second or two, and re-apply, so as to allow only very small quantities of the poison to get into the circulation, and yet to avoid gangrene; incision; cauterization; inject into the puncture made by the fangs 40 min. of solution of permanganate of potash, or 20 min. Condy's red fluid; or 20 min. of a solution consisting of 1 part of liquor potassæ and 6 parts of water; or 10 min. of liquor ammoniæ; or 40 min. of a 2 per cent solution of calcium hypochlorite; stimulants very freely; bleeding and intravenous injection of warm saline solution (1 dr. of common salt to 1 pint of warm water); artificial respiration; hypodermic injection of solution of strychnine (1 per cent), 5 min., to be repeated until symptoms of strychnine spasm appear. For the bite of a rattle-snake, olive oil freely by the mouth, and also to be rubbed into the skin.
- Soap Lees.**—(See CAUSTIC POTASH.)
- Soda, Caustic.**—(See CAUSTIC POTASH AND SODA.)
- Soothing Syrup.**—(See OPIUM.)
- Spirit of Hartshorn.**—(See CAUSTIC POTASH.)
- Stramonium.**—Emetics; tannin; stimulation; morphine hypodermically.
- Strychnine.**—
Immediate treatment: wash out stomach at half-hour intervals with solution of permanganate of potash diluted three times with warm water; emetic and stomach tube; injection of apomorphine, 5 min. hypodermically; bromide of potassium, 1 dr. in water every half hour; chloral hydrate hypodermically, 5 gr. repeated, or by rectum; chloroform inhalations.
Later: inhalation of chloroform, if convulsions are very severe; artificial respiration.—(See also CRAMP.)
- Sugar of Lead.**—(See LEAD.)
- Sulphuretted Hydrogen.**—(See SEWER GAS.)
- Sulphuric Acid.**—(See ACID, SULPHURIC.)
- Tartar, Emetic.**—Stomach tube; tannin, 30 gr. in water; vegetable astringents; tea; coffee.
Later: stimulants.
- Tobacco.**—Emetic; tannin; hypodermic injection of strychnine, $\frac{1}{16}$ gr.; stimulants; recumbent position.
- Turpentine.**—Stomach tube or emetic; magnesium sulphate, $\frac{1}{2}$ oz. in 2 oz. of water; demulcents.
Later: morphine.
- Vegetable Irritants.**—(Where symptoms of gastro-intestinal irritation follow the ingestion of some vegetable product.)—Stomach tube or emetic; glycerin of tannic acid, 2 dr. in 5 oz. of water; or tannic acid, 30 gr. in 5 oz. of water; white of egg; or gruel; linseed tea; arrowroot; stimulants; hot bottles and blankets; friction.
Later: morphine.
- Veratrine.**—Stomach tube or emetic; glycerin of tannic acid, 2 dr. in 5 oz. of water; or tannic acid, 30 gr. in 5 oz. of water; stimulants; enema of warm coffee, $\frac{1}{2}$ pint; hot bottles and blankets; recumbent position.

Verdigris.—(See COPPER, SALTS OF.)

Vermín Killers.—Battle's contains 10 per cent of strychnine: Butter's contains 5 per cent of strychnine; Roth and Ringensen's contains phosphorus and arsenic: Simpson's contains 40 per cent of arsenious acid. Many contain arsenic, and, exceptionally, barium carbonate.

Veronal.—(See BARBITONE.)

Vitriol, Blue.—(See COPPER, SALTS OF.)

Vitriol, White.—(See ZINC, SALTS OF.)

White Precipitate.—Treatment as for CORROSIVE SUBLIMATE.

Yew.—(See VEGETABLE IRRITANTS.)

Zinc, Salts of.—White of egg; washing soda in dilute solution; demulcents; strong tea; hot fomentations; morphine.

Robert Hutchison.

POLIOMYELITIS AND ENCEPHALITIS, ACUTE.—This disease is now recognized as one of the acute specific fevers, having an incubation period of from 4 to 12 days, and liable to be communicated from person to person. The causal organism of the disease has been obtained in culture and its characters described by Flexner and Noguchi. It belongs to the class of filtrable viruses.

There is some, but at present incomplete, experimental evidence that the disease may be carried by the stable fly (*Stomoxys calcitrans*). In dealing with the acute stage of this disease it is advisable to keep the individual isolated, and to take such precautions as would be adopted in nursing a case of typhoid. No statement based on bacteriological evidence can be made as to how long such precautions should be continued, but a period of at least fourteen days from the subsidence of the temperature to normal should be insisted on. It must be recognized that this disease may manifest itself simply by malaise, fever, and sore throat, of short duration; or it may affect any part of the nervous system, giving rise to a variety of symptoms, slight or severe, due to lesions spinal, cerebral, cerebellar, or meningeal. Various members of a family may be affected, and will exhibit a variety of symptoms.

The disease may, for the convenience of describing the method of treatment, be divided into three stages:—

(1) *The acute stage*; (2) *The stage of recovery*; (3) *The late stage*.

1. The Acute Stage.—The patient should be kept in bed and allowed to lie in whatever position is most restful. It is a mistake to insist on the prone position, however advisable it may seem to be from theoretical considerations. The bowels should be evacuated by calomel, or a glycerin suppository or enema. If fever be present, the diet should be fluid. Pain is often severe, especially on movement; and this symptom in cases seen during the acute stage often suggests that the case is one of acute rheumatism. It can often be relieved by careful support of the limbs by a water bed, and freedom from all movement. Hot applications may be of some service. Acetyl-salicylic acid or salicylate of soda in 5- to 10-grain doses every four hours is a most valuable remedy for this symptom. Lumbar puncture may be performed, but it is quite uncertain in its result as to the relief of pain; in those cases in which the fluid is under pressure, pain is generally relieved. In the severest cases morphia is needed.

All cases of acute poliomyelitis should be given 5 to 10 gr. of hexamethylenamine every four hours during the acute stage; for it has been shown experimentally that the drug passes into the cerebrospinal fluid and prevents the extension of the disease. It can with safety be given in the above doses to quite young children. In dealing with acute ascending forms of poliomyelitis, it would be well to use the intrathecal injections of serum obtained from a recovered case of poliomyelitis; for this has been used by Netter, and appeared to have a marked effect in limiting the spread of the disease.

When the disease is of wide extent and has affected the muscles of the thorax, the upper extremity, and neck, great care should be exercised in feeding the

patient. Should there be any evidence of failure of the closure of the glottis in deglutition, it is advisable to feed with a nasal tube. A patient with an attack of acute poliomyelitis should be kept at rest in bed for at least *four weeks*.

2. The Stage of Recovery.—After the acute stage, which usually lasts from five to ten days, has passed, recovery begins to take place. The treatment during this period consists in (a) The application of splints; (b) Massage (c) Passive and resistance movements; (d) Exercises; (e) Electricity; (f) Warmth to the limbs; (g) Drugs.

a. Splints.—These are necessary, first to keep the paralyzed muscle at rest; secondly, to prevent the occurrence of deformity; and thirdly, if the lower limbs are paralyzed, to help the patient to walk. For this purpose there is no doubt that a celluloid splint, which is made to fit the limb accurately, is the best; it is light, can be worn day and night, can be easily removed for the application of massage and movements, is easily replaced, and also aids the patient in walking (*Fig. 62*). Such splints should be used not only for the legs, but also for the arm and trunk if the muscles of these are paralyzed. For details as to the making and use of these splints, reference may be made to *The Clinical Journal*, 1913, xlii, 529.

b. Massage.—In those cases in which there is no pain on movement and no elevation of temperature, massage may be begun about ten to fourteen days after the onset of the disease; in many cases, however, owing to the pain, it is quite impossible to begin for three or five weeks, or even longer.

c. Passive and Resistance Movements.—These movements are of the greatest importance, not only in giving a physiological stimulus to aid the muscle in recovery, but also in tending to prevent the occurrence of deformity. Passive movements should be followed by active movements. The patient should be encouraged to make a movement against resistance. In many instances he is at first quite unable to perform any movements with the paralyzed leg. In this event, both legs should be held by the masseuse, and the patient told to attempt to extend and flex both legs against this resistance. In this manner, movement of the paralyzed limb can be sometimes brought out which the patient cannot otherwise produce.

d. Exercises.—From the end of the fourth to sixth week after the onset of the disease it is well to get the patient to perform exercises. The form of these must depend upon the muscles paralyzed.

Walking exercises are good so long as the limbs are so splinted that no deformity can occur. In those cases in which there is considerable paralysis of both legs, so that the patient cannot stand without support, both legs should be splinted from the heel to the

groin, and a walking apparatus such as is shown in *Fig. 63* should be used.

Complete rest for many months with the limbs in a fixed position has been advocated by some observers; but the above method of treatment is more advantageous so long as the limb is so splinted that no deformity can arise.

e. Electricity.—If the paralyzed muscles react to faradic stimulation, it is

Fig. 62. — Celluloid splints reaching from the foot to the groin. Note the flexion of the splint at the knee, and the shoes worn over the splint.

Fig. 63.—Form of walking apparatus used in encouraging children to make an attempt to walk.

advisable to use this form of current for treatment; if on the other hand the muscles react to galvanism alone, then that form of current should be used, and the pole, negative or positive, which causes the most active contraction, should be applied over the muscle, the current being made to vary rhythmically, or interrupted by a make-and-break key. If a contraction cannot otherwise be obtained, the current may be alternately reversed. The sinusoidal and condenser discharges are considered by some to be less painful and more effectual than other forms of current. The application of faradism is best carried out by two electrodes applied to the paralyzed muscle. The galvanic current may be applied in a similar manner, or the positive pole may be placed on the back and the negative pole moved slowly up and down over the paralyzed muscle. The application of the galvanic current can also be conveniently made in a bath. (See ELECTROTHERAPEUTICS.)

Although it is generally advisable to apply faradism to muscles which react to such a current, yet there are some exceptions. In a case, e.g., in which there is considerable affection of the muscles below the knee, it may be found that the gastrocnemius and soleus muscles respond to faradic stimulation, whereas the anterior tibial group responds only to galvanism. In such a case galvanism should be used only to the anterior tibial group of muscles, and no form of stimulation employed for the posterior group; for the stimulation, and consequent contraction, of the gastrocnemius tends to stretch the anterior tibial group and produce an equinus.

f. Warmth.—The attention of the parent and nurse should, in the case of children, be especially directed to this point. Warm baths and douches are useful, but it is of still greater importance to maintain the temperature of the limbs during the day and night by loose woollen garments, and by frequent rubbing of the limbs. A warm, equable climate will also be beneficial, but home comfort and convenience should not be sacrificed for the sake of climate.

g. Drugs.—Apart from general tonics, such as iron, cod-liver oil, and maltine, the only drug which seems to be beneficial is strychnine. This may be given at first in doses of $\frac{1}{100}$ gr. and gradually increased.

3. The Late Stage.—During this period the treatment consists in: (a) Mechanical support; (b) Division of tendons; (c) Nerve resection and reunion; (d) Resection of a joint; (e) Transplantation of tendons; (f) Amputation.

a. Mechanical Support.—During the early stage of the disease the limb should have been placed in a celluloid splint to keep the paralyzed muscles at rest and to prevent deformity; and in the later stage, this same splint answers the purpose of mechanical support and enables the patient to walk. Celluloid splints may in some cases, and especially in the case of young children, be worn for two to four years after the acute attack with advantage; but in those cases which still require a mechanical support after two years, it is probable that an instrument fitted with a movable joint is more convenient and gives the patient a greater play of movement. In those cases in which the muscles about the hip-joint are much affected, so that there is difficulty in maintaining the erect position, a steel instrument is of greater service than a celluloid splint.

b. Division of Tendons.—In many cases, before any mechanical support can be applied, division of one or more tendons is required. The simple shortening or lengthening of a tendon will in some cases greatly increase the usefulness of a limb—apart from any other measure. The more carefully a limb is splinted in the early stages of the disease, the less will tenotomies be required.

c. Nerve Resection and Reunion.—The principle of this operation depends upon the observation that when the proximal end of a degenerated nerve is connected with the distal end of a nerve in connection with a healthy nerve centre, the peripheral portion of the nerve regenerates, and hence impulses

are able to pass from the centre to the muscles. The successful application of such an operation depends on several factors. First, on the possibility of obtaining a healthy nerve in proximity to the degenerate nerve; secondly, on the paralyzed muscle retaining muscle fibres capable of regeneration when normally innervated; and thirdly, that the interference with the healthy nerve will give rise to no loss of power of serious importance. As may be readily understood, the number of cases in which such treatment is applicable is small, and they are most likely to be found among those in whom the disease has affected the muscles of the upper extremity. The operation should be performed before the sixth month after the onset of the disease. No improvement is to be expected in the condition of the muscle for at least six months after the operation. The results obtained from this operation are not encouraging, the percentage of improvements being very small.

d. Resection of a Joint.—The object of this operation is to give a fixed instead of a flail-like joint, and thus dispense with the necessity of mechanical support. The knee and ankle are the joints to which this form of treatment is generally applicable. The knee-joint should never be resected in children.

e. Transplantation of Tendons.—This method of treatment is—in selected cases—one of the most successful for correcting and preventing deformities. The method adopted is to insert a slip from the tendon of a healthy muscle into the tendon or insertion of the paralyzed muscle. The use of silk ligaments for the correction of deformity and replacing tendons has been strongly advocated, and good results have been published. For details of this mode of treatment, a surgical work should be consulted.

f. Amputation.—This has been advocated in cases in which there is complete paralysis of the whole leg, with arrested growth and with trophic sores.

It must be urged that, whatever method of treatment be adopted, it is essential to keep the limbs warm; this is in part accomplished by loose woollen garments, stockings, and overalls, but superficial rubbing and passive movements of the limbs, twice or thrice a day, are of the greatest importance.

F. E. Batten.

POSTERIOR BASIC MENINGITIS.—(See MENINGITIS.)

POST-NASAL GROWTHS.—(See ADENOIDS.)

POTT'S DISEASE.—(See SPINE, CARIES OF.)

PREGNANCY, DISORDERS OF.

Vomiting.—If the vomiting be only slight and confined to the beginning of the day, breakfast in bed may be all that is required. If more severe, a careful search for the cause should always be made, as the vomiting is not necessarily due to the pregnancy. Oral sepsis is frequently found in cases of severe vomiting during pregnancy, and much good may be done by the use of antiseptic mouthwashes. In some cases the condition of the teeth and gums makes it necessary that a dentist should be called in. In other cases constipation is the cause of the vomiting. "Pernicious vomiting" due to toxæmia is very rare in this country, and the induction of abortion on account of vomiting is seldom necessary. Albuminuria and rapidity of the pulse are two of the most important signs that the vomiting is toxæmic in origin. If treatment designed to combat the acidosis is not almost immediately successful, the uterus must be emptied.

Conditions which have absolutely nothing to do with the pregnancy, such as gastric ulcer, appendicitis, and cerebral tumour, have been found in so-called cases of severe vomiting of pregnancy. If no cause for the vomiting can be found beyond the facts that the patient is pregnant, and, probably, that she is neurotic, the case should be treated on general principles, that is, by rest in bed, attention to the bowels, and careful feeding, if necessary only peptonized milk and soda-water being allowed at first. Suggestion often plays an important part in the treatment, and sometimes a threat that the stomach must be washed out, if the vomiting does not cease, acts like a charm. Seclusion and the services of a trained nurse are all-important in severe cases where the neurotic element is prominent. As regards drugs, alkalies given by mouth, and saline solution per rectum, are successful in many cases. An effervescing mixture containing bismuth and dilute hydrocyanic acid, cerium oxalate (10 gr. in cachet), chloretone (5 gr. every four hours or oftener), menthol ($\frac{1}{2}$ gr. with milk-sugar in cachet), and $\frac{1}{2}$ minim doses of tincture of iodine in a little water, are all useful remedies. Administration of potassium bromide per rectum is worth a trial.

If the vomiting persists in spite of this treatment, it is possible that twenty-four hours' rest to the stomach may be successful. During this time nothing is given by mouth except albumin-water, and possibly the effervescing mixture, saline enemata being administered if necessary. (See also VOMITING, and SEASICKNESS.)

Salivation.—The treatment of this very unpleasant complication of pregnancy is most unsatisfactory. Belladonna has very little good effect, at least in many cases. Large doses of alkalies sometimes relieve it, but the doctor often has to be content with pointing out to the patient that her health is not suffering, and with assuring her that the trouble will cease soon after labour.

Heartburn.—This is best treated by such a mixture as the following :—

R Sodii Bicarbonatis	gr xx	Glycerini	℥xxx
Spiritus Ammoniae Aromatici	℥xx	Aquae Anethi	q.s. ad ʒj

Or the following powder :—

R Sodii Bicarbonatis		Bismuthi Oxycarbonatis	āā partes aq.
Magnesii Carbonatis Ponderosi			

One teaspoonful to be taken occasionally.

Pruritus Vulvæ.—This may be very resistant to treatment. If any vaginal discharge is present, lukewarm douches of lead lotion (liq. plumbi subacetatis 1 dr. to the pint) should be given. Rest with the pelvis raised, to diminish the congestion, bathing with lead or other suitable lotion, e.g., calamine lotion or carbolic acid lotion $\frac{1}{80}$, dusting with dermatol, and avoidance of constipation are the best measures to adopt. (See also PRURITUS.)

Toothache.—The aching may be relieved temporarily by bicarbonate of soda taken into the mouth dry. A dentist should always be consulted, as caries may make very rapid progress during pregnancy.

H. Russell Andrews.

PRESCRIBING.—Prescriptions are written directions :—

- | | | |
|------------------------|---|--------------|
| 1. For the preparation | } | of remedies. |
| 2. For the use | | |

The directions for the preparation of remedies are addressed to the dispenser, and are usually written in Latin. Those for the use of remedies are for the patient, and are usually written in English.

The directions for the dispenser consist of three parts, i.e., directions (a) to take; (b) what to take; (c) what to do with that which he has taken. Thus :—

Superscription. R = Recipe = Take.

Inscription, or }
Designation of } Quantity of substance or substances.
material.

Subscription. Mix, dissolve, etc.

The directions for the patient are called the "Signature," and are sometimes preceded by the word "Signe" or "Signetur" = sign, or, let it be signed, and this is usually abbreviated to "Sig."

The quantity—ounces, drachms, etc.—is to be put in the accusative and after the substance itself, which is written in the genitive, e.g. :—

Take—of Rhubarb rhizome—1 oz., is rendered—

Recipe—Rhei rhizomæ—unciam unam.

The word "misce" (mix) is the word which occurs most commonly in the subscription, and is usually abbreviated to "M."

The *model* prescription contains four parts :—

The Basis : the chief active ingredient.

The Adjuvant : aids the action of the basis.

The Corrective : counteracts any ill-effects of the basis or adjuvant.

The Vehicle : the diluent.

Of course many prescriptions do not contain all four parts.

Example :—

Superscription. Recipe.

Inscription {
Magnesii Sulphatis uncias duas c̄ semisse (basis).
Extracti Glycyrrhizæ Liquidi drachmas quatuor (adjuvant).
Tincturæ Cardamomi Compositæ unciam unam (corrective).
Spiritus Ammoniz Aromatici drachmas quatuor (corrective).
Infusum Sennæ ad uncias decem (adjuvant and vehicle).

Subscription. Misce.

Signature. One tablespoonful to be taken when required.

Written in the ordinary way the above prescription would be as follows :—

December 13th, 1914.

R Magnesii Sulphatis	℥iiss	Sp. Amm. Aromat.	℥iv
Ext. Glycyrrh. Liq.	℥iv	Inf. Sennæ	ad ℥x
Tinct. Card. Co.	℥j		

Misce. One tablespoonful to be taken when required.

Mrs. Jones.

J. C.

The directions to the patient, usually written in English, may of course be written in Latin. But as the directions appear on the label of the bottle of medicine, when they are written in English on the prescription the patient has the opportunity of checking the dose with the dose on the label.

It is usual nowadays to prescribe a *single dose*, and to direct the dispenser to send an appropriate number of doses, as follows :—

December 13th, 1914.

R Ferri et Ammoniz Citratis	gr v	Spiritus Chloroformi	℥v
Sodii Bicarbonatis	gr x	Infusum Calumbæ	ad ℥j

Fiat mistura ter die sumenda.

Mitte ℥xij.

It is evident that by writing the prescription in this way the physician has escaped the labour of multiplying the dose of each ingredient by 12.

Written in the older way it would be as follows :—

December 13th, 1914.

R Ferri et Amm. Cit.	℥j	Spiritus Chloroformi	℥j
Sodii Bicarbonatis	℥ij	Infusum Calumbæ	ad ℥xij

Misce. Two tablespoonfuls three times a day.

Incompatibility.—Unless the prescriber be content to recline entirely on his hospital pharmacopœia or on the tablets of the manufacturing chemist, he must know the elements of incompatibility. Now incompatibility can be a very large subject, one full of confusion and of never-ending exceptions; but even in a short article it is possible to point out the very common examples which are constantly occurring in prescribing the common drugs.

1. *Carbonates and bicarbonates are decomposed by free acids.* This rule is of course well known to everybody, but it is often transgressed because the acid may not be quite in evidence.

Example :—

R Ammonii Carbonatis	gr v	Aquam Destillatam	ad 3j
Syrupi Scillæ	℥xxx		

The Syrupus Scillæ is made from the Acetum Scillæ, and contains free acetic acid. The free acid, reacting with the Ammonium Carbonate, gives off CO_2 , and leaves in the mixture Acetate of Ammonium, which is diaphoretic, not expectorant. The Tinctura Scillæ, not the Syrupus, should have been prescribed.

(It should be remembered that the Syrupus Limonis, a very common flavouring agent, contains a considerable quantity of free citric acid. The Tinctura Limonis, the Tinctura Aurantii, and the Syrupus Aurantii contain no free acid.)

The following prescription, found in many of the hospital pharmacopœias, is another example of the same kind :—

R Bismuthi Subnitrat	gr x	Infusi Calumbæ	3j
Sodii Bicarbonatis	gr x		

The oxycarbonate of bismuth is formed and CO_2 is given off. It is better to prescribe the carbonate of bismuth with the bicarbonate of soda.

(Acid. Hydrocyanicum Dil. does not decompose carbonates or bicarbonates; it is often prescribed with bicarbonate of soda as a gastric sedative and antacid.)

2. *When solutions of two soluble salts are mixed and an insoluble compound can be formed by an interchange of radicles, this compound will, as a rule, be formed, and a precipitate will occur.*

The examples of incompatibility coming under this heading are very numerous, and can be avoided only by knowing which salts are insoluble.

Examples :—

(i) R Magnesii Sulphatis	3j	Aquæ Destillatæ	3j
Sodii Carbonatis	gr x		

Carbonates, except those of the alkalies, are insoluble in water.

Therefore magnesium carbonate is precipitated. The bicarbonate of soda should be used; it will not cause a precipitate. Magnesium Sulphate is not incompatible with Ammonium Carbonate, e.g., they are both contained in the Mistura Sennæ Composita of the B.P.

(ii) R Plumbi Acetatis	gr v	Aquam Destillatam	ad 3j
Acidi Sulphurici Diluti	℥x		

Lead sulphate is precipitated.

(iii) R Liquoris Bismuthi et Ammonii		Tincturæ Cardamomi Co.	℥xv
Citratis	℥xxx	Infusum Rhei	ad 3j

Tannate of bismuth is precipitated. Preparations of rhubarb are frequently added to bismuth mixtures with the idea of counteracting the constipating effect.

3. *Salts of alkaloids (omit caffeine).*

a. Should not be prescribed in alkaline solutions, because the alkali seizes the acid and the alkaloid is set free, and being only very sparingly soluble in

water, it may be precipitated ; e.g., Liq. Strychninæ Hydrochlor. ℥v, prescribed in ʒj of alkaline solution, will probably not precipitate the alkaloid, because the amount of strychnine contained in 5 minims is soluble in ʒj of water ; but if the dose of the Liquor be increased, or if the amount of the vehicle be diminished, precipitation will take place.

Examples :—

- (i) R Quininæ Sulphatis gr j | Spiritus Ammoniaë Aromatici ℥xv
Acidi Sulphurici Diluti ℥j | Aquam Destillatam ad ʒj

The quinine will, of course, be precipitated by the alkaline spiritus, which also contains Ammonium Carbonate, so that any free acid will cause effervescence.

- (ii) R Ferri et Quininæ Citratis gr v | Aquam Destillatam ad ʒj
Spiritus Ammoniaë Aromatici ℥xv

This is a combination often seen in prescriptions, probably due to the mistaken generalization that the scale preparations of iron—e.g., the Ferri et Ammonii Citras—are not precipitated by alkalies, but the *alkaloid* will be precipitated.

(The Tinctura Quininæ Ammoniata is a solution of Quinine Hydroxide in alcohol and in excess of ammonia. When water is added the alkaloid is precipitated. Therefore, in a mixture the tincture should always be prescribed with mucilage. Quinine precipitated in water is not so bitter as when in solution.)

Borax (biboate of sodium) is alkaline, and therefore precipitates alkaloids.

If the amount of alkaloid in a mixture be small, or if the alkali be weak, e.g., Sodii Bicarb., or Pot. Bicarb., no reaction may take place.

The bicarbonates and Ammonium Carbonate do not precipitate solutions containing atropine.

b. Iodides, bromides,* salicylates, benzoates, and tannates form insoluble salts with alkaloids, and therefore as a rule they are not prescribed together except in some formula which experience has shown to be satisfactory.

Examples :—

- (i) R Quininæ Sulphatis gr j | Potassii Iodidi gr v
Acidi Sulphurici Diluti ℥j | Aquam Destillatam ad ʒj

This is the Haustus Quininæ c̄ Pot. Iod. of the St. B. H. Pharmacopœia. On the face of it the prescription looks impossible, because of the presence of the alkaloid and of free acid with Potassium Iodide. But the mixture can be dispensed successfully in the following manner :—

Dissolve the quinine sulphate in the smallest possible amount of acid (℥¼ to each grain), so as to have the smallest possible amount of free acid present, then dilute the solution with half the vehicle.

The potassium iodide is dissolved in the other half of the vehicle, and, having thus diluted the two salts to the utmost, bring them together.

If excess of acid be used, or if the two salts be brought together in stronger solution, reaction will be inevitable.

- (ii) R Quininæ Sulphatis gr j | Infusum Rosæ Acidum ad ʒj
Acidi Sulphurici Diluti ℥j

Tannate of quinine is precipitated.

Only two infusions can be prescribed with alkaloids, viz., Inf. Calumbæ and Inf. Quassiaë, because they contain no tannin.

- (iii) R Quininæ Sulphatis gr j | Aquæ Chloroformi ʒj
Sodii Salicylatis gr x

* The hydrobromide of quinine is very soluble in water. Dilute hydrobromic acid is an excellent solvent of quinine salts, and tends to prevent the headache and singing in the ears which they may produce.

Salicylate of quinine is precipitated. It is often prescribed in this way, and dispensed with a "Shake the bottle" label. The prescription should contain Pulv. Tragacanthæ Co. (B.P.) gr. v, in order to suspend the precipitate.

Acetate of potash is often combined with quinine in a febrifuge mixture :—

(iv) R Quinina Sulphatis	gr j	Potassii Acetatis	gr x
Acidi Sulphurici Diluti	℥j	Aquam Destillatam	ad 3j

Acetate of quinine being insoluble is precipitated.

c. *Double iodides* are prompt precipitants of alkaloids. In most hospital pharmacopœias there is a Mistura Hydrarg. Perchlor. c Pot. Iod. This mixture by interaction contains a double iodide of mercury and potassium, and being somewhat depressant, Liq. Strychnina Hydrochlor. has often been added to it, resulting of course in a precipitate of iodide of strychnine. Donovan's solution—Liq. Arsenii et Hydrarg. Iodidi—readily precipitates alkaloids.

(Mercuric Chloride alone will precipitate most alkaloids—indeed the drug is incompatible with so many things that it should never be prescribed except in some formula which experience has shown to be satisfactory.)

4. Iron salts.

a. Not generally prescribed with anything containing tannin ; the tannate of iron is ink. The preparations of Calumba and Quassia do not contain tannin.

Example :—

R Ferri et Quinina Citratis	gr v	Spiritus Chloroformi	℥x
Liquoris Strychnina Hydrochloridi	℥iv	Aquam Destillatam	ad 3j
Tinctura Cardamomi Co.	℥xxx		

The tannin in the compound tincture will tend to precipitate the iron and quinine and strychnine. Tinct. Calumbæ ℥xxx would be compatible.

The preparations of digitalis are sometimes said to be incompatible with iron salts, as they contain a little tannin, but the incompatibility may be neglected.

Example :—

R Liquoris Ferri Perchloridi	℥x	Aquam Chloroformi	ad 3j
Tinctura Digitalis	℥x		

No doubt a little tannate of iron will be precipitated—but it is not important. (The addition of Acid. Phosph. Dil. ℥x will make the mixture clear—for the tannate of iron is substituted the phosphate of iron soluble in the excess of phosphoric acid and of the free hydrochloric acid of the Liquor.)

b. The ordinary iron preparations, e.g., Liq. Ferri Perchlor., or Tinct. Ferri Perchlor., are precipitated by alkalies. Ferri et Am. Cit. and Ferrum Tartaratum are not precipitated by alkalies.

Examples :—

(i) R Liquoris Ferri Perchloridi	℥x	Infusum Quassia	ad 3j
Sodii Bicarbonatis	gr xv		

This will throw down a hydrate of iron.

(ii) R Ferri et Ammonii Citratis	gr v	Infusi Quassia	3j
Sodii Bicarbonatis	gr xv		

This will not precipitate.

5. *Liq. Potassii Arsenitis being alkaline*, should be prescribed with Ferri et Am. Cit. or Ferrum Tartaratum. *Liq. Acidi Arsenosi, being acid*, should be prescribed with the ordinary iron preparations, e.g., the Liq. Ferri Perchlor. or Tinct. Ferri Perchlor.

Example :—

R	Liquoris Potassii Arsenitis	℥iv	Spiritus Ammoniaë Aromatici	℥x
	Ferri et Ammonii Citratis	gr v	Aquam Destillatam	ad ʒj

However, we often see prescriptions such as this :—

R	Liquoris Potassii Arsenitis	℥iv	Spiritus Chloroformi	℥xv
	Liquoris Ferri Perchloridi	℥x	Aquam Destillatam	ad ʒj

Theoretically, the alkaline Liq. Potassii Arsenitis should precipitate the iron, but no precipitate takes place, because the iron solution contains so much free acid that the resultant mixture is still *acid*.

Evidently also the acid solution of arsenic should be chosen to combine with alkaloids, for example, with strychnine or with quinine, or with the cinchona preparations.

Example :—

R	Liquoris Acidi Arsenosi	℥iv	Tincturaë Ferri Perchloridi	℥x
	Liquoris Strychninaë Hydrochloridi	℥iv	Infusum Quassiaë	ad ʒj

People have died from the prescription of Liq. Potassii Arsenitis with Liq. Strychninaë Hydrochlor., the alkali precipitating the alkaloid to the bottom of the bottle, so that the patient has taken the whole of the poison in one dose.

Again, the acid solution should be used with Liq. Hydrarg. Perchlor. (B.P.), because the alkaline solution will throw down mercuric oxide.

Liq. Potassii Arsenitis, however, is sometimes added to a Mistura Hydrarg. Perchlor. c̄ Pot. Iod. to prevent the appearance of iodism, but this mixture really contains a double *iodide* of mercury and potassium, with which alkalies and not acids are properly prescribed (see *Iodides*).

Liq. Sodii Arsenatis is generally alkaline, and therefore tends to precipitate alkaloids or ordinary iron salts, whilst Donovan's solution, Liq. Arsenii et Hydrargyri Iodidi, is, of course, a typical precipitant of alkaloids (see *Alkaloids*).

6. *Iodides and bromides* should be given in neutral or alkaline solutions—most acid solutions tend to set free iodine or bromine—therefore they are compatible with Ferri et Am. Cit. or Ferrum Tartaratum, and incompatible with Liq. Ferri Perchlor. or Tinct. Ferri Perchlor.

Caffeine Citrated and Bismuth Subnitrate both give acid solutions in water, and are therefore incompatible with iodides and bromides.

Example :—

R	Bismuthi Subnitratis	gr x	Aquæ Destillatæ	ʒj
	Potassii Iodidi	gr v		

Iodine is set free, and in a few minutes the mixture becomes yellow from formation of Iodide of Bismuth. Bismuth *Carbonate* will go well with iodides.

Iodides are often prescribed with nitrites, e.g., Sp. Æth. Nitrosi. Nitrites tend to decompose in water, with formation of nitrous acid. Thus nitrites may become incompatible with iodides. It is usual in dispensaries to keep a few crystals of Pot. Bicarb. in the Sp. Æth. Nitrosi bottle to neutralize any acid formed.

Iodides with alkaloids (see *Salts of Alkaloids*).

7. *Sodium salicylate.*

a. This cannot be prescribed in acid solutions, because any acid will turn out the weak salicylic acid, which, being insoluble, may be precipitated. The same applies to benzoates.

Example :—

R	Sodii Salicylatis	gr x	Aquam Destillatam	ad ʒj
	Syrupi Limonis	ʒj		

The Syr. Limonis contains much free citric acid, therefore Sodium Citrate will be formed and Salicylic Acid thrown down.

Sod. Salicylate should be prescribed with Caffeine itself, not with Citrated Caffeine, because it easily dissociates in water and citric acid is set free.

b. Sodium Salicylate is often prescribed with Iron. Rheumatic fever rapidly causes anæmia. Ferri et Am. Cit. or Ferrum Tartaratum should be chosen, because the Liquor (or Tincture) Ferri Perchlor. will give a deep purple coloration, or even precipitate.

Example :—

R Sodii Salicylatis	gr x	Glycerini	℥ xxx
Ferri et Ammonii Citratis	gr v	Aquam Destillatam	ad ʒj

The mixture may turn somewhat redder in colour, but there will be no precipitate.

c. Acetyl-salicylic acid (aspirin) is very sparingly soluble in water, and as it dissociates in water it is best prescribed in the form of a tablet or cachet. It is swiftly split up by an alkali, and should not be prescribed in alkaline solution. Prescribed with sodium bicarbonate, as it so often is, the mixture contains sodium salicylate, not acetyl-salicylic acid.

8. *Chloral hydrate* prescribed with alkalies splits up, with formation of chloroform.

Example :—

R Chloral Hydratis	gr x	Aquæ Destillatæ	ʒj
Ammonii Carbonatis	gr v		

9. *Hexamethylenamine* is a compound derived from ammonia and formaldehyde. It is not in itself antiseptic, but in a solution sufficiently acid it is split up and the formaldehyde set free. Hexamethylenamine is said to be antiseptic only in acid solution.

The commonest use of the drug is as a urinary disinfectant, and for this purpose it is often prescribed with Pot. Citrate—a combination which seems unfortunate, because the Pot. Citrate, excreted in the urine as a carbonate, renders the urine less acid, or even alkaline, and thus tends to hinder or prevent the setting free of formaldehyde. In cases where the urine is alkaline, neutral, or faintly acid, it would seem more reasonable to prescribe Hexamethylenamine with Acid Sodium Phosphate, the drug most successful in increasing the acidity of urine, or—as some prefer—to precede the exhibition of Hexamethylenamine by a course of Acid Sodium Phosphate until the urine is sufficiently acid.

12 FR 1

James Calvert.

PRIAPISM may occur (1) As the result of injury to the spinal cord ; (2) In association with prostatic enlargement ; (3) In the course of leukæmia (probably from thrombosis in the cavernous sinuses) ; (4) As a local manifestation of gout.

In addition to treatment of the primary condition, the following may be useful :—

R Pulveris Camphoræ	gr. xvj	Tincturæ Lupulinæ	ʒij
Tincturæ Belladonnæ	℥i		

Misce et adde :—

Mucilaginis Tragacanthæ	ʒiv	Aquam Camphoræ	ad ʒiv
-------------------------	-----	----------------	--------

ʒss an hour after breakfast and at bedtime for three or four days.

Bromides in 30-gr. doses at bedtime are effective in some cases.

Locally, cold applications are helpful, or the patient may be instructed to place some cotton-wool beneath the foreskin at bedtime, and on waking inject into this a few drops of a 10 per cent solution of cocaine by means of a pen-filler. This will sometimes effectually control the condition.

Robert Hutchison.

PROCIDENTIA.—(See RECTUM, SURGICAL DISEASES OF.)

PROCTITIS.

Acute Catarrhal Proctitis.—Rest in bed is essential until all symptoms have disappeared. The bowel should be thoroughly washed out with a saline laxative, and afterwards irrigation of the bowel with hot or cold water is often most comforting. Suppositories of iodoform and opium, or an ounce of flax tea containing $\frac{1}{2}$ gr. of opium and 30 min. fl. extr. of krameria, will allay the tenesmus and spasm at once. The diet must be regulated so as to leave as little residue as possible, but it is better to avoid the use of milk. After the acute stage is passed, irrigation of the bowel with 1 per cent of argyrol or argonin will hasten convalescence, especially if combined with strychnine and iron by the mouth.

Gonorrhœal Proctitis.—The best treatment in acute cases is to stretch the sphincters under an anæsthetic and then introduce a tube so as to drain the bowel. Frequent irrigation with saline or weak antiseptics is indicated.

Chronic Proctitis.—A very good plan is to start the treatment with large rectal injections of warm olive oil, which should be retained as long as possible. After this, irrigation of the bowel twice daily with 1–2000 potassium permanganate or 1 per cent argonin is useful if it can be properly carried out. Careful regulation of the diet to prevent intestinal fermentation, combined with a daily dose of sulphate of magnesia or Carlsbad salts, is also indicated. Full doses of arsenic are beneficial, and in many cases an intestinal antiseptic is useful. Often the quickest and most satisfactory method of treating chronic proctitis is to dilate the sphincters and apply pure fuming nitric acid to the inflamed mucous membrane. This, however, must be done very carefully, and the acid be used in very small quantities. The object is not to cause severe burning of the mucosa, but to destroy the surface epithelium only. Or instead of the nitric acid, silver nitrate, 30 gr. to the ounce, may be used. A very valuable method of treatment in these cases is by electric ionization. In fact, so satisfactory has this treatment proved, that it has now almost replaced the use of irrigation in those cases where it can be applied. It requires, however, proper apparatus, and some person skilled in the administration of drugs by this method. The treatment is carried out as follows: A special electrode having a bag made of animal membrane surrounding it is introduced into the rectum, and the bag is then distended with a 2 per cent solution of zinc sulphate; a current of about 6 to 10 milliamperes is then passed for about twenty minutes, the other pole being applied to the back or abdomen. Treatments are given every 4 or 5 days for three or four times; after this at intervals of a fortnight or three weeks. *J. P. Lockhart Mummery.*

PROLAPSUS ANI AND RECTI.—(See RECTUM, SURGICAL DISEASES OF.)

PROSTATE, ENLARGEMENT OF.—Setting aside chronic inflammatory enlargements of the prostate, which are met with at any age, obstruction to micturition and the secondary changes caused by it in the urinary system are seldom encountered before the sixth decade of life. Enlargement of the prostate is commonly called hypertrophy of that organ, but in examination of a large number of specimens the writer has not come across a single instance of true hypertrophy—i.e., a general enlargement of the organ in which each several element—glandular, connective tissue, and vascular—was enlarged in its right proportion to the whole. On the contrary, the enlargement is due either to an abnormal increase of the epithelial or the connective-tissue portions of the gland in the one case or the other, and it must be remembered that this increase may be either of an innocent or a malignant character.

TREATMENT.—The treatment of enlargement of the prostate must be considered separately for each variety.

Carcinoma in the great majority of cases can be treated only palliatively. Careful aseptic catheterism should be instituted and persevered with until the pain or hæmorrhage caused by it becomes severe, or the difficulty of catheterism becomes too great. At this point a carefully performed suprapubic drainage should be done. If great attention is paid to the fitting of the suprapubic tube very little leakage occurs, and the patient is able to get about in fair comfort. Perineal drainage should never be undertaken for carcinoma of the prostate.

It is only quite recently that a serious and sustained attempt has been made to remove the growth. No mere enucleation will serve, but the prostate and the whole lower portion of the bladder up to the inter-ureteric bar, together with the seminal vesicles, must be excised. The bladder is then sewn up and anastomosed to the cut urethra. The patients are, of course, completely incontinent after this operation. Sufficient time has not yet elapsed to speak with certainty as to the radical nature of this operation, but results are fairly encouraging.

Fortunately, in a large number of cases the growth does not tend to encroach very much upon the urethra or cavity of the bladder, and catheterism remains fairly easy up to the end. In a few cases of apparent malignant disease of the prostate, of so large a size and so advanced a nature that an operation for removal could not be contemplated, radium has recently been tried with some apparent success; i.e., the enlarged prostate has decreased almost to a normal size, the hours of micturition and the general health have improved, and loss of body weight has ceased. It is only right to state, however, that in none of these cases within the writer's knowledge has the carcinomatous nature of the enlargement been proved by microscopical examination; but the clinical symptoms were typical of carcinoma of the prostate.

Fibrous Enlargement.—Palliative treatment consists in careful catheterism; but these prostates are particularly well suited to complete cure by operation, and without much danger. The operation of enucleation, so successful in adenoma of the prostate, is neither easy nor very satisfactory in these cases. Piecemeal excision, or prostatotomy by the perineal route, are the two operations which give the best results. In the former the posterior aspect of the prostate is freely exposed by careful dissection, and the gland recovered from its sheath by scissors and forceps and a blunt dissector. Prostatotomy should be done through a median perineal incision, the urethra being opened well in front of the compressor urethræ muscle and the prostate incised from within in any desired direction. The writer has performed this operation frequently, and has found the results immediately and lastingly satisfactory. Great care must be taken to leave the compressor urethræ intact, or the patient will be incontinent. The operation may be performed through a suprapubic incision, the cuts in the prostatic urethra being made from within the bladder, but the writer has found the former operation much more satisfactory.

Adenoma.—The most common enlargement of the prostate is the adenomatous type, which formerly went by the name of "senile hypertrophy of the prostate." It may be said at the outset that in the case of patients who are unfitted for operation by some intercurrent disease of the cardio-vascular or respiratory systems, or in those of generally very feeble health, and whose condition of life permits them to take the stringent precautions necessary, catheterism will ensure a comfortable existence without much risk. But in the majority of these cases complete removal of the prostate is the method of choice for their treatment, and the risk is very different in degree in those cases where the operation is one of expediency on the one hand or of urgency on the other. By expediency is meant that the operation is performed whilst the patient is in good general health and has not had his powers undermined by

long-continued suffering. An urgent prostatectomy, upon the other hand, is done when the patient is in serious straits; where, after long-continued overdistention, with consequently damaged kidneys, catheterism has been tried and is failing; where sepsis has been introduced, hæmorrhage has been often repeated, and possibly calculi have formed several times in consequence of decomposition of urine in the bladder.

It is often wise in these cases to do the operation in two stages, first draining and cleaning the bladder by a suprapubic cystotomy, and removing the prostate after a week or two when the conditions are much better. The writer has met with great success by following this plan, and has saved cases which in his opinion would have been lost had the operation been performed immediately. There are some aged men, whose expectation of life is not very long in any case, who, with capacious bladders, need the catheter only twice or three times in twenty-four hours, and to whom the use seems merely a part of their ordinary toilet operations. These patients appear to have an extraordinary tolerance of catheterism, and, though they treat the operation with scant ceremony as regards asepsis, suffer only the most transient attacks of epididymitis, and slight and passing exacerbations of the slight grade of cystitis which is invariably present. All practitioners are familiar with such cases, and it is not a duty to urge prostatectomy upon them, though it may very well be left to them to accept it if they will.

On the Continent and in the United States perineal prostatectomy is more favoured for adenoma of the prostate than it is by British surgeons. The writer has tried both, and finds the suprapubic method quicker, easier, and more thorough than the perineal operation.

CONCLUSIONS.—1. Except in very early cases it is not permissible to operate for malignant disease of the prostate, except for the purpose of permanent suprapubic drainage.

2. In the case of fibrous enlargement, interfering with micturition, piecemeal enucleation, or a prostatotomy should be done. The mortality of the latter operation is practically nil, and the results are satisfactory, both immediately and permanently.

3. Some few aged men suffering from adenomatous enlargement of the prostate show a very marked tolerance of catheterism, and live comfortable "catheter lives." In these cases surgical interference is unnecessary.

4. Unfortunately catheter life to the great majority of sufferers has serious dangers and discomforts, and for these prostatectomy is by far the best treatment. It should be done at the period of election, namely, when the symptoms of obstruction are becoming marked, but before cystitis, infection of the kidneys, and their results have placed the patient in a position of danger; in the writer's opinion the best method is complete suprapubic enucleation.

5. The surgeon should not refuse operation to cases seriously infected and very ill. Their lives are sure to be painful, and seldom prolonged, if operation is refused; and although the mortality is higher than in selected cases, it is not unduly high, and much may be done to ensure success by preliminary cystotomy for thorough drainage and clearing up of septic conditions.

The writer has in this article recommended those procedures which are serving him well, and has omitted mention of methods of treatment which are widely advocated in some quarters; for instance, Bottini's galvano-caustic incisions, combined perineal and suprapubic prostatectomies, and so forth. But the simplest operations are usually the most successful, and those recommended here have been found amply sufficient to meet all cases. *John George Pardoe.*

PRURITUS.—Before deciding on the treatment, it is necessary to determine whether the case is one of primary or secondary pruritus. No case can be regarded as a true primary pruritus until all possible causes of external irritation have been eliminated. If after very careful examination no such causes can be found, inquiries must be made as to how far the patient's mode of life transgresses the usual hygienic principles, and whether there is any evidence of diabetes, gout, or intestinal disease, as shown by investigation of the urine and blood and by general physical examination. Any circumstances which might predispose to, or determine the onset of, pruritus must be enquired into, and the patient's diet and mode of life regulated accordingly. In almost every case alcohol, tea, and coffee must be forbidden, as also rich and highly-seasoned dishes. Some patients find their symptoms are improved by a vegetarian diet with plenty of milk, or, in default of this, they should live chiefly on poultry, green vegetables, and milk puddings, with plenty of *Salutaris* or slightly alkaline mineral waters. Rest and absence of worry have a favourable effect on neurotic patients, and it is often wonderful how much good a few weeks in bed or in a nursing-home will do. Some pruritics are benefited by a change to the country or the mountains, or to a spa like Royat or Aix-les-Bains.

Internal Treatment should begin by giving preparations of salicylic acid; salol, sodium salicylate, or salophen may be given alone, or in combination with antipyrin, acetanilide, or phenacetin. Carbolic acid in pill form is successful in some cases; arsenic and atropine may be tried, and pilocarpine (10 to 20 drops of a 1 per cent solution) occasionally gives good results. But greater success is usually obtained with sedatives, especially bromide of sodium in combination with *cannabis indica*, or tincture of aconite with tincture of gelsemium. In more severe cases where insomnia is a marked symptom, hypnotics are necessary: sulphonal, trional, chloral hydrate, or medinal.

External Treatment must always be employed in addition to internal remedies, and one of the simplest and most effectual applications is an evaporating lotion. Equal quantities of eau de Cologne and water applied on lint, which is kept moist with the liquid, or lavender water dabbed on every few minutes, often affords great relief, especially if preceded by hot applications. Sponging with water as hot as can be borne, with or without the addition of bicarbonate of soda, or a hot bath, or better still a vapour or Turkish bath, causes dilatation of the capillaries of the skin; and the subsequent constriction of these vessels brought about by cooling or evaporating lotions is not only more complete, but also induces a more lasting cessation of the itching. The addition of oatmeal to a hot bath is usually beneficial, or still better, half a pound of gelatin made into a jelly with warm water and then added to the bath, or one pound of starch worked into a smooth paste with cold water and boiled, or half to one pound of linseed. Alkaline baths often give relief in the milder cases, and they are easily made by adding 2 or 3 oz. of either sodium carbonate, bicarbonate, or borate to a bath of 30 gallons of water. The patient soaks in the bath for about twenty minutes, dries himself with a soft towel, and then rubs in a weak cocaine ointment, containing 1 gr. to the ounce of soft paraffin. Creosote and sulphurated potash are somewhat objectionable to sensitive patients, but the sulphur powders are a convenient method of making a not unpleasant sulphur bath. A combination bath of sulphur and pine-oil is obtained by dissolving piutanol in the bath, and it gives good results. Of cooling lotions, the simplest is one containing 2 dr. of liquor plumbi subacetatis to 1 oz. of lavender water and 7 oz. of distilled water. A lotion containing hydrocyanic acid which is very successful is the following:—

R Acidi Hydrocyanici Diluti
Spiritus Rosmarini

$\frac{3}{ss}$ | Glycerini
 $\frac{1}{j}$ | Aquam

$\frac{3}{ss}$
ad $\frac{3}{x}$

Carbolic acid made up in the strength of 1 dr. to 10 oz. of water, with the addition of $\frac{1}{2}$ oz. glycerin and $\frac{1}{2}$ oz. eau de Cologne, gives a useful lotion; if necessary, to any of these lotions 1 dr. of cocaine may be added to give a greater anti-pruritic effect.

The best way to apply them is to soak a single layer of lint or linen with the lotion, lay it lightly on the itching surface with no covering over it, and sprinkle or spray on fresh lotion every five minutes so as to keep the lint thoroughly moist.

Alkaline lotions consisting of either 2 dr. bicarbonate of soda, 2 dr. carbonate of potash, or 1 dr. borax, to 8 oz. water are all useful for cases where large areas of skin are involved, and the addition of a little menthol will increase the effect.

The following lotion often gives relief, and may be used for weeks without harmful effects:—

R Ichthyolis	$\overline{3}^{ss}$	Spiritus Lavandulæ	$\overline{3}^{ss}$
Sodii Bicarbonatis	$\overline{3}^{iss}$	Aquam	ad $\overline{3}^{viii}$

For general pruritus, ointments, sprays, paints, and varnishes are rarely suitable, but they all find their uses in the following localized forms of pruritus.

In *pruritus genitalium*, and especially pruritus of the vulva, the hygienic and dietetic rules already discussed in detail must be adhered to. In the more usual cases of *pruritus vulvæ* (q.v.), where there is a uterine or vaginal discharge, strict cleanliness must be enjoined, with a plentiful use of soap and water, and douches of 1-5000 potassium permanganate, 1-5000 perchloride, or 1-1000 zinc sulphate. After this a vaginal tampon must be inserted and the external parts covered with Lassar's paste containing 1 per cent silver nitrate or lenigallol. An ichthyol ointment or paste may be substituted, or an ointment containing 30 min. of chloroform to 2 oz. of lard, or the ordinary aconitine ointment (B.P.). An ointment which often gives good results is the following: chloral hydrate, menthol, and camphor, each 45 gr., lanolin and vaseline, each $\frac{1}{2}$ oz. If there is any induration of the skin in the pruritic area, a dressing of Lassar's paste containing a small percentage of salicylic acid must be applied continuously until this has been got rid of or has diminished in amount, and any excoriations present have healed. An ointment containing liquor carbonis detergens, $\frac{1}{2}$ dr., unguentum conii 1 oz., will then relieve the itching, or the following ointment:—

R Creosoti	$\overline{3}^j$	Hydrargyri Chloridi Mitis	$\overline{3}^{ss}$
Tincturæ Aconiti	\overline{m}^{iss}	Olei Rosmarini	\overline{m}^x
Zinci Oxidi	$\overline{3}^{ss}$	Vasellini Albæ	$\overline{3}^j$

These ointments may be alternated with the following:—

R Chloralis Hydratis	$\overline{3}^{ss}$	Cerati Simplicis	$\overline{3}^j$
Camphoræ	\overline{aa}		
R Chloroformi	$\overline{3}^{ss}$	Adipis Benzoati	$\overline{3}^j$
Olei Lavandulæ	\overline{m}^x		

These ointments are best used at night, bathed off in the morning with some olive oil, and the following powder applied: chloral hydrate and cocaine, each 40 gr., powdered starch, 1 oz.

The advantage of using an ointment is, that the parts are protected from the action of any discharge which, in spite of the tampon, comes in contact with them. In my experience, fluid solutions of menthol or carbolic acid usually cause intense smarting and soreness in these cases, as do also many spirit applications.

The addition of cocaine in the strength of 5 per cent is often advantageous, and may be combined with oil of cade or anthrasol in the form of an ointment. The more inveterate cases respond well to applications of a Paquelin cautery,

to excision of kraurotic skin areas, or to turning up a flap of skin all round the vulva and division of the afferent nerve fibres. In cases of diabetes, the patient must be strictly dieted, and, if the urine cannot be always drawn off with a catheter, the vulva should be covered with some protective sedative dressing in the form of an ointment or soluble varnish. One of the best of these latter is ung. casein with the addition of 2 per cent ichthylol or 1 per cent tar. Casein ointment is composed of alkali caseinate, glycerin, vaseline, and water, and forms a thick white emulsion which dries on the skin in a minute or two, forming an elastic dry covering, readily washed off. On the one hand it is porous enough to permit of evaporation, on the other it can be combined with fat, which helps the added ichthylol or tar to make its way deeply into the tissues. It is therefore more than a protective varnish, and holds a position intermediate between the ointments on the one hand and the pastes and powders on the other. Methylene blue given in pill form, one grain night and morning, with a paint of methylene blue, 4 gr. to the ounce, applied at frequent intervals, has the objection that it stains the urine blue, but if this does not contain sugar the treatment is often successful.

When there is marked insomnia, especially in the aged, where the skin is naturally dry and the itching at night often intense, it is frequently necessary to order suppositories of cocaine, morphia, or medinal. It must be remembered that many patients scratch quite unconsciously during their sleep until the cutaneous nerves have been numbed by the vasomotor dilatation and resulting exudation; and this in spite of any dressings, unless these are fixed so tightly as to be uncomfortable. Such scratching may undo the whole benefit of treatment applied during the day, and leave an excoriated and inflamed surface which takes some time to heal up. In such cases suppositories are of the greatest service, but they must be looked upon merely as a temporary means of relief, and be discontinued as soon as possible.

In the most obstinate cases, a rapid application of the actual cautery to the most irritating areas often causes great amelioration of the symptoms. The high-frequency current applied with a glass electrode is occasionally successful, and cases frequently react well to two or three half-pastille doses of x rays at intervals of ten days. The action of x rays in pruritus is not easy to explain, but I have seen cases cured, at least for a time, by this means, which had resisted all other treatment.

The pruritus which is brought on by baths can be diminished by regulating the temperature of the bath, and by avoiding the use of any but superfatted soaps, employing even these but sparingly. The patient must not stay in the bath for more than a few minutes, and the bathroom must be warmed to a temperature of 70° F., so that the change of temperature on leaving the bath shall not be too great. After drying, a very weak carbolic ointment should be rubbed lightly into any itching skin areas, and a dusting powder of vasenol applied freely. In these cases the skin is as a rule rather dry and harsh, and the use of greasy applications is to be recommended in preference to lotions. In very susceptible patients, the addition to the bath of half a pound of starch stirred into a paste with cold water will often diminish or prevent any pruritic after-effects. Attention must be paid to the underwear; silk or linen garments should be worn next the skin, and woollen undergarments strictly forbidden. Internal treatment does not appear to have much effect in these cases.

In *pruritus hiemalis*, or winter itch, the best results can be obtained by wintering in a warm climate, such as Egypt or Algiers. Failing this, the rooms and corridors should be heated by radiators, and all sudden changes of temperature avoided. A simple cream of zinc oxide, lime water, and olive oil, containing 1 per cent of menthol or $\frac{1}{2}$ per cent of cocaine, should be rubbed

in night and morning. Alcohol in all forms, and also strong coffee, must be forbidden.

The treatment of the itching which is a common symptom of many skin affections is primarily and essentially that of the accompanying skin disease.

J. L. Bunch.

PRURITUS ANI.—The treatment of pruritus ani is both difficult and tedious, and the results are unfortunately often far from satisfactory. One of the most important factors is to make a very careful examination of the anus and rectum. If there is a local cause for the itching—and there usually is—and it is not discovered, the treatment is more than likely to completely fail.

If a fissure, polypi, or piles exist, they must be treated by operation. External skin tags—often called external piles—may cause itching, owing to dirt and secretion being retained in the folds between them; little sores are thus formed which keep up the irritation. These skin tags should be cut off.

When the pruritus is due to proctitis, this must be first treated by daily irrigations, etc. (see PROCTITIS). If the external skin is red and eczematous, applications should be applied to restore its normal condition. For this purpose lead lotion, liq. carbonis detergens, or resorcin ointment 10 gr. to the ounce, is useful. Patients suffering from pruritus should keep the anal region scrupulously clean. The parts should be washed twice a day, and after an action of the bowels, with Castile soap and warm water applied with a soft sponge. The parts should then be dabbed dry and powdered with boracic powder. A little orthoform powder blown on to the parts with an insufflator is effectual in some cases.

When there is much thickening of the skin round the anus, fomentations of carbolic lotion 1-60, applied every night for a week, will often rapidly bring the skin back to its normal condition; or the skin can be painted over with pure carbolic acid.

The following ointments will be found to give relief in many cases:—

R Hydrargyri Subchloridi	℥ij	Glycerini	℥ij
Bismuthi Subnitratiss	℥iss	Unguenti Sambuci	
Tincturæ Aconiti	℥iv	(Ph.D. 1826) q.s. ad	℥j
R Balsami Peruviani		Vaselini	q.s. ad
Acidi Borici	aa ℥j		℥j

In some patients lotions are more effectual:—

R Liquoris Plumbi Subacetatis	℥j	Lactis (nov.)	q.s. ad
R Campho-phenique	℥j	Aquæ Destillatæ	q.s. ad

This should be applied after washing the parts with hot water.

In bad cases of pruritus an anæsthetic should be given and the sphincter stretched. The anal canal and rectum should then be thoroughly explored, and any local condition, such as an ulcer or submucous fistula, be treated. It cannot be too strongly insisted upon that there is almost always a local cause for the itching: in some persons, however, diet has much to do with it, and in such cases must be regulated, alcohol, tea, coffee, and tobacco being interdicted. Very good results have recently been obtained by the author with iodine applications (2 per cent), this drug being driven into the skin by cataphoresis. Mr. Dwight Murray, of the United States, has recently published several papers to show that pruritus ani is in many cases due to infection of the anal skin with the *Streptococcus fecalis*; and he publishes reports to prove that good results can in these cases be obtained by micro-organisms (*Proc. Amer. Proct. Soc.*, 1912).

Lastly, in those cases of old intractable pruritus where all forms of treatment have failed and the patient's life is rendered miserable by the constant irritation, Ball's operation is the best treatment. This is similar in principle to the operations for "tic douloureux," and consists in dissecting up flaps on each side

of the anus, and dividing all the cutaneous nerves to the affected area. This operation stops the itching at once, and the results appear to be permanent in most cases. The author has had excellent results in bad cases from this operation, and believes it to be indicated in such cases when other measures have failed to give relief. Exposing the parts to the action of radium or the x rays has been advocated in these cases, and good results have occurred. Great care, however, must be exercised to avoid burning the patient; a pastille dose of the x rays is the correct dosage—repeated in fourteen days.

J. P. Lockhart Mummery.

PRURITUS VULVÆ.—The first thing to do is to search for and, if possible, remove the cause of the pruritus. The urine should be tested, and if it is found to contain sugar, antidiabetic treatment should be given. Any vaginal discharge should be treated. Imperfect local cleanliness may be the cause, sebaceous matter being retained in the folds of the vulva. Threadworms coming out from the anus are occasionally the cause of intolerable itching. *Pediculi pubis* may be the cause of pruritus, but probably only when their presence is accidental rather than habitual. External piles and constipation must be treated. Pruritus vulvæ may occur during pregnancy (see **PREGNANCY, DISORDERS OF**).

It must be remembered that pruritus is often the only symptom complained of by a patient who is suffering from carcinoma of the vulva.

If no cause can be found, the treatment consists in cleanliness, bathing with *lotio plumbi* (liq. plumbi subacetatis 1 dr. to the pint), liq. carbonis detergens (2 dr. to the pint), a lotion of carbolic acid (1-60 or 1-80), or lotion of calamine, and powdering with dermatol. Menthol used locally is sometimes effective. Cocaine is unsatisfactory as a rule. If these measures fail, cauterization or even excision of the itching skin and mucous membrane may have to be considered.

The thickening of the skin and mucous membrane often found in long-standing cases of pruritus vulvæ may be looked on as a precancerous stage.

In cases where the scratching has caused a raw eczematous surface, an ointment of zinc oxide or subacetate of lead should be used. (See also **DIABETES** and **PRURITUS**.)

PSILOSIS.—(See **SPRUE**.)

PSOAS ABSCESS.—(See **SPINE, CARIES OF**.)

PSORIASIS.

Internal Treatment.—Of the many internal remedies which have been at one time or another recommended, only a few have stood the test of time. Of these the most popular is arsenic, which in suitable cases is of undoubted value. If the disease is recent, and if the spots are increasing in number, and are deep red in colour, it should not be given, as it will almost inevitably aggravate the disease; if, on the other hand, the disease has begun to retrograde, if the spots are pale pink in colour, and, most important, if the patient's digestive functions are in good order, small doses of arsenic will hasten its disappearance. The disadvantages attendant on its use must not be forgotten; the least of these is the deep pigmentation of each spot; more serious is the development of peripheral neuritis; and most serious of all is the occasional development of malignant growths. The cacodylates and other organic preparations have been recommended in its place, but experience seems to show that their action is essentially that of arsenic, and that they are no more efficient (see under **PEMPHIGUS**). Various salicyl compounds may be administered. In some cases, particularly the inflamed ones, the effects are often favourable. The dose must be a generous one, and usually several days elapse before any benefit is shown. Thyroid is, or

rather was, a very favourite remedy, and it undoubtedly causes the disappearance of the eruption in many cases ; but the dose required is often a dangerous one, and it should be used only in such cases as respond to moderate amounts. It is perhaps best prescribed combined with a small dose of arsenic, as recommended by Ewald. Large doses (1 dr. t.i.d.) of iodide of potassium may sometimes be administered with benefit, but there are many disadvantages, including the expense of the drug, attending this treatment, and it is not often resorted to. Every now and again one meets with a case which improves markedly under doses of a quarter of a grain of the green iodide of mercury given thrice daily. Unfortunately, though many dermatologists are familiar with the good results occasionally produced by this remedy, no one is able to indicate the sort of case in which these may be expected. But no harm results from an experimental trial in obstinate cases.

External Treatment.—Perhaps the most important points to realize in connection with external treatment of psoriasis are the almost invariable presence of the disease in the scalp, and the importance of treating it in this situation. If the body surface alone be dealt with, no matter how successfully, the eruption will inevitably extend from the untreated scalp. Systematic washing of the scalp with soap spirit, and the application of some suitable drug, are essential to success. The most commonly prescribed drug is salicylic acid ; but sulphur, pyrogallol, resorcin, white precipitate, and tar are all valuable. For the eruption on the body and limbs one has a rich choice, which must be determined in each individual case by the form and extent of the disease, and by the circumstances of the patient.

Chrysarobin, which is certainly the most efficient application, has so many disadvantages that, unless full advantage be taken of its virtues, the disadvantages outweigh these. The ordinary plan of rubbing the ointment in twice a day, and allowing the patient to go about, involves a treatment extending over weeks, and is generally unsatisfactory even then. The writer never uses chrysarobin except as follows, and then only after explaining to the patient the object of the treatment :—

An ointment of 5 per cent chrysarobin is applied to the skin after a bath. This is well rubbed in, and pieces of lint freely spread with the ointment are applied to the affected surfaces, and bandaged on. This application is renewed twice daily. In five or six days there is marked improvement, and in eight or ten the discomfort is considerable, the healthy skin being violently reddened, and the diseased spots standing out white against it. If possible, the treatment should be continued until the redness is universal. Some soothing application, such as zinc paste, is then made, and in a few days desquamation takes place.

It is important to keep a strict look-out for any patches which are lagging behind, for the treatment is so disagreeable that it is not easy to keep it up on isolated patches after the greater part of the eruption is gone. These may be dressed, in addition to their share in the general treatment, with a strong compound chrysarobin ointment, made as follows : chrysarobin, 10 parts ; acid. salicyl., oleum rosei, of each 20 parts ; vaseline 50 parts. This almost dissolves the spots away, and must be used with caution. If the patient be unable to submit to this treatment, which involves confinement to the house, the use of chrysarobin should be eschewed ; and of the various other remedies, the most generally useful is tar, which may be used in the form of ointment, or as a varnish, such as : picis carbonis, 1 dr. ; benzol, 2 dr. ; acetone, 1 oz. This has the great advantage over ointments that it dries almost immediately, and, though not quite so efficient, is in the majority of cases more likely to be persevered with than the more unpleasant ointment. Common crude gas-works tar is often very useful, and usually very cheap. It should be applied with a

stiff brush in as thin a layer as possible. Another application commonly made is salicylic acid, regarding which it is necessary only to say that, though perhaps the most cleanly of all preparations, its effects must be watched, for the drug is readily absorbed when applied over a large area. With some hesitation, for his experience with it is quite recent, the writer records some excellent results from the local application of olive oil, either alone or along with a small amount of salicylic acid or one of the tar oils (ol. cadini, ol. rusei, etc.). The comparative cleanliness of this method makes it popular with patients.

To the chronic sufferer from this disease one or other of the many spas should be suggested. There is no doubt, though the effects of these are not all that is claimed for them by the physicians practising among them, that baths, particularly sulphur baths, have a distinctly beneficial influence, and intelligent patients are often convinced that they suffer less during the year following a course of these than in other years.

Recently, electricity has been used in this as in so many other diseases, and it has been demonstrated beyond doubt that under high-frequency currents and x rays psoriasis does sometimes disappear. To the former probably no objection can be urged; but it seems doubtful how far, at least systematically, one should use, in the treatment of a benign disease, a remedy so potent for evil as the x rays.

After the psoriasis has been temporarily got rid of by any method, the patient should have impressed upon him the necessity of keeping the scalp free from dandruff, and should be urged, even if no sign of the disease appear, to keep up the systematic washing of the scalp, and the application of salicylic acid—the least unpleasant of the applications mentioned—for at least several months, and the longer the better.

Norman Walker.

PSYCHOANALYSIS.—(See PSYCHONEUROSES.)

PSYCHONEUROSES.—The morbid conditions denoted by the term psychoneurosis have varied according to the ideas of the different writers who have used the word. Thus, as employed by Morton Prince, it means a synthesis of functions into a complex which does not serve a useful purpose but rather is harmful to the individual. Krafft-Ebing uses the term as covering all diseased states of the normal brain other than those associated with an anatomical lesion, thus including melancholia, mania, and delirium, and excluding neurasthenia, hysteria, hypochondria, etc. Dubois, on the other hand, makes the word include "neurasthenia, hysteria, hysterical neurasthenia, and the lighter forms of melancholia and hypochondria." Freud classifies neurasthenia and anxiety-neurosis as actual neuroses (presumably somatic in origin), while he uses the term psychoneurosis for hysteria (both of the "conversion" and anxiety types), together with phobias and obsessional states. Bernheim specifically excludes neurasthenia from the psychoneuroses.

Considering then this latitude of denotation, we may be allowed to make use of the word in a vague but not unserviceable way, to include the conditions frequently referred to as "functional nervous diseases," without pledging ourselves to any strict classification, whether on an etiological or symptomatic basis. At the present stage of psychopathology, every man's idea on this subject is different from his fellow's. Some can only think of states like obsession in terms of organic processes; for others none but a psychological conception has any significance. One investigator thinks of the mental unrest of exophthalmic goitre as caused by hyperthyroidism; another regards the disease as one the onset of which is generally determined by emotional shock. One man, in treating a case of so-called neurasthenia, restricts himself to a persevering, and

often futile, search for some source of auto-intoxication ; another sets himself to discover a repressed psychosexual trend : and so on. In short, our conception of disease from the psychic standpoint is so undeveloped, that the first difficulty of the writer on this subject is to attain intelligibility and ensure comprehension. To describe the methods and technique of any department of therapeutics can only be profitable when the pathology and symptomatology are already understood. This cannot be said of the psychoneuroses ; and therefore it appears desirable to devote some space to the etiology of these conditions, as being the surest way to make clear the true nature of the therapeutic indications.

Let us then begin with two exceedingly simple postulates, which cannot be considered contentious. The first is merely this : *What mind can cause, mind can cure.* In other words, in so far as a morbid condition is psychogenetic, it is capable of cure by psychotherapeutic methods. We are accustomed to accept a purely psychic explanation of a few diseased conditions—probably far fewer than will be the case fifty years hence—but we are still very slow to adopt purely psychic methods in dealing with these same cases.

The second postulate is this : *If we accept purely subjective evidence of the existence of a symptom, we must be prepared to accept purely subjective evidence of its cure.* Many physicians adopt the manner of its cure as a test of the genuineness of a complaint. A backache that did not yield to salicylates and massage, but was cured by an unqualified mental healer, need not be classed as “imaginary”—if, that is to say, we imply by that term that it was not genuine. On the other hand, it may very properly be called imaginary if we use the word in the sense of psychogenetic.

This point brings us to the very important consideration of pain as produced by mental causes. Hitherto it has been usual to conceive of functional pain as a fictitious by-product of a disordered psychic life. Of later years, thanks mainly to the work of Freud, a new and truer view has been taken by some physicians. It depends on the fact that, in general, a human being prefers physical to mental pain, and that, in consequence, relief from mental pain is experienced on the incidence of physical pain. By this process of transference the patient seeks—unconsciously, of course—to attain peace of mind through a substituted bodily suffering. That this frequently takes place can be proved by any experienced psychotherapist beyond all cavil, yet it is probable that the medical profession in general has only an inkling of the number of obstinate “functional pains” which are purely psychogenetic. The commonest forms of these appear as headache, lumbago, sciatica, gastralgia, appendicular colic, and neuralgia (generally referred to as “neuritis”), the latter especially in the shoulders and eyes.

The particular factors which determine the form and location of the painful condition in each case are too complicated and technical to be entered into here, but the following examples may be referred to. A girl deeply in love has a misunderstanding with her fiancé ; she keeps the whole affair to herself, and suffers intense mental pain ; she is in great perplexity as to whether she should write and offer an explanation ; she develops “rheumatic neuritis” in her right shoulder and arm ; the doctor orders the limb to be put at rest, and forbids writing. Hence the general conflict between aspiration and actuality is relieved by the bodily pain, while the particular conflict between writing and keeping silence is relieved by the nature of the pain (defence symptom), which determines the alternative to be chosen.

A nurse suffers from great pain in the right elbow and forearm : all ordinary treatments are unsuccessful : after an attempted suicide, analysis reveals the fact that she is a confirmed masturbator, and that the pain is located in the arm used, and depends in intensity on the frequency of self-indulgence.

A woman of thirty, happily married for eight years, and the mother of two children, has had abdominal crises (pain, spasm, vomiting, diarrhoea) at intervals of one to six weeks for twelve years. Treatment has been continuous and varied—massage, baths, drugs, diet, appendicectomy, etc., etc. By dream-analysis the entire condition was traced back to an attack of colic after a severe illness, during which an intense emotional conflict had been set up over a very passionate *affaire du cœur*. The emotional state had been “fixed,” and the nature of the physical pain was determined by synchronism.

Apart from this conception of pain as being of psychic origin, there are of course many other forms of psychoneurosis, the nature of these being vascular, secretory, or co-ordinative, and, less frequently, purely motor or sensory. In the first group we have morbid blushing, asthma (in many instances), and stammering, all of which are common conditions that are relatively little studied by clinicians; whereas the much rarer functional hemiplegiæ and anæsthesiæ of the second group are constantly being lectured about and reported. As a matter of fact, the importance of the psychoneurosis is but a poor indication of the extent of the psychic disturbance. Many physicians seem incapable of realizing the extent to which, in abnormal individuals or in abnormal psychic states, the vasomotor system responds to emotional changes. It is usual to think of ordinary blushing as the limit of psychovascular control, and to reject as scientifically impossible such a legend as that of the stigmata of St. Francis. As a matter of fact this particular phenomenon has been produced by two French observers, working under strictly scientific control, on a subject in deep hypnosis.

Freud's Methods—Psychoanalysis.—The mechanism whereby ideas become fixed, and phobiæ and obsessions arise, has been studied very fully by the Freudian school; and though some of their tenets are extreme, and the entire system of their psychology tends to be narrow, it must be admitted that, in the main, Freud's discoveries are epoch-making, and that his methods are of immense value in certain conditions. Like many other pioneers, the Freudians have shown their inability to conserve what is good in the old while displacing what is bad in it by the new and better.

As has already been pointed out, Freud divides the psychoneuroses into hysteria, phobiæ, and obsessional states. On the data which he has derived from psychoanalysis he has based a system of conceptual psychology which departs in many respects from the accepted psychology of the day. He begins by drawing a distinction between the conscious and the unconscious which is somewhat at variance with the usual definitions of these terms. He also postulates a “Fore-conscious,” which corresponds to some extent to the “subconscious” of many other systems of psychology, and which is equivalent to the mental background of the conscious life. The unconscious is, of course, the storehouse of memory, in which every experience is stored up with the normally attached “affect”: that is to say, the feeling tone which has been associated with any given experience remains attached to it, so that when the experience is recalled into consciousness a similar feeling tone accompanies it. Furthermore, every new experience tends to have a feeling tone similar to that which was associated with like experiences in the past. Hence the mind approaches almost all new experiences in life with a bias towards the feeling tone which has previously been experienced in the same connection.

Freud postulates a censor, which must keep guard, as it were, at the gate of consciousness, to exclude from it memories from the unconscious which might be painful or undesirable, thus representing the tendency of every individual to maintain mental peace by eliminating from his conscious life distressing memories of every kind. When an individual has had an experience of a

definitely painful nature, he invariably attempts to promote its elimination from his conscious mental life by a process of purposeful forgetting, and to this process Freud has given the name of "Repression." Now if the feeling tone or affect associated with an experience is very intense, the process of repression will need to be correspondingly conative or artificial, as opposed to the spontaneous character of obliviscence where neutral memories are concerned. But in this process of active forgetting the affect becomes separated from the "complex" (the term which is used to denote a group of ideas with an emotional value attached to them).

Let us suppose that an individual has had an experience which has stimulated a powerful desire in his mind. He may deal with that in three ways, which we may conveniently refer to as positive, negative, and neutral. In the first place, the positive treatment of the wish would be to determine to gratify it, in which case the feeling is discharged, and the affect is said to have "abreacted." In the second place, he may determine upon various grounds that the wish must not be indulged, and he accepts various conflicting considerations as more powerful than the desire, and thus allows them to overcome it. For instance, he may realize that the indulgence in the desire would conflict with his social ambition, and he may definitely accept his social aspirations as of greater value to him than this particular desire; therefore he treats it in what has been referred to as the negative way, allowing the wish to be cancelled by more powerful, but conflicting, aspirations. Finally, there is the third or neutral way of dealing with the situation, and this is the method that leads to a psychoneurosis. The individual may refuse himself the pleasure of indulging his wish, and he may at the same time refuse to put it out of his mind on grounds of expediency, etc.; but he may derive pleasure from the thought which lived in his conscious mind as a phantasy. This leads to a mental situation which gradually becomes less and less tolerable, till finally something has to be done to resolve it. The obvious solution is what has already been referred to as repression.

Now in every individual there is a certain "mental breaking point" at which he can no longer tolerate the repression of a powerful emotion. This mental breaking point is of course high in individuals who are particularly stable, and who are at the same time in good health; and low in individuals who are degenerate or particularly unstable, and especially so if they are in bad health at the time. It varies for every individual according to his state of health, mental and physical, at a given moment, and it varies also according to the individual's hereditary characteristics. The normal individual of good mental stability, with good education and wholesome habits of thought-control, has no difficulty, when he is in good health, in tolerating a fair amount of repressed emotion, and can therefore get along in a satisfactory and efficient way in his daily life without any manifestations to indicate the presence of painful submerged complexes. But on the other hand the weakling, the degenerate, the man who has never developed habits of mental control, the individual who is convalescing from an acute attack of influenza, etc., will not be slow to manifest the presence of a submerged complex—or, as is more probable, of several—indicating that his powers of resistance have been lowered by some cause, either psychic or somatic. In this event, a process will take place which is referred to as the detachment of the affect: that is to say, while the buried complex remains buried, and beneath the level of consciousness in so far as the actual incidence or experience is concerned, the affect or emotion normally belonging to it will make its appearance by some devious channel, physical or psychical. When the affect is transferred to the body, hysteria is developed; when the affect reappears as an uncontrollable fear, we call it a phobia; when it makes its way into consciousness as an insistent and meaningless emphasizing

of some trivial or neutral idea, we call it an obsession. The manner in which relief is obtained by this discharge of the detached affect through a morbid channel has already been explained above.

With regard to the nature of the psychic experiences which ultimately lead to psychoneuroses, it should be noted that Freud, in his original investigation, laid great stress upon the "psychic trauma," a painful psychic experience exactly analogous to the "fixed emotional state" of Déjérine. Later, however, Freud discarded the psychic trauma theories, and has tended recently to refer all these conditions ultimately to infantile psychosexual impressions. It is not within the scope of this article to deal with so abstruse a point as this, but it may be pointed out that there is a very large amount of evidence from many different quarters to show that certain morbid conditions which unquestionably deserve to be classified as psychoneuroses have been cured permanently and successfully without carrying back an analysis to infantile experiences.

We now pass to the *methods of treatment* employed by Freud and his school. These all constitute different forms of psychoanalysis, and each has its usefulness.

1. *Hypnotic Analysis*.—This method has been discarded by Freud, who used it in his earlier investigations. It resembles very much the treatment largely used and advocated by Boris Sidis, and known as "hypnoidal analysis." It consists in throwing the individual into a state of modified consciousness in which, the control of the discriminating and rational function being withdrawn, it is easier to trace associations which have been buried in the subconscious, and so to reveal the actual complex responsible for the morbid state.

2. *Dream Analysis*.—The analysis of the patient's dreams forms a source of ever-increasing importance in obtaining the material for a successful investigation of a psychoneurosis. Freud's work upon this subject is unequalled for extent and originality; and it is doubtless becoming every year easier for the average medical man to attain a superficial knowledge of dream interpretation which will allow him in many of his cases, with comparatively little trouble, to form an opinion as to the individual's mental life which otherwise would have necessitated much more laborious investigation. According to Freud's psychology, every dream is divided into two parts, the manifest content and the latent content, and it is only from the latent content that the associations of real importance can be reached. A dream is, in general, a compromise whereby the conflict between aspiration and actuality is resolved by this form of phantasy. In order that the true nature of the dream may be disguised from the ego, and thus interfere as little as possible with the mental peace which is desirable for sleep, the whole train of thought is subjected to various processes of disguise known as condensation, dramatization, and inversion. The actual technique of dream interpretation is, of course, very elaborate; but at the same time it is possible for every physician to take a practical interest in it, although he should be chary about basing definite conclusions on a superficial dream analysis.

The following instance is useful, in the first place because the patient was a doctor, and in the second place because it is a very typical instance of the childish kind of punning which is so common in dream consciousness, and which is responsible for many of the associations, symbolisms, etc., for which the Freudian school has incurred criticism.

The patient had just undertaken some professional work for a colleague, and promised to attend five of his patients; one of these cases, that of a priest, was very complicated; the rest of them were relatively simple. He dreamed that he was sitting at a desk, holding a prescription in his hand; the doctor who was going on holiday was looking over his shoulder; the patient saw that one of

the items in the prescription was Tr. Benzoini Co.; he could not remember the others. He said to his colleague, "That is the only item that matters in that prescription." On associating over "Tr. Benzoini Co.", the meaning was revealed: Friars' Balsam—Friar—Priest. The five items in the prescription were, therefore, the five patients.

It is often said that Freudian interpretations of dreams are arbitrary; but those who have no experience must accept, on the authority of those who are experienced, the two following points:—

a. Before asking a patient whether he has any recurrent type of dream, it is very often possible for the observer to speculate with amazing precision on the answer. For instance, the types of patients that dream of train-catching, or walking on edges of precipices, or snakes, become familiar to the psychotherapist who gives any sort of observation to the matter.

b. When the interpretation of an image is reached by free association, the patient is aware of its correctness, and very frequently manifests considerable surprise, horror, or amusement. Usually the analyst has no scope for being arbitrary in the way that is usually attributed to him, because an artificial interpretation evokes no confirmatory response from the patient.

3. *Time Association*.—This is an interesting method which has of late fallen into disfavour amongst many psychoanalysts, but it is none the less of considerable value, especially to the beginner. A series of a hundred words is taken, and as each word is called out by the observer the patient utters the first associated word that comes into his mind. This is noted, together with the exact time. The average reaction time for normal adults is found to be 2.4 seconds. Each reaction provides information, both in the character of the reaction word and in the length of the reaction time. When the whole series has been gone through in this way, it is repeated, with a view to obtaining a reproduction of the same reaction word for each stimulus word. When the test has been completed, information can be derived from the average reaction times, the maximum reaction times, and the nature of both reaction and reproduction. It is possible to hit upon clues of a most striking character at times, the words in question being called "complex indicators." For instance, a married woman, who had suffered from neurasthenic symptoms for all the fifteen years of her married life, gave good average reaction times and very commonplace reaction words all through. There were two exceptions, one of which was the following: Baker—Butler—16.2 seconds. The association referred, of course, to Joseph's dream, and in itself was not specially indicative; the very prolonged reaction time was obviously important; and on further investigation it was found that she had been seduced by a man of the name of Butler before her marriage. This was the repression that had affected her psychic life all these years; and the ease with which it was discovered was chiefly due to the method employed.

4. *Free Association*.—This is the method of psychoanalysis most largely used at present. The patient is put into a state of somewhat modified consciousness. Even though no special methods or instructions are resorted to for this purpose, the fundamental aim of the observer is to produce a state of consciousness in which the attentive field is so diffuse that association takes place more spontaneously than in any normal waking state. The physician uses words, episodes or characters from the patient's previously supplied account of his case, or from his dreams that have already been noted down, and from these he strives to get associated ideas that will reveal the true value and significance of the various concepts and complexes in the narrative.

Having now reviewed—very imperfectly, but as concisely as possible—the Freudian views and treatment of the psychoneuroses, we may be allowed to

refer to other methods employed by different schools of psychotherapy for their treatment.

Hypnotism and Suggestion.—These are used very largely, and to an increasing extent in recent years. For full information on this subject, see **HYPNOTISM**.

Persuasion.—This is the term used technically to cover such psychotherapeutic methods as are carried out in a state of normal consciousness. This is, obviously, an essential factor in all medical practice, although the physician who cultivates it is apt to refer to it (with modest pride) as suggestion. Persuasion consists in a variety of expedients whereby we strive to alter the patient's mental attitude. Psychologically, persuasion differs from suggestion in that, whereas with suggestion the mental change is on an inadequate rational basis, with persuasion it is, or should be, on an adequate one. The ability of the physician to carry out psychic treatment of this kind will, of course, depend entirely on his own outlook on the case. If he believes or suspects that the symptoms are entirely accounted for by a morbid physical process, he can only attack the case from the physical point of view; but if he has a clear conception of a psychic etiology, either partial or complete, he will be able with a little resource and commonsense to alter to some extent, if not entirely, the patient's mental attitude towards his suffering. Though the technique of the method of persuasion is unimportant when the physician has a true comprehension of the case, it may be helpful to enumerate a few of the doctrines which have to be most frequently instilled into the patient's mind.

1. Every abnormality of peripheral stimulation, from a mosquito-bite to angina, has a psychic factor in apperception. That psychic factor may be great or small, depending as it does on the level of the threshold of consciousness at the time being, but it must be recognized. The threshold is never at a constant level, even normally. Hence the perception of pain involves a factor which can be controlled by the individual.

2. The passive attitude towards physical pain logically implies a lowering of the threshold, and is the negation of the active attitude, which—with comprehension—involves a raising of the threshold.

3. To indicate that a symptom has a partial or complete psychic origin does not imply in any way that the patient is malingering or is (in the popular sense of the term) hysterical; therefore inability to control a symptom before explanation and education does not imply a similar disability afterwards.

4. An objective symptom, particularly if the mechanism is vascular, may well have a purely subjective origin.

5. It is a universal tendency of human beings to evade the responsibility for disease by transferring its presumed origin from the mental to the bodily sphere.

6. It is only a partial cure which depends on the modification of the environment to suit the patient's power of resistance. The man who is content to expect a limited cure will never be surprised by a complete one.

7. If improvement or cure depends on a belief in physician or method, it is only a partial cure. The patient is only cured when he really believes in himself and his own power of controlling his condition.

8. All effort that is expended in controlling symptoms is worse than wasted if apprehension dominates the mental field. Every effort that is put forth to ensure self-confidence is more than repaid.

9. Sufferers from the psychoneuroses are rarely capable of resting (in the ordinary sense of the word) without detriment; and yet the cardinal doctrine of their belief is that rest is essential to them, and exertion intrinsically injurious.

10. It is imperative for mental peace that every painful complex be, as far as possible, stripped of its emotional significance, and that the patient be taught to handle it fearlessly.

11. In every case of *aboulia* (weakened will-power) it is of paramount importance to train the patient to make his determinations beforehand—preferably the day before—when the feeling tone of the moment cannot interfere with his efforts.

12. Anxiety and defence symptoms logically demand opposite lines of treatment. It is better not to treat them at all than to confuse them.

13. All occupations which are intended to divert the patient's attention from introspection should be selected on the ground of being the most suited to satisfy suppressed tendencies—e.g., the married woman whose maternal aspirations are unfulfilled will do better breeding chickens than playing golf, because in the former occupation there is free scope for the sublimation of certain factors in the thwarted parental instinct.

It will thus be seen that the physician in practising methods of persuasion is endeavouring to bring the psychoneurotic to deal with his affective life in a wholesome way—i.e., in either of the ways that have previously been referred to as positive or negative—and to instil into him the danger of playing with his phantasy in the neutral way already described.

Provided the physician fully realizes the different spheres in which these various methods may be employed, there is no reason why he should not employ them all; nor is there any reason why the different schools advocating these various methods should exhibit such antagonism as is the case. The future of psychotherapy will unquestionably depend upon a blending of the various methods at present used, as well as on a considerable abbreviation of the methods at present employed for analysis; and associated with this will probably come a much broader outlook with regard to the applicability of different methods of psychotherapy to different cases and individuals.

Re-education.—In conclusion, reference must be made to the methods which are technically grouped under this heading; of these, the most important are the ones which refer to *attentive control*. Will-power is essentially the power of determining the area and focus of attention, in that all cognition is determined by the perceptions and appetitions within the field of awareness. For this form of re-education many of the ordinary methods of education are valuable, and many other expedients can be easily devised. All breathing-exercises are intrinsically methods of developing attentive control, and have been known and practised by oriental mystics for thousands of years. The rationale of these exercises depends on the very simple fact that as soon as the volitional control of the respiration flags—in other words, as soon as the mind wanders—the breathing reverts to the normal automatic rhythm, thus providing an unfailing objective indication of the subjective change. All exercises such as adding up columns of figures, proof-correcting, striking out a given letter in a column of print, balancing, etc., can be utilized. Vittoz, of Lausanne, has elaborated a very full system of simple exercises which are of great help to many patients of the diffuse and absent-minded types, in spite of the fact that his presentation of them is painfully empirical.

Finally, the practitioner whose idea of the value of psychotherapy depends on a printed list of diseases, will necessarily make mistakes, both of omission and commission; whereas he who has firmly grasped the fundamental principles which this article is intended to set forth, will realize that the field of psychotherapy is not only a very wide, but an elusive one, with ill-defined boundaries and shifting frontiers; that in many diseases symptoms are partly somatic and partly psychic in origin; and that only careful study of each case, without bias or prejudice, can determine the true place of psychic, as opposed to physical, methods of treatment. (See also HYPNOTISM, HYSTERIA, NEURASTHENIA, INSOMNIA, DRUG HABITS, DIPSO MANIA.)

H. Crichton Miller.

PTERYGIUM is the triangular portion of conjunctiva which invades the cornea, always in the line of the palpebral aperture, usually from the inner side, only very rarely from the outer. It occurs especially in eyes which have been exposed to weather or dust. Treatment is called for only under two conditions: (1) When the pterygium is advancing, in which case the apex is red, succulent, and fleshy; (2) When, though stationary, in which case the apex is flat and membranous, its appearance is unsightly.

Its removal is a simple matter. We only have to bear in mind that the head is firmly adherent to the cornea, and must be got away completely. After instilling a few drops of cocaine, the head is picked up with a pair of forceps, and is pared off with a very sharp knife right down to the corneal tissue. This being done, two converging incisions are made in the conjunctiva from the upper and lower margins of the head, meeting about a quarter of an inch from the limbus, and the included portion of conjunctiva, together with the excised head, is removed.

Some prefer to remove first a triangular portion of conjunctiva up to the head of the pterygium, and then to tear off the head from the surface of the conjunctiva. In either case the main point to keep in mind is the complete removal of the head itself. To allow of the cut edges of the conjunctiva coming together nicely, a small vertical incision is made in the conjunctiva at the limbus, both above and below, and the edges having been freed by undercutting, they are brought together with two or three sutures placed very close (about 1 mm.) to the cut margin. The eye is bathed daily with boric lotion and kept bandaged for three or four days. If the stitches have not cut out by the fourth day, they can be removed.

W. Tindall Lister.

PTOSIS.—(See EYELIDS, DISEASES OF.)

PTYALISM.—(See SALIVARY GLANDS, AFFECTIONS OF.)

PUERPERAL SEPSIS.—The treatment of puerperal sepsis is so entirely based on pathology and bacteriology that it is impossible to discuss it adequately without first taking a brief survey of the factors concerned in the causation and morbid anatomy of the disease.

The condition called in the past "puerperal fever" is now known to comprise many different lesions of the genital tract, with only this in common, that they are all due to infection by micro-organisms. The infecting organism differs in different cases. The following results of an investigation into the bacteriology of puerperal infections, carried out some years ago by the writer and A. G. Foulerton, may be briefly given.

The normal puerperal uterus is probably nearly always sterile, but the vagina usually contains organisms, rarely however of much pathological virulence. In puerperal pyrexia organisms are found in the cavity of the uterus in the large majority of the more severe cases (those with a temperature over 100° F.). The organism most commonly present is the streptococcus. In a smaller number of cases pneumococcus or staphylococcus can be isolated. *B. coli communis* is very generally met with, but probably in most instances represents a secondary infection. In severe or actually fatal cases it is very frequently conjoined with the more virulent organisms named.

In the slighter degrees of puerperal pyrexia, the uterine cavity is either sterile or contains staphylococci and other organisms of less virulence. In those cases where the uterus is sterile, the fever is due to infection of vaginal or cervical lacerations, usually by staphylococci or colon bacilli; but other organisms, including streptococci, occur occasionally. The anaerobic bacteria which were stated by some German authorities to play a considerable part in puerperal sepsis, were rarely found by us, and never in circumstances suggesting that they materially affected the process. The gonococcus, while occasionally the cause of puerperal pyrexia, is relatively uncommon.

Our findings, therefore, indicated that the processes concerned in puerperal pyrexia are identical with those of wound sepsis occurring in other parts of the body, and that the conception of a "sapræmia" as distinct from wound infection has no foundation in fact.

The lesions of puerperal fever are divisible into three groups: (1) The primary lesion, i.e., the point where the organism first finds entrance to the tissues. This is usually situated in the natural wound of the placental site, but it may occur at a laceration of the uterine, cervical, or vaginal wall; (2) The consecutive lesions, which proceed from the primary by direct extension along lymphatics, veins, and other natural channels. To this group belong the peritonitis, cellulitis, and phlebitis, so commonly seen in puerperal sepsis; (3) The generalized lesions, due to septicæmic or toxæmic conditions of the blood, and of which septic pneumonia, ulcerative endocarditis, or acute toxic degeneration of the heart muscle or liver are good examples.

Puerperal infection is either heterogenetic, the organism being brought to the patient from without; or autogenetic, when it already pre-exists in the body.

In regard to heterogenesis, the medium of conveyance is usually the hands or instruments of the attendant. Autogenesis may occur in several ways. Thus, the uterine cavity, normally sterile, may be infected before labour; the vagina may contain actively pathogenic organisms, such as the gonococcus or even the streptococcus; while occasionally the streptococcus occurs in the vulva. In regard to the last two possibilities, infection of the placental site may occur from the organisms being carried up on the hands or the instruments of the attendant. Lastly, organisms may make their way from the bowel to the genital tract, especially under conditions of tissue damage.

Bearing in mind this slight sketch of the processes at work in puerperal sepsis, a discussion of its treatment may now be proceeded with under the heads of: (1) *Prophylactic*, and (2) *Curative treatment*.

1. Prophylactic Treatment.—The importance of cleanliness and cleanly surroundings to a lying-in woman should be sedulously impressed on the lay mind. The filthy conditions under which labour often has to be conducted amongst the lower classes are notorious. The continued occurrence of puerperal sepsis is often held up as a reproach to the medical profession; how unjustly may be seen from the fact that in lying-in hospitals where the will of the doctor is supreme, the disease in its graver form is rarely seen.

In this regard a duty lies with the public as well as with the practitioner, for it is impossible to conduct a labour single-handed in a dirty patient amongst dirty surroundings, and yet preserve surgical asepsis.

The use of sterilized rubber gloves is strongly to be insisted on. They protect the patient and the practitioner, the former from the importation of sepsis on the hands of her attendant, and the latter from infection of his hands by vaginal or vulvar organisms. All instruments and appliances must be boiled before use.

As regards the conduct of the labour, the practitioner should recollect that a well-retracted empty uterus is the least favourable to the growth of organisms; and further, that bruised devitalized tissue is a direct incentive to the occurrence of sepsis. Where intra-uterine manipulation has been necessary, this cavity, after being thoroughly emptied, should be well washed out with an antiseptic solution.

The vagina should always be douched out after labour, and I am strongly in favour of routine vaginal douching during the puerperium, as a reasonable cleanly practice strongly appealing to all women with a sense of nice feeling. The maintenance of dorsal decubitus results in the lochial discharge being pent up in the vagina, with the result that often it becomes offensive. The modern practice of encouraging patients to sit up, and even get up, on the second or third day, has everything to recommend it on the score of free drainage from the uterus and vagina.

2. Curative Treatment.—The curative treatment of puerperal sepsis may be divided into *operative* and *non-operative treatment*. Before discussing these, however, it is necessary to emphasize: (1) The necessity for early active measures if good results are to be expected; (2) The importance of getting as soon as possible a bacteriological report of the germ contents of the uterus.

1. The Necessity for Early Measures.—It cannot be too strongly emphasized that the successful treatment of puerperal sepsis chiefly depends on the earliness with which the disaster is recognized and treatment is initiated.

Every one has a natural tendency to dissent from the view that a case under his care has gone septic. Thus several days are not infrequently wasted on the assumption that the fever is due to the "milk coming in," to constipation, to influenza, or to any other straw to which the self-persuaded judgement can cling. The vast bulk of cases of pyrexia in the puerperium are due to septic infection of the genital tract. Many, by aborting, lend colour to the mistaken diagnoses cited, and bias the practitioner's judgment for future cases. All cases of pyrexia in the puerperium should be assumed to be due to sepsis until good proof is forthcoming that they are not so. Pending such proof they should be treated as septic. A temperature of over 100° F., maintained for twenty-four hours, is an indication to act; a temperature over 101° F. is an indication for immediate action. To treat as septic a case not in reality so is a far less grave error than to delay treatment until puerperal infection has so established itself that the possibility of curing it becomes a matter of grave doubt.

2. *The Importance of a Bacteriological Report.*—For this purpose a piece of wool sterilized by heating or flaming, mounted on a long forceps, may be thrust through the cervix, the latter having been exposed by a speculum. If this is not feasible, the swab should be passed into the vaginal vault, and a specimen of the lochial discharge obtained just as it leaves the uterus. Where the uterus is about to be explored under an anæsthetic, the passage of a swab into the uterus is simple. Further, the fragments of clot and detritus brought away by the finger should be preserved for examination. In either case the swab or fragments should be placed in a test-tube sterilized by boiling, and plugged with cotton-wool passed through a flame. It should then be despatched to a competent bacteriologist with a request for: (a) An immediate microscopical report; (b) A report of the result of culture; (c) The preservation of the cultures, in the event of a pathogenic organism being isolated, in case a vaccine should be required later.

If the practitioner possesses the necessary bacteriological knowledge and a $\frac{1}{2}$ oil-immersion objective, he can make an immediate smear preparation himself, staining it with methylene blue, or better, by Gram's method.

In cases where a general blood infection is feared, the blood should be examined. For this purpose a considerable quantity should be withdrawn from one of the superficial veins by means of a sterilized syringe (a serum syringe for instance, if a fine needle can be affixed to it), and immediately used to inoculate culture tubes. As the process requires a degree of special skill, it is better in most instances to get the bacteriologist to do this.

The following should be requested: (a) A report as to culture; (b) A report on the leucocyte count. The former is the more important, but the latter is sometimes of use where, a pelvic mass being felt, the question of the presence of pus has to be decided.

OPERATIVE TREATMENT.—*Uterine Exploration.* The value of uterine exploration is considerable when carried out early. It should be performed under anæsthesia, with the patient lying on a douche bath or bidet in the long axis of the bed. This is better than the lithotomy position, because more direct pressure can be brought to bear on the uterus from above. The operator, sitting or standing on the right side of the patient, first thoroughly douches the vulva and vagina with an antiseptic solution, and then introduces one and afterwards two fingers through the cervix. By making pressure with the left hand on the fundus of the uterus, every part of its cavity is rendered accessible. This is then evacuated of any retained clot or débris, and the wall, and particularly the placental site, are scraped with the gloved finger-tips until no further loose fragments are detached. The fingers being withdrawn, the uterus is washed out with two quarts of a hot antiseptic solution (biniodide of mercury 1-2000

at a temperature of 117° F. is excellent), and the external parts having been cleaned up the patient is allowed to come round from the anæsthetic. The effect of uterine exploration is usually excellent when carried out within twenty-four hours of the initial rise of temperature; it probably owes its good results to the improved drainage of the cavity and the increased tone given to the walls of the uterus. It is increasingly less successful after this period, because the organisms probably penetrate deeper into the uterine wall as time goes on—moreover there is a risk of disturbing thrombi in the vessels of the uterine wall by the manipulations necessary for exploration, and thus converting a purely local process into one of general septicæmia. Much judgement is required in deciding whether to explore the uterus or not in any given case. If it appears likely that a portion of placenta, membrane, or blood-clot is retained in the uterus, the indication is strengthened, and vice versa.

Curettage.—The practice of curettage in puerperal sepsis is lauded by some experts and condemned by others. Its object is to ablate all infected tissue from the uterus. In puerperal infection the organisms are located not only in the clot and débris inside the uterus, but also more or less deeply in its wall.

To ablate completely all the infected tissue would necessitate extensive denudation of the surface, and this attained, there is no possibility of excluding the chance of re-infection. If curettage is employed, it should be followed by the use of a strong antiseptic, such as tinct. iodi fort. (B.P.), applied on wool swabs. A large sharp curette is required, and the patient must be placed in the lithotomy position. The operation takes some little time, and is a more severe procedure than simple exploration. Personally I am not in favour of it, believing that it more often does harm than good.

General Remarks on Cæliotomy.—In bad cases of puerperal sepsis the infection is no longer limited to the uterus, but has spread to the peritoneum, and to the cellular tissue, large veins, and trunk lymphatics of the pelvis, whilst in many instances a generalized infection is present as well.

In considering the propriety of a surgical attack on the consecutive lesions of puerperal infection, the possibility of a co-existent generalized septicæmia is to be taken into account, for in its presence the likelihood of operative measures proving successful is small. On the other hand, the distinction between a generalized septicæmia and a profound toxæmia of local origin is often difficult. But the most difficult point of all is the diagnosis of these consecutive lesions, the signs of which are as a rule obscure. Thus, the only evidence of peritoneal infection as a rule is slight distention and tenderness over the lower abdomen, while extensive thrombosis of the broad ligament veins may at first produce no tangible swelling.

Therefore it happens that the idea of opening the abdominal cavity does not arise as a rule until the disease is already very far advanced.

Drainage of the Pelvic Cavity.—The pelvic cavity in bad cases of puerperal sepsis usually contains a blood-stained serum containing streptococci in large numbers. In many instances there is no peritonitis, the condition being one of infection without inflammation, a peculiarly fatal conjunction. In other examples frank peritonitis is present. Drainage of the pelvic cavity may be effected either through the vagina or through the abdomen, or by both routes simultaneously.

Vaginal drainage is easily effected by incising the posterior vaginal fornix into Douglas's pouch. The opening having been made, a tube or gauze packing must be inserted, or it will rapidly close. The method of Pryor consists in first exploring the uterus and packing it with iodoform gauze, and then opening the posterior fornix and packing Douglas's pouch with the same material.

Abdominal drainage is effected through a middle-line incision in the first instance; but if extensive peritonitis be found, other incisions should be made over the flanks and iliac region. Tubes are inserted through the openings, and the patient is propped up in bed to promote drainage. Before inserting the tubes the pelvic cavity is mopped clear of the serum it contains, and in some cases definite operations on the Fallopian tubes or uterus are also necessary.

After the employment of drainage, either by the vaginal or the abdominal route, continuous saline infusion is strongly indicated. It may be administered either subcutaneously or per rectum. The details of the methods will be referred to later on.

Salpingectomy and Oophorectomy.—The spread of puerperal sepsis from the placental site to the pelvic peritoneum may occur through the uterine wall or through the Fallopian tubes. If limited to the latter route, the removal or ligature of the tubes would be logical. Unfortunately it is rarely so limited, and in any event the peritoneal infection is already advanced before operation is undertaken. As a rule the tubes merely appear a little swollen and red, and a whitish-looking serum can be squeezed out of them. Occasionally, however, they contain definite collections of pus. In such cases they should be removed. The ovaries sometimes contain abscesses, and in this event one or both will have to be removed.

Hysterectomy.—The cure of puerperal sepsis has been sought in removal of the infected uterus. The operation has been performed sufficiently often to show conclusively that it should never be done except under one of three conditions:—(1) When the uterus is ruptured; (2) When it contains an infected myoma; and (3) When an abscess or abscesses are present in the uterine wall.

If the infection was limited to the uterus the removal of the latter would be rational, but in all cases sufficiently bad to warrant an operation of this magnitude, it has spread into the peritoneum, cellular tissue, and large veins. The patients are already very ill, and stand a severe operation badly, while the opening up of large areas of cellular tissue to infection cannot be avoided.

In the exceptional circumstances named, however, the uterus must be removed, though in the case of a large solitary abscess, drainage of the sac might be employed instead.

Ligation of the Pelvic Veins.—Ligation of the principal veins of the uterus has been strongly advocated in Germany on the analogy of ligature of the internal jugular vein for lateral sinus thrombosis. The two cases are, however, not parallel, on account of the large number of veins affected in puerperal sepsis. Moreover, there is great difficulty in diagnosing thrombosis of the pelvic veins, except in a few instances. The repeated occurrence of rigors is said to indicate it, and some authorities consider that after the fifth rigor an operation should at once be undertaken, especially if in addition a swelling can be felt in the broad ligament.

The operation may be either extraperitoneal or transperitoneal, the latter being the better in my opinion, because all the veins can be reached through one incision. In some cases it suffices to place ligatures round the ovarian veins only, but in others the internal iliac veins of both sides may also have to be dealt with. The ligature must be placed above the thrombus, but the vein need not be divided.

The operation has not been much performed in this country, and a perusal of the German literature leaves one unimpressed with its value. If employed, it should be reserved for the more prolonged type of case with repeated rigors, especially when a definite swelling due to thrombophlebitis can be felt in the broad ligament.

Drainage of the Cellular Tissue.—In some of the more prolonged cases of

puerperal sepsis an abscess forms in the broad ligament, and may attain a large size, burrowing into the thigh or buttock. Abscesses of the broad ligament must be evacuated by incision as soon as they are diagnosed. As a rule the swelling tends to mount upwards into the iliac fossa, and is best incised just above Poupart's ligament; but where it burrows downwards and presents as a hard mass in the vagina it is best opened there. Very large abscesses require incisions at several points, especially if they have extended outside the pelvis into the buttock or thigh. After incising, a large-sized drain tube must be inserted. As the discharge grows less, one of a smaller size may be substituted, which later is removed altogether.

Other Operative Measures.—The remaining surgical measures used in puerperal sepsis do not require separate mention. They consist in evacuating the pus and draining the secondary inflammatory foci which manifest themselves in some of the septicæmic (pyæmic) types of the disease. Thus an empyema may require resection of the ribs, or a hepatic abscess incision.

Non-operative Treatment.—*Douching.*—The use of an intra-uterine douche uncombined with any other form of treatment is not to be commended. It is not always easy without an anæsthetic to douche out the uterus satisfactorily; more often than not the fluid fails to be distributed all over the cavity. But perhaps the greatest reproach to the intra-uterine douche is the frequency with which its use is adopted, to the fatal postponement of more radical measures. It is very doubtful whether the proceeding as ordinarily carried out does much good, whilst in some cases it undoubtedly distresses the patient greatly. If the uterus has been thoroughly emptied by the fingers, nothing further can be expected from the douche in this respect, whilst it is impossible to believe that a weak antiseptic solution, ill applied, can affect organisms implanted in the uterine wall. Intra-uterine douching, if done at all, should be employed *after exploration under an anæsthetic*.

Vaginal douching, on the other hand, should always be employed. In the case of intra-uterine sepsis it frees the vagina of a puddle of retained bacteria-laden lochia, whilst if vaginal or cervical lacerations be present, it is directly curative. It should be carried out frequently, say every four hours, and the solution used should be weak boric acid, or much diluted lysol or cyllin. In cases where infected perineal or vulval lacerations are present, much benefit, besides comfort to the patient, is obtained by substituting warm boric acid fomentations every four hours for the usual pad or diaper. Peroxide of hydrogen (10 vols.) is a useful local application.

Intra-uterine Applications.—The application of a powerful antiseptic to the interior of the uterus has more to commend it. Its use after curettage to prevent re-infection has already been mentioned. Various substances have been used, of which strong iodine tincture (B.P.) is probably the best; but carbolic acid, iodal, formalin, and pure lysol are all serviceable.

For such applications to be done efficiently, the patient must be in the lithotomy position with the cervix pulled down and exposed. A general anæsthetic is therefore advisable. Previous to the application the interior of the uterus should be explored as already described. The application should be made by a wool swab mounted on a long forceps, and before this is inserted the cavity should be mopped dry as far as possible.

Serum Therapy.—The results of serum therapy in puerperal sepsis are unequal. In some cases very marked improvement follows the administration of an immune serum, but not in others. There is no doubt that in the worst cases the toxæmia is complex in character, on account of the several species of organisms present in the uterus. Thus in nearly all the fatal cases of the series investigated by the writer and Foulerton, *B. coli communis* was isolated from

the uterus as well as organisms of the pyogenic cocci group. The importance of immediately obtaining a bacteriological report on the organismal contents of the uterus has already been insisted on. Where this has been done, and the infecting organism distinguished, no time should be lost in administering the appropriate serum. In most cases this will be antistreptococcic serum. It should be given in large doses—20 c.c. immediately, followed by another 20 c.c. in six hours, and by 10 c.c. six hours after that. If at the end of that time no beneficial effect is noticed, it is useless to proceed further with that particular serum. The serum should in all cases be "polyvalent."

Where it is certain that the infection is streptococcal, and yet no good results follow the administration of a polyvalent antistreptococcic serum, it is well before abandoning the use of serum to try another make, in the hope that the second may contain the correct antidote for the particular variety of streptococcus present in the case.

As regards the method of administration, it is best, I think, to begin with hypodermic injection, but later to give by mouth or rectum. Repeated hypodermic injections are painful, and produce a troublesome serum rash; and further, much larger doses can be given by the mouth or rectum.

If *B. coli communis* be isolated, anticoli serum is indicated, and since this organism so commonly complicates streptococcus infection, the administration of anticoli serum with antistreptococcic serum as a routine practice would seem to be indicated.

In staphylococcic infection serum treatment is not indicated.

In those cases where the nature of the infecting organism is unknown, and pending bacteriological investigation, antistreptococcic serum should be given because of the frequency with which the streptococcus is the cause of puerperal sepsis.

On occasions, the administration of serum, while not followed by marked improvement in the symptom, appears to benefit the patient slightly, or at all events to assist in preventing the condition from becoming worse. In such circumstances its administration should be continued, for next to definite improvement, maintenance of the *status quo* in these cases of puerperal sepsis is most favourable. In other words, the longer a patient can be kept alive the better the chance of ultimate recovery.

Vaccine Therapy.—The use of vaccines in the treatment of puerperal sepsis is most indicated in the more prolonged type of case. In fulminant, acute disease but little is to be hoped from it. The cases that exhibit marked variations of temperature, indicating the absorption of successive doses of toxin from the seat of infection, are more favourable to vaccine treatment than those in which the temperature and symptoms are more continuous and constant. Those that are characterized by marked exacerbations and remissions of symptoms over a week or more are the most favourable of all.

The vaccine should be made from the organism isolated from the patient, but in the absence of this a stock laboratory culture may be employed, provided the nature of the infecting organism is known.

The use of vaccines, especially streptococcal, requires great care, for they are potent for harm if the dose and the time of injection be wrongly chosen. I have seen two cases of streptococcal infection in which comparatively mild symptoms were converted into those of the utmost severity within a few hours of an overdose of streptococcal vaccine.

In the case of infection by the streptococcus, a dose not exceeding 5 millions should be first given, and in cases of continued fever and constant symptoms a still smaller quantity should be used. Staphylococcal infection and *B. coli* infection require larger doses of vaccine. Where the fever is markedly remittent,

the injection is best made when the temperature is as near the normal as it is accustomed to go.

The effect of the vaccine on the pulse and temperature must be carefully noted, and in general it should be administered during a phase of improvement in the patient's general condition.

The estimation of the opsonic index is an additional help in determining when to inject, but I am of opinion that the general condition of the patient as clinically deduced by careful observation is at least as useful.

In all cases of puerperal infection requiring vaccine treatment, the services of a competent "opsonist" should be sought, i.e., one who combines the scientific knowledge of the laboratory with the acumen of the clinician.

Saline Infusion.—In certain cases of puerperal sepsis the use of saline infusion is beneficial. Thus, where the pelvis has been drained for peritoneal infection, continuous saline infusion, either into the cellular tissue or the rectum, assists drainage, dilutes the toxins in the blood, and promotes transudation from the vessels rather than absorption into them.

Again, where by reason of vomiting or some other cause mouth-feeding is impossible, life may be maintained for many days solely on saline solution administered by the bowel. In this case the saline solution may be administered in 6-oz. doses every four hours, like a nutrient enema, with a No. 12 catheter and a glass funnel; or the continuous method may be adopted by means of syphon action from a large container. If this plan be used, the inflow must be very slow, the syphon being adjusted till the fluid merely drops out.

Lastly, in cases where vomiting and diarrhoea preclude the introduction of anything into the gastro-intestinal tract, life may still be maintained by continuous saline infusion into the cellular tissue. The syphon apparatus mentioned above is used, but the tube terminates in a hollow needle which is thrust under the breasts or into the skin of the flanks or thighs. The inflow should not exceed half a pint an hour, and it should be stopped directly swelling appears. The proper temperature of the solution for this form of continuous infusion is 108° F. in the container.

Drugs.—There is not much scope in puerperal sepsis for drug treatment. Alcohol and strychnine are the two most often indicated. They should be given directly the patient's strength shows signs of flagging. Alcohol may be administered as brandy or champagne. Strychnine may be given either by the skin or the mouth, as much as 3 min. of the liquor (1 per cent) every four hours. Digitalis and digitalin are not of use, as neither appears to act beneficially on the heart muscle in states of acute toxæmia. Quinine is often prescribed in these cases, but it is doubtful with what propriety. It can have no action on the toxæmia, and its antipyretic properties are scarcely indicated unless the temperature is exceptionally high.

Antipyretic drugs are not indicated to reduce fever, which should be treated by tepid sponging if the temperature is persistently maintained above 103.5°. This, however, is rare, and most cases require no treatment for the pyrexia *per se*. Acetyl-salicylic acid is, however, useful to alleviate headache and pain, to quiet the patient, and to assist sleep.

Hypnotics are usually indicated sooner or later, for these patients sleep badly or not at all, the mind being extremely alert, as is common in severe sepsis due to this or any other cause.

Opiates act badly as a rule. Chloral, sulphonal, or veronal is better. Where active delirium is present paraldehyde may be tried. The preparation known as "bromidia" has acted well in my experience in all cases of sepsis, puerperal and otherwise.

It usually suffices if the bowels are opened every other day, and an enema is

the most useful way of achieving this. Sometimes at the outset a good dose of castor oil is given with advantage. In bad cases diarrhœa is common, and is of bad import. It is difficult to check. Opium is the most likely drug to succeed.

Nursing.—The nursing of a case of puerperal fever plays an important part in the treatment. The patient should be elevated in the bed to promote drainage from the uterus. The best method of retaining this position is to sew a piece of bandage to each end of a bolster, which is then placed under the thighs just below the buttocks, and fixed so by attaching the free ends of the pieces of bandage to the posts of the bed-head.

The vagina should be irrigated every four or six hours with a weak antiseptic solution such as lysol 1 dr. to 2 pints, and the vulva should be swabbed with the same every time the pad is changed. In doing these things the nurse must be careful to avoid giving pain if septic lacerations are present. Such are best treated by frequent boric acid fomentations.

The skin of the back will require careful attention, especially in those cases where diarrhœa or incontinence of urine is present.

The tongue and mouth soon become dry, and oral sepsis is very common. For this reason the mouth must be frequently cleaned with glycothymoline, listerine, or any other similar mouth-wash.

If femoral thrombophlebitis is present, the leg must be elevated on a cushion and every effort made to prevent the patient moving it. If much pain is complained of, it may be painted with glycerin and belladonna, and wrapped in cotton-wool, or it may be fomented.

In some cases there is much abdominal pain. Boric acid fomentations are then indicated every three or four hours. With peritonitis, flatulent distention may be distressing; it is best relieved by rectal "wash-outs" thus administered: Half an ounce of turpentine is stirred into a pint of soap and water. A long rubber rectal tube is then passed twelve inches into the bowel. To its outer end a glass funnel is attached, and this being elevated, from 6 to 10 oz. of the solution are allowed to run slowly into the bowel. After remaining in for a few minutes, the funnel end of the tube is depressed and the solution allowed to run out again, aspirating the flatus from the bowel as it does so. The proceeding is then repeated till the solution originally made is used up.

The nurse will have to administer enemata every other day if constipation is present and the state of the patient does not warrant a purgative. If diarrhœa sets in, great cleanliness must be observed, and the skin round the anus should be protected by vaseline.

In very bad cases retention of urine, or retention with incontinent overflow, occurs. The nurse should carefully observe the amount of urine passed and the appearance of the abdomen, in order to guard against the latter happening.

If it is necessary to catheterize the patient, the very greatest care must be taken not to introduce septic organisms into the bladder from the vaginal discharge.

In some cases with extensive perineal laceration, acute inflammation of pre-existing hæmorrhoids occurs, causing great distress to the patient. This is best treated by painting with a 10 per cent solution of cocaine and then applying boric acid fomentations.

In performing all offices which involve touching the patient's genitals or anything connected therewith, the nurse cannot be impressed too strongly with the advisability of preserving her own hands from infection. She should wear boiled rubber gloves on these occasions, if they are obtainable, and if not, should most carefully wash and sterilize her hands after each time of attending to the patient.

Diet.—Provided that it is nutritious and retained by the patient without

discomfort, as much food as possible should be given. The maintenance of the patient's strength is sometimes the only consideration of the case, for where both operative measures and specific therapy fail, the only hope is in the personal resistance of the sufferer.

The diet should be liquid, and given at short intervals. Milk, eggs, beef-tea, meat extracts, malted foods, and such like, are all useful.

Where the patient cannot be induced to take food by the mouth, rectal feeding must be adopted. In this case predigested absorbable nutriment is required. The use of rectal saline injections at regular intervals is sufficient to keep a patient alive for many days.

Attendance on other Cases.—Although conveyance of infection from one patient to another is entirely preventable by the use of rubber gloves, strict cleanliness, and sterilization of all instruments and appliances, yet the practitioner who is unfortunate enough to have a case of puerperal sepsis on his list would be well advised to temporarily desist from attending other labours. For it is to be remembered that should a second case become septic, the blame is likely to be laid on him, however unreasonably. Moreover, he himself may be unable to dismiss from his mind the possibility of his having been the agent of the disaster, and thus both his reputation and his peace of mind may suffer.

Victor Bonney.

PULMONARY ABSCESS.—This condition is unfortunately but seldom amenable to direct surgical treatment, owing to the great difficulty in satisfactorily localizing the abscess. In a few cases, however, where an abscess happens to be near the surface of the lung, and its site has been successfully determined by means of the exploring needle, the cavity may be drained through an opening made in the chest wall, by resection of portions of one or more ribs, as in the operation for empyema (q.v.).

F. J. Steward.

PULMONARY CONGESTION.—(See CONGESTION, PULMONARY.)

PULMONARY TUBERCULOSIS.—In undertaking the treatment of pulmonary tuberculosis, three considerations must especially be kept in view.

1. *The great Curability of the Disease in its Earlier Stages.* Success in treatment is proportionate to earliness of diagnosis.

2. *The Constitutional Nature of the Disorder.*

Although the disease has a local seat, the significance of the local process is small compared with that of the constitutional disturbance which is speedily superadded. In invading the lung tissue, the tubercle bacillus interferes with the function of the lungs, and may lead to a variety of local accidents of varying degrees of gravity. But of still greater importance are the constitutional effects which are traceable to the influence of the bacillus and the toxins which it elaborates.

3. *The extreme Variability of Clinical Type.*

Cases differ much in clinical features, from the very early type with a limited local lesion, and little, if any, constitutional prejudice, to the hectic type—whether with much or little local lesion—with wasted frame, intractable, swinging temperature, and hardly countable pulse. There is an infinite variety of progress, from the galloping type where death may occur in the course of a few weeks, to the sluggish fibrous type where the patient may show little change for many years. Then there are groups of cases liable to special accident, notably those with recurrent hæmoptysis.

It is clear that, in the application of the principles and rules which follow, much judgement is necessary. It is impossible to formulate a uniform line of treatment. Each case must be judged on its own merits. The determination, by physical signs or by bacteriological examination, that the lungs are affected, is only the first step to the completer diagnosis of the extent and special character of the involvement, both constitutional and local.

In most cases, it is wise to explain to the patient the nature of the disorder, and its curability when taken in hand sufficiently early and thoroughly. Thereby, from the

first the co-operation of the patient is likely to be obtained, and all occasion removed for the statement frequently enough heard in the later stages, "If only I had been told in time." Recovery, even in early conditions, depends much on the patient's intelligent appreciation of what is needed.

Manifestly, for a considerable number of patients of excellent constitution, with only slight disturbance of an apex, the rigid discipline which is necessary for those with more widespread disorder may be much relaxed. Such relaxation will be possible in proportion as the patient appreciates the significance of the hygienic principles which govern successful treatment of all cases. Thus, in the case of a schoolchild slightly affected, the chief indications for treatment may be realized sufficiently if the patient be removed from school and allowed for a year or two, perhaps, to run wild, under suitable surveillance, in some country place, education in the ordinary sense taking a back seat, or education may be maintained at an open-air school. So, in the case of young adults affected in the course of a sedentary life, it may be sufficient to explain the nature of the disorder, the principles on which a natural cure depends, and the necessity for a changed mode of life. Such patients, while requiring wise direction for varying periods, according to the principles to be discussed, may not need the strict application of every detail.

It is another matter when the disease has got a more definite hold. In this case the treatment cannot be too careful and systematic. The patient must now be freed from all cares of work, and from social and even domestic ties. He should know that it is a hand-to-hand struggle in which he is engaged, and be made to realize that the programme of treatment is one which, to be effective, may involve much time, and perhaps sacrifice.

After an effective arrest—a so-called economic cure—has been attained, the patient should be thoroughly imbued with the notion that, in order to maintain health, he must be prepared to carry out, more or less fully, for the rest of his life, the physiological principles which have ensured his recovery.

From the point of view of both pathogenesis and treatment, it is convenient to distinguish between—(1) The Soil, (2) The Seed.

1. *The Soil*.—The liability to tuberculosis is not the same in all individuals or tissues. Certain individuals and families present a proneness, or at least a diminished resistance, to invasion by the tubercle bacillus. Such a diminished resistance may either be a more or less permanent attribute of the tissues in a given individual, or may be the expression of a transient condition resulting from precedent illness or other devitalizing influence. It must be the aim of all sound treatment to place tissue resistance to tuberculous invasion on as high a level as possible. In this way we oppose the tubercle bacillus by rendering the soil as unsuitable as possible for its growth.

2. *The Seed*.—Direct attack on the tubercle bacillus within the body is less easy and effective than similar attempts on the bacillus *in vitro*. Within the body, consideration must be had, not only to the bacillus itself, but to the anatomical and physiological resultants of its life history.

The aim of rational treatment of pulmonary tuberculosis may be conveniently formulated as follows :—

- I.—To Increase the Natural Resistance of the Tissues.
- II.—To Oppose the Tubercle Bacillus more directly.
- III.—To Meet Symptoms and Complications.

I.—TO INCREASE THE NATURAL RESISTANCE OF THE TISSUES.

This is the sound order of approach, Nature cures tuberculosis daily without the help of the doctor. Pathological statistics afford abundant proof of this. More than 50 per cent of all dead bodies show definite trace of tuberculosis. Nägeli puts the percentage as high as 97. In a large proportion, the tuberculous lesion is found to be cured. Such natural cures are frequently hindered by the prescription of unphysiological methods. The physician must be content to be an auxiliary of nature. He must remove obstacles as far as possible, and aid the natural tendency towards cure by every means in his power.

All prejudicial influences in the patient's life must be removed. The unphysiological must be replaced by the physiological. There must be a simple, trustful return to nature. The methods are few, and easy of application, provided there be a proper understanding of the *motif*. If this be rightly apprehended, the essentials can be attained anywhere. They comprise :—

1. Open Air and Sunlight.—This is the foundation on which all other procedure should rest. In proportion as this is sufficient, everything else becomes easier.

The patient should be bathed in fresh air throughout the whole twenty-four hours. Apart from complications which may require special treatment, this cannot be too complete. Experience, prolonged through many years in the treatment of very many patients in all stages of the disease, thoroughly justifies the statement that the fullest exposure of tuberculous patients to such influence, by day and night, is free from risk and followed by striking benefit in almost every case.

This applies both to pyretic and apyretic cases, and none the less to patients with bronchitic and pleuritic disturbance. It is a mistake, in presence of increased pyrexia or the signs of bronchitis or pleurisy, to limit the amount of exposure to the open air. Nor must it be lessened by reason of changeable weather. It is equally safe, if perhaps less certainly serviceable and pleasant, during rain and mist. In the denser fogs it is possible to screen the patient from smuts and other aerial impurities by means of a fine veil of gauze stretched over the widely-opened windows.

Where convenient, the patient is best outside entirely, resting either on a couch or reclining chair or other seat, for varying periods according to the stage of the illness. Chilling of the extremities can readily be obviated by suitable clothing and shelter. Where there is a garden, more formal *shelters* can readily be arranged. These should be shallow from front to back, say 4 ft. 6 in. They should be shelters, *not* rooms. The roof should slope from the back forwards and upwards, *not* downwards, so as to avoid the production of a *cul de sac* in the roof, where foul air would collect. The roof, which should be provided with some means of ventilation, and the sides of the shelter, are conveniently made of glass. Many of the shelters seen in sanatoriums, and advertised commercially, are faulty in one or other of these respects. The shelters may either be fixed—when two or three may be necessary facing different directions—or they may be rotary. Simple folding screens, adjustable to any angle, may be attached to corners of buildings or elsewhere.

Open-air treatment is not to be used in summer only. It is a method for all seasons. Indeed, the writer's experience is that, even in northern climates, the treatment is, as a rule, more efficacious during the colder than during the warmer months of the year. At such times it is, of course, essential that due attention be given to the peripheral circulation. This is readily maintained by a sufficiency of woollen garments and warm wraps.

Although, for many reasons, it may be desirable to have patients indoors by night, there can be no doubt that the treatment is beneficially maintained during sleep. A large proportion of the writer's hospital patients sleep in open shelters; and this by preference. There is usually keen desire among the patients to be placed on the list of outside sleepers, no less in winter than in summer.

When, for any reason, it is necessary to keep the patient indoors, the room should be as fresh and free of furniture, carpet, and hangings as possible. The patient's bed should be close to the window, which should be made to open, and be kept open, as freely as possible. In dusty neighbourhoods—in the case of private houses—and in the presence of fog, the patient may be protected from noxious influence by the thin gauze screen already mentioned. The nonsense that used to be talked about draughts may be discounted if only the inlet of fresh air be rendered sufficient.

2. Dietary.—Loss of appetite and digestive disability are common complaints of the tuberculous patient at one or other stage. They are especially frequent in patients treated indoors on protective lines. Nothing is more remarkable

than the rapidity with which healthy appetite and natural digestion return when the patient is transferred, so to speak, from the hothouse to the garden. Often the appetite becomes voracious. There is little call for forced feeding. The patient eats of his own accord. It is sometimes helpful to serve meals in the open air. With the disappearance of digestive troubles, and the return of a normal appetite, the quantity of food may be increased. To avert a tendency to sickness, which some patients manifest to an extraordinary degree, it is well, not only to insist on prolonged rest before and after meals, but to feed the patient reclining.

The number and constitution of the meals must vary with the state of the patient. As to number, in most instances three meals of approximately equal value are sufficient and best. Thereby nutrition is ample, and the stomach is adequately rested between meals. This tends to the restoration of natural secretions, and activity of stomach and bowels.

The meals may be arranged as follows: Say breakfast at 9 a.m., luncheon 1.30 p.m., and dinner 7 p.m. In some cases it is advantageous to allow a slight snack on waking, say at 7 a.m., e.g., a little rum and milk, or a cup of tea and toast, and again, say at 4 p.m. In most cases, nothing should be allowed between meals or after dinner. The patient usually sleeps better on an empty stomach. If, for any reason, something is desirable at bedtime, or through the night, a cup of thin meat tea, or diluted hot milk, may be allowed. The treatment of digestive disabilities will be considered later on.

If the patient manages the three meals well, they may be varied to please his palate, provided they include a sufficiency of nitrogenous food, fats, and carbohydrates. Much may be achieved by skill in cooking, and daintiness in serving, the various dishes. In this way the kitchen replaces the dispensary.

The following may be taken as a suitable, comprehensive menu from which selections may be made from day to day.

Breakfast may include porridge (preferably made with half milk, and boiled for forty-five minutes), cream, milk, toasted stale bread, butter, eggs, mild bacon, well-hung underdone meat, raw meat in various forms, fish of different kinds, and tea, coffee, or chocolate, well diluted with milk.

Luncheon may include a cup of soup (to which may be added, just before serving, a varying quantity of raw meat pounded), fish with simple butter sauce, well-hung underdone steak, roast beef or other meat, chicken, game, vegetables (e.g., potatoes, onions, spinach, peas, beans, lentils, etc.), farinaceous puddings, stewed fruit, cream, butter, cheese, and a glass or more of milk.

Dinner should be similar to luncheon, advantageously on the lighter side.

The question of *stimulants* must be decided in the individual case. Guides as to their use are the pulse, temperature, and the patient's custom. Many apyretic patients with satisfactory pulse are better without stimulants at all. On the other hand, stimulants are often serviceable, more especially in patients with feeble circulation and irregular temperature. They help to pick up a flagging appetite, and aid digestion. Under their use, tendency to flatulence and other gastro-intestinal discomfort is lessened.

The form of stimulant is similarly various, and depends in part on the taste of the patient. Most frequently whisky (one or two tablespoonfuls added to a tumblerful of milk) is best. To other patients, an equivalent quantity of alcohol may be given in the form of sound wine (Hock, Moselle, Burgundy, Sherry, Port, Champagne, according to circumstances). Others prefer, and benefit by, an equivalent quantity of beer or stout.

Where such a regimen is accompanied by digestive disturbance—more particularly in patients whose nutrition is much disturbed—the diet is simplified with advantage.

It may then consist chiefly of raw meat—*zomotherapy*. The systematic exhibition of raw meat is a therapeutic as well as a dietetic procedure. Form and dosage require to be regulated as we regulate the exhibition of other therapeutic agents. It has been shown conclusively in the case of dogs inoculated artificially with tuberculosis, that such animals when fed in the ordinary way undergo progressive emaciation, while those fed on raw meat put on weight more or less rapidly. To be efficacious, the doses of raw meat must be sufficient in proportion to the weight of the animal. Under these conditions, raw-meat treatment is effective even when the animals seem *in extremis*. Cooked meat has been found of no value in the case of tuberculous dogs. Zomotherapy is thus something more than a question of extra feeding. When systematically pursued, there follow increase of nitrogen retention, improvement in intestinal metabolism, an increase in hæmoglobin, and a striking increase in digestive leucocytosis (lymphocytosis).

Raw meat may be exhibited in several ways: (1) Pounded raw meat, i.e., finely minced or bruised fresh beef (mutton may be used, if preferred), seasoned with salt, etc., according to taste, served *natural*, like mince collops, cold or gently warmed throughout, say $\frac{1}{2}$ lb. twice or thrice daily. The meat may be served with salad, or along with aspic jelly, or in a variety of other ways. (2) Beef juice prepared as follows: Extract $\frac{1}{2}$ lb. of meat in $\frac{1}{2}$ pint of cold water, plus $\frac{1}{2}$ teaspoonful of salt, for $1\frac{1}{2}$ to 2 hours at 100° F. Express the liquid through a cloth, and serve. Or, the juice may be squeezed from the meat directly by more powerful pressure, without the addition of water. Worcester sauce or other flavouring agent may be added. (3) Raw meat soup, prepared as follows: Take $\frac{1}{2}$ lb. finely minced meat and mix in a bowl with sufficient milk to produce a thick, uniform paste. Immediately before serving, add $\frac{1}{2}$ pint of milk at 150° F. In place of milk, the soup may be made in similar fashion with stock of beef, chicken, veal, or mutton.

In all cases the meat should be *as fresh as possible*. Meat juice especially must be freshly prepared *immediately before use*. Prepared juice speedily undergoes changes which both detract from its value and tend to irritate the gastro-intestinal tract.

In the same dietetic category may be included raw eggs. The patient's meals may be prefaced with one, two, or three eggs—*nature*—swallowed like oysters. The eggs should be quite fresh, i.e., newly laid. They should not be switched or mixed with milk, or other ingredients, apart from a sprinkling of pepper or salt. In cold weather the chill is better taken off all raw preparations by *gentle* exposure to warmth just before use.

Short of exclusive zomotherapy, it is frequently well to limit the patient to a dietary of raw and underdone meat, butter, toasted bread, and milk, with perhaps a little stimulant, avoiding much vegetable or farinaceous food. Thus, breakfast may consist of raw meat rissoles, toast and butter, and a glass of warm milk slightly diluted, to which, in some cases, a tablespoonful of rum has been added; lunch and dinner of raw meat juice, and lightly grilled minced beef or tender steak, butter, toast, stewed fruit, and a glass of milk as above, or a little light wine. Such a dietary sometimes starts healthy nutrition as nothing else will. It may be necessary to maintain such a dietary for weeks. As the condition improves, a more varied menu may be again sanctioned.

The use of milk to some extent is commonly advantageous. The amount to be ordered is not the same in all cases. The determination of the *optimum* quantity requires considerable discrimination.

If the patient can take full ordinary dietary, there is no need to push milk further than already indicated. Excess is apt to disturb stomach and bowels. Where, however, the patient cannot manage a varied dietary, the amount of

milk may be increased. When taken solely, or chiefly, 3 to 4 pints may be allowed in twenty-four hours. Where any possible doubt exists as to the purity of the supply, the milk should be sterilized.

Where there is definite irritability or disease of the gastro-intestinal tract, a more rigid dietary is sometimes indicated. Thus, a milk dietary may be made to alternate, at varying intervals, with raw-meat feeding. The milk may be given in different forms according to the needs of the patient. In most cases it is advantageously diluted with barley-water, soda- or lime-water, or sound buttermilk, according to circumstances. It may be combined with eggs, or tea, coffee, cocoa, or alcohol in some form. Or again, it may be fermented, as in koumiss or kefir; or be peptonized. In critical cases, where assimilation is feeble, there is need for patience and skill in the selection and apportionment of these from day to day.

3. Rest.—Discrimination is required in the determination of the amount of rest. In dealing with most patients for the first time, it is well to maintain rest until the condition is fully known.

The best index from day to day as to the amount of rest is to be found in the pulse and temperature. In proportion as the temperature continues to swing and the pulse remains rapid and soft, the patient should rest chiefly or entirely. It is a handy enough rule to insist on complete rest when the temperature tends to rise above 100° F., or when the pulse beats *constantly* more than 90 per minute.

As the temperature and pulse improve, the rest should be made less absolute. The amount of movement should, however, be carefully detailed to the patient. Thus, he may be allowed ten or fifteen minutes' slow walking every hour or two, resting for the remainder. With a continuance of improvement, the periods of activity may be lengthened, and perhaps combined, so that the patient may walk for three-quarters of an hour to two hours in the forenoon, and perhaps for a similar period in the afternoon, resting between times. In most cases, rest for half to three-quarters of an hour should be insisted on before and after meals. The effect of movement will be carefully gauged by the pulse and temperature. If these are disturbed to any marked extent, the amount of activity should be readjusted accordingly. By way of variety, when his strength permits, the patient may be allowed carriage or gentle motor riding, care being taken to avoid dusty roads and undue effort.

4. Activity.—If the pulse and temperature are not disturbed—and they are often conspicuously benefited—by regulated movement, the periods of activity may be advantageously increased.

As to the kind of exercise, walking is most suitable in the majority of instances. It should at first be slow, say at the rate of two to three miles an hour. The patient should not talk, and all hurry must be excluded. It should be practised at first on the level. With increase of strength, slight inclines may be faced, and still later, more definite hill climbing may prove advantageous. When the patient has been sufficiently tested, mild golfing exercise may be allowed. The interest of the game, and the swing of the club, if not too violent, are distinctly helpful. By this time, horseback exercise may be permissible, and, in some cases, *easy* cycling. The patient must, of course, be warned against over-fatigue and chill. More rapid activity, such as tennis, hockey, and the like, are less desirable, and should be sanctioned in exceptional cases *only*.

Respiratory exercises are helpful. These should be simple, and practised in the open air, or at least at the widely opened window. The patient should be taught to respire slowly, through the nose—not the mouth. Both inspiration and expiration should be slow and full.

The patient's carriage should be as erect as possible. This may be helped,

and faulty chest architecture remedied, by carrying a stick behind the back in front of the folded elbows, which may be brought together behind by straps. Simple movements of the arms backwards, and upwards and backwards, and so on, are also helpful. All such movements, to be effective, must be slow, in correspondence with a slow rate of respiration. If dumb-bells, Indian clubs, or other apparatus be used, the weight should be light and the movements slow.

Such physical treatment is an important element in the regimen of the consumptive. It should be arranged in graduated stages. Thus, at the Royal Victoria Hospital for Consumption, Edinburgh, the regimen has been somewhat as follows.

Three stages are recognized: (I) Resting Stage; (II) Stage of regulated exercises; (III) Stage of graduated work. Each patient begins at the first stage, and is gradually advanced through the other stages, according to his physical condition. The nature and amount of activity are prescribed just like drug treatment. The dose is increased or diminished as the temperature chart, pulse-rate, and other indications suggest.

I. *Resting Stage*.—On admission, all patients are enjoined complete rest, lasting from a few days to several weeks according to the case.

II. *Stage of Regulated Exercises*.—This includes (1) Walking from $\frac{1}{4}$ to 5 miles, (a) on the level, (b) on sloping ground. (2) Various respiratory exercises. (3) Other forms of movements to improve shape of chest, carriage, etc.

III. *Stage of Graduated Work*.—The work may be chosen with a view to utility, with due regard to the patient's inclination, his past occupation, etc. This stage is subdivided into four grades: Grade A, including, e.g., collecting light rubbish from grounds, etc. Grade B, e.g., carrying light baskets for various gardening purposes. Grade C, e.g., raking, hoeing, mowing. Grade D, digging, sawing, wheeling full barrow, etc.

In the last three grades patients may be allowed to make their own beds and do a number of minor domestic matters for themselves.

5. **Clothing and Skin Hygiene**.—The functions of the skin in respect of heat regulation and excretion must be looked to. While the patient should be kept sufficiently warm, he should not be overclothed. Most patients err much on the side of over-clothing. I have known of twenty-three layers between the skin and the air. Excessive clothing seriously interferes with the skin as a heat regulator.

Woollen garments are, as a rule, best. A knitted undersuit, or combination, with a single flannel shirt or its equivalent, is usually sufficient under the outer clothing. The texture should be as light and loose as is compatible with sufficient warmth. Chest protectors, flannel bandages, rolls of cotton wadding, and the like, should be forbidden. Corsets are better absent.

In the same way, bed-clothing should be on the light side. The patient, while sufficiently warm, ought not to be overheated in bed. The bedstead should be as open as possible. Curtains and hangings should be forbidden.

Water may be used to the skin freely. In most cases this will be advantageously attained by a morning dip into tepid, cool, or cold water, according to circumstances. Other things being equal, the cooler the water and the more rapid the bath, the better from the therapeutic point of view.

Where the patient is confined to bed or couch, rapid sponging, followed by dry rubbing, will be sufficient. Even for such cases, sometimes a rapid dip into a long bath is more satisfactory. Generally it is better to arrange for a nurse or other assistant to be in attendance to rub the patient. Rapid improvement frequently follows the institution of a regular daily bath.

6. **Drug Treatment**.—There should not be too much of this. For the

purpose of increasing tissue resistance, and repairing loss and generally improving tone, certain drugs and other agents are serviceable. In the first place, especially when an insufficient amount of butter and ordinary animal fat is taken at meal times, oils are helpful. Of these, perhaps the most generally available and satisfactory is cod-liver oil. It may be exhibited pure, or emulsified in a variety of ways. The form is pretty much a matter of palate. As to dosage, this varies from 1 to 4 drachms twice or thrice daily. Patients on open-air lines take cod-liver oil more readily, and tolerate it better, than do others. Butter, cream, and other animal fats serve a similar purpose. The patient may tolerate and even enjoy such fats, when he rebels against cod-liver oil. In this case, certainly let him have what he prefers.

Various other oils, notably preparations of petroleum, have been proposed as substitutes for cod-liver oil. It has been shown, however, that little, if any, of such oil is absorbed from the gastro-intestinal tract. Although not absorbed, such oils are not without value as scavengers and cleansers of the digestive tract, thereby rendering intestinal metabolism healthier.

Malt preparations are undoubtedly of service. They may be given by themselves, or conveniently in combination with cod-liver oil. There are several good preparations of the sort available. Hypophosphites of calcium, potassium, and sodium have tonic value. They may likewise be given in combination with one or both of the above. The *Syrupus Hypophosphitum Compositus* U.S.P. 1 to 2 dr. is a serviceable preparation. It contains hypophosphites of calcium, manganese, potassium, iron, quinine and strychnine.

Arsenic, in one or other form, is a drug of much value in the early stages, particularly in young subjects. To be effective, it must be continued for a considerable length of time, that is, weeks or months. During its prolonged use, an occasional interruption for a week or ten days is wise. As to form, it is conveniently exhibited as liquor potassii arsenitis (say 1 to 5 min. thrice daily), or arsenious acid (say $\frac{1}{10}$ to $\frac{1}{12}$ gr.), or cacodylate of sodium ($\frac{1}{2}$ to 1 gr.). Some have maintained that special advantage results from the subcutaneous or intravenous use of arsenic, more particularly in the form of cacodylate of sodium. While the writer is convinced of the value of the prolonged exhibition of arsenic, especially in early cases, he has been unable to trace any special advantage from subcutaneous injection. In more dilute form, arsenic may be given conveniently in La Bourboule water, say half a tumbler, thrice daily. This is taken with advantage immediately before meals. The special efficacy of arsenic seems to lie in its influence over the blood-forming mechanism. Not only is secondary anæmia lessened, but tissue resistance is increased. Glycerin appears likewise to be of some value. It may at least be conveniently added to various tonic mixtures.

Sanatoriums.—Sanatoriums are now available in most countries for the special treatment of tuberculosis. It is of course unnecessary to send all patients to such institutions. Most of the measures which have been already indicated can be carried out in reasonably well-equipped private dwellings, provided the doctor realizes what is necessary and can get the assistance of a suitably trained nurse, and can persuade the friends to carry out the system rigidly.

It is usually easier to attain what is wanted in a sanatorium. For a good many cases it is helpful if the patient live for a time, at least, in a sanatorium, so that he may become acquainted with the system which he will have to follow for a long period. He is there taken thoroughly in hand. Strict regularity is introduced into his life, and slight aberrations from the path of recovery are quickly noticed. With more thorough training of doctors and better education of nurses and persons generally regarding the physiological principles of treatment, sanatoriums will become less and less necessary.

In the selection of a sanatorium, it is efficiency and thoroughness of régime which should be sought, rather than climatic or other of the much advertised advantages. There are not a few risks in connection with the commercial and social side of sanatoriums, which unfortunately are likely to grow rather than to diminish. What is especially desirable is the close personal supervision of a physician who has a wide experience of tuberculosis in its extremely varying manifestations. Other things being equal, a smaller sanatorium, where each patient is directly under the care of the physician-in-chief, is better than very large institutions.

Climate.—Formerly, climate played the chief part in treatment. This was largely owing to the belief that pulmonary tuberculosis resulted from a neglected cold, and that such colds were more likely to occur and continue in certain countries. More recent observations have proved that the disease is not materially influenced, either in origin or course, by climate as such. It has been conclusively shown that the disease occurs in all climates, at all latitudes, and at most elevations. Certain climates are better than others by reason of their comparative sunniness, dryness, equableness, and other qualities. After all, the best climate is undoubtedly that which brings patients most into the open air, and frees them from the prejudicial system of protection. The cure of tuberculosis may be successfully carried out in all ordinary climates, provided the air be pure, the physiological regimen realizable, and a sufficiently early diagnosis has been made.

While this is true, it is none the less certain that change of climate, if it can be effected with sufficient comfort, does exercise a helpful influence in many instances. This influence is frequently wanting, or rather is entirely neutralized, by the absence of other hygienic requirements. Many hotels and so-called sanatoriums at climatic resorts are anything but satisfactory. It should also be remembered that there is a growing objection to receiving tuberculous patients into ordinary hotels and apartments.

It must also be kept in view that in sending a patient to another climate there is necessarily a large expenditure, both of physical energy and of means. This expenditure may be in excess of the patient's resources in one or other direction. In either instance, his condition is apt to be injured rather than benefited by the strain. It is wrong to send him far afield if he is not in a fit state to stand fatigue, the possible discomforts of hotel life, and the absence of home attention. It is no less a mistake to allow him to go far from home if he has to economize at every turn.

In deciding the question of sending a patient away, a good rule to keep in view is that the more advanced the disease the less likely is the patient to benefit from the transference. It is patients in the early stage of the disease who may be expected to do well. It is not advisable to let pyrexical patients undertake long journeys. If complications are present, it is generally best to be content with treatment nearer home. All patients in the more advanced stages, and all dying persons, should be kept at home. It is an egregious sin to sanction risk and inconvenience at such a time.

Selection of Climate.—The selection of a climatic resort depends a good deal on the patient's taste and disposition, no less than on his actual condition. There is probably less virtue in the actual climate than was at one time supposed. The most important point to be determined is that, in the selected climate, really suitable conditions of residence and life can be obtained.

For working purposes, climates may be roughly grouped as follows:—

1. *Sea-coast Climates, including Sea Voyages.*—The advantages are pure air frequently in movement, ozone, maximum of sunlight, relatively equable temperature, and comparative warmth in relation to latitude. Disadvantages

are wind—often boisterous, which disturbs many patients, upsetting their nervous system—clouds of sand, and moisture. Such climates are probably protective rather than curative. Patients sleep well usually, and there is a whetting of appetite. On the other hand, some patients suffer much from the irritation referred to, and constipation and other gastro-intestinal discomforts are common. As a rule, patients with pulmonary tuberculosis do better away from the sea. This group (of seaside resorts) may be sanctioned in chronic cases, more especially when complicated by catarrhal tendency or albuminuria. They are particularly serviceable in children with glandular, osseous, or articular disturbances. Examples are found along the south and south-west coasts of England, at Forres and Nairn in Scotland, along the south-west coast of France (Arcachon, Biarritz), the south-east coast of Spain, the French and Italian Riviera, the Sicilian coast, the north coast of Africa, and in the Canary Islands, Madeira, West Indies, and Florida. In tropical countries, as a rule, coast towns are undesirable, and indeed so is the sea border generally.

A sea voyage has the same kind of advantages, with the absence of sand storms. The great drawback is the insufficient ventilation generally found in both public and private cabins. In proportion as much time has to be spent in these, for one reason or another, the advantages of the voyage are neutralized.

2. *Desert Climates*.—Desert climates enjoy a maximum of sunshine and heat, and the further advantage of purity and dryness of air. Sand and dust storms are, however, frequent. Desert climates offer the same kind of advantages as do coast climates. They are well adapted for chronic cases, and exert a curative influence on slowly progressive cases. Examples of this type of climate are found in Egypt (Helouan, Luxor, Assouan) and Algeria (Biskra).

3. *Forest and Woodland Climates at Relatively Slight Elevation (say 150 to 1500 feet)*. These may be found in almost any country and are correspondingly convenient. The character of these, in respect of dryness, warmth, and suitability generally, necessarily varies with the latitude, distance from sea-board, and nature of country. They have more or less the advantage of purity of air, absence of dust, and, where trees are present, shelter from wind and sweetness, even fragrance, of atmosphere (pine woods). Such resorts are favourable for most cases, even acute progressive conditions. Provided the stay be long enough, and other physiological indications are fulfilled, patients generally do well. Numerous examples might be cited from the Highlands of Britain and Ireland, Switzerland, the Black Forest, France (Pau), Austria (Tyrol, Dolomites), and the Italian lakes.

4. *Mountain Climates (say 1500 to 10,000 feet or more)*.—The advantages are great purity, rarity, dryness, and coolness of atmosphere, brilliance and warmth of the sun's rays, and, in many cases, extreme stillness. These properties differ considerably according to elevation. In varying degree, they stimulate respiration, circulation, and blood formation, improve appetite and digestion, and promote healthy activity of skin. The higher elevations have the disadvantage sometimes of over-stimulation, with resultant sleeplessness and other irritation. Such resorts are generally suitable for most cases, even those far advanced. It is, of course, unwise to transfer patients to such altered conditions during acuter manifestations. Probably cases with albuminuria or tuberculous enteritis are better elsewhere. In selecting a mountain climate, regard must be had to the fact that often food supplies are less abundant and less satisfactory than is desirable. This is specially true of some places in South Africa, where neither food nor accommodation is very good, and where the dust storms during dry weather are trying. Such resorts are not available in the United Kingdom. Examples may be found in Switzerland—Leyzin (4757 feet), Davos Platz (5115),

Arosa (6035), St. Moritz (6090) ; in South Africa—Beaufort West (2800), Cradock (3000), Middleburg (4200), Aliwal N. (4350), Bloemfontein (4500), Pretoria (4500), and Harrismith (5280) ; in New South Wales—the Blue Mountains ; in North America—the Rocky Mountains, Denver (5196), Colorado Springs (5992) ; and in South America, the Andes.

II.—TO OPPOSE THE TUBERCLE BACILLUS MORE DIRECTLY.

This is the sphere of specific treatment, and especially of *Tuberculin*. From the experimental side, many attempts have been made in this direction, with varying results. On the clinical side, the results are encouraging, if less uniformly successful than might be desired. Lack of success is frequently due to lack of patience, on the part both of doctor and of patient, and to lack of sufficient experience. There has been want of exactness in the selection of suitable cases, and a hasty, sometimes reckless, employment of the remedy.

It is important to determine whether the tuberculous lesion is chiefly local, or whether systemic involvement is also great. In proportion as the disease is localized and the systemic disturbance is relatively slight, tuberculin is likely to be of service. The defensive mechanism must be capable of ready response. If, contrariwise, the system is already saturated with tuberculous toxins, the exhibition of tuberculin may serve to aggravate the condition. It is in the selection of suitable cases, the exact proportioning of the initial dose, and the rate of increase of dosage, that experience and judgement are required.

The Tuberculins.—Since Koch's earliest announcement in 1890 various modifications and refinements have been proposed. The several recognized tuberculins possess specific properties. They have certain features in common, and also present certain differences. The feature in common is their relationship to the tubercle bacillus. The differences are dependent on their source and method of extraction : (a) Whether of human or bovine origin ; (b) Whether they constitute chiefly an extract from the culture medium, in which case exotoxins are especially present, or an extract from the bacilli themselves, in which case endotoxins are especially present. Some tuberculins combine both exotoxins and endotoxins.

For convenience of reference, the tuberculins which at present are chiefly used may be grouped as follows :—

1. Containing Exotoxins.—

Koch's Old Tuberculin, T, or, if of bovine origin, PT : a glycerin extract obtained from recent, six to eight weeks' old, broth cultures of tubercle bacilli, and concentrated by evaporation to one-tenth of its volume. Initial dose, for an ordinary case with local lesion in excess, may be stated at 0·00001 c.c. to 0·0001 c.c., diluted with normal saline solution or $\frac{1}{2}$ per cent carbolic acid.

Tuberculin TO, or, if of bovine origin, PTO : Essentially the same as the former, with the difference that the extract is not evaporated. This is a milder preparation, and has a special value on that account. Initial dose, for an ordinary case, may be stated at 0·0001 c.c.

Denys' Tuberculin : A simple filtrate obtained by passing tubercle cultures through porcelain. Initial dose similar to that of *P T O*.

2. Containing Endotoxins.—

Tuberculin, TR : An extract obtained from recent cultures dried *in vacuo* and pounded in a mortar, the more soluble exotoxins being removed before the extract is made. Initial dose, for an ordinary case, may be stated at 0·00001 c.c.

Tuberculin BE (Bacillary Emulsion) : An emulsion of desiccated, pulverized tubercle bacilli in equal parts of glycerin and water. Initial dose, for an ordinary case, may be stated at 0·00001 c.c.

3. *Containing Exotoxins and Endotoxins in Combination.*—

Béraneck's Tuberculin, T Bk: Containing (a) Exotoxins obtained from a culture of tubercle bacilli on a special peptone-free medium; (b) Endotoxins extracted from the bodies of bacilli by orthophosphoric acid (1 per cent). This tuberculin, while highly potent, is, in the writer's experience, less toxic than some of the others. Initial dose, for an ordinary case, may be stated at 0.5 c.c. of T B_k, i.e., a dilution of 1–1,000,000 of normal saline.

Regulation of Dosage.—Such initial doses as have been proposed produce in suitable cases a very slight, perhaps hardly traceable, reaction. Within the first twelve to twenty-four hours, the patient may experience slight malaise; the temperature may show slight perturbation; the pulse may become more rapid; the symptoms may become more pronounced (cough, expectoration, etc.), and the physical signs more definite.

The following practical rules may prove of service. Judge each case on its merits throughout. The initial dose will be fixed after a careful estimate of the local lesion and systemic disturbance, and subsequent dosage must be regulated by the effect produced, not by rule of thumb. Fixed scales of dosage are apt to be fallacious, and, if prescribed, should be followed with discrimination according to the effect. Better begin with too small a dose than an excessive one. The object is to reach the *optimum* dose, that is to say, that which affects the patient and the local lesion without disturbing overmuch; this can only be determined by careful clinical examination from time to time. Watch carefully for evidence of hypersusceptibility (anaphylaxis).

Routine of Method.—In many cases it is sufficient to give a weekly dose. Sometimes, in persons of marked susceptibility, the interval between the doses may be wider, e.g., ten days or a fortnight. In other cases a more intensive line may be followed, and the injections may be repeated every third to fifth day. In all cases, the determination of frequency and amount of dosage must rest on the effects produced systemically and locally. This implies careful clinical observation from day to day. The endeavour to determine the point by certain blood tests—e.g., by estimation of the opsonic index—has not proved quite satisfactory.

It is a good rule to repeat the same dose once or twice, especially at the commencement, to avoid the fallacy of a missed reaction.

The duration of a course of tuberculin will depend on the case. Under ordinary conditions, it is frequently a matter of six months. A second course may be required. It is practicable to allow an interval of three months between the first and second courses. The second course may be a matter of three months, followed by a further pause of three months, and so on.

Advantage is claimed for alternation of different tuberculins. One of the milder preparations may be used first, and this may be followed by one of the more potent. Or an exotoxigenic variety may be used first, followed by an endotoxigenic. It is one of the advantages of Béraneck's tuberculin that it combines both exotoxins and endotoxins and yet is mild in action, with little tendency to disturb the patient.

Excessive sensitiveness may show itself unexpectedly when the progress of treatment has seemed satisfactory. A slight increase of dosage over one which has not caused disturbance, or the repetition after due interval of the same dose, may be followed by pronounced reaction. After a further interval, it may be found that even a smaller dose gives rise to disturbing reaction. In such cases it is prudent to increase the intervals and fall back on still smaller doses. By this means the hypersusceptibility is commonly overcome, and a gradual return to larger dosage becomes possible.

Every case does not lend itself to tuberculin treatment. It is especially serviceable in early cases where the local lesion is in excess of systemic disturbance. It is preferably used in the absence of pyrexia. In such cases the results are commonly good, and frequently remarkable. But carelessness in dosage and too frequent repetition may prove unfortunate. A violent reaction may occur, and pyrexia—difficult to restrain—may be induced, with evidence of extension of the local disease.

In pyretic cases the use of tuberculin is not entirely contra-indicated. If sanctioned, the dosage must be considerably less, and the effects checked with discriminating care. In suitable cases, such regulated dosage seems to exert an antithermal influence. In highly pyretic cases it may be wiser to refrain from the use of tuberculin.

Technique.—Any good hypodermic syringe may be used. The essential point is that it can be readily sterilized. This is best done by boiling. The injections are best made deeply under the skin in the interscapular region. The site has several advantages. The outer aspect of the upper arm has the advantage of convenience. The skin is suitably sterilized by means of alcohol or ether followed by alcohol.

Serum.—Various attempts have been made to obtain a serum, possessed of immunizing properties, from the blood of animals, themselves rendered immune by means of bacilli or their products. Of these the serum of Maragliano and that of Marmorek are best known. But, while the results justify the continuance of observation and research on this and similar lines, such sera have not yet obtained a therapeutic position of first-class importance. (See also SPECIFIC THERAPY.) The same remarks apply to the use of simple horse serum.

Drugs.—Apart from tuberculin and sera, which derive their specific properties from their relationship to the tubercle bacillus, certain drugs have been credited with a more or less germicidal influence on the tubercle bacillus. The number of these is great. The limits and purpose of the present article admit citation of the chief only.

As to *mode of administration*, practice varies considerably. Rather an over-estimate is sometimes made of the value of certain modes of exhibition. The most natural method is administration by the mouth, whether in solution, emulsion, pill, or other form. Where, for any reason, continuous oral administration is undesirable, e.g., in presence of gastro-intestinal irritation, use may be made of subcutaneous or rectal medication. The disadvantage of either of these is that it is generally desirable to have it carried out by a skilled attendant, which for obvious reasons may not always be possible. Intratracheal injection is also a ready means of continuous medication. It is doubtful if any real advantage is obtained by the use of the respiratory passages for the purpose of *direct* combat, although absorption proceeds readily, as from other mucous surfaces. The intratracheal method is easy in trained hands, but has the disadvantage that, to be effective, it must be carried out either by a doctor or by a thoroughly trained nurse. Intravenous injection of various drugs has been frequently proposed. It seems likely that all the benefit to be obtained through this channel can be achieved by subcutaneous or intramuscular injection. The value of drugs by inhalation is periodically insisted on by some enthusiastic re-discoverer of a method which, while it seems natural and is invitingly easy, has been discarded by most observers. The method has little more than symptomatic value. It plays a more definite rôle in tuberculous laryngitis and in the limitation of mixed infections.

Of germicidal agents, *Creosote*, or one of its congeners, is the most important. Almost all observers are agreed that, if not possessed of specific properties, it exerts a most wholesome influence. It is sometimes objected regarding such

drugs, that it is impossible to introduce into the system an amount sufficient to kill the organisms without at the same time gravely damaging the living tissues. In answer to this, it has to be borne in mind that it is not a question of killing the bacillus, but rather of so modifying the conditions of environment as to make these unsuitable, or at least less suitable, for the development of the bacillus. It is further possible that creosote acts by neutralizing some of the products of the bacillus. It may be that its chief activity is in the gastrointestinal tract, which it puts into better order, thereby improving intestinal metabolism.

In exhibiting creosote orally, care must be taken that it is a *pure* preparation of beechwood creosote. Cruder preparations tend to cause gastric irritation, with resultant dyspeptic phenomena. As to dosage, 2 to 5 min. may be given, gradually increasing to 15 or 20, three times daily. When the larger doses are reached, the kidneys should be carefully watched. The urine tends to become dark as the result of over-dosage. It is conveniently exhibited in capsule form, preferably along with, or after, food. Although less pleasant, it may be given in liquid form, e.g., in wine, or emulsion of cod-liver oil. Carbonate of creosote (creosotal) is said to contain 90 per cent creosote and to be less irritating. It may be given in doses of 5 to 30 min., thrice daily.

Creosote may also be administered hypodermically, dissolved in sterilized oil (5 to 10 per cent), or per rectum as in the following formula :—

R Creosoti	℥xv-lx	Ovi Vitellum	j
Olei Olivæ	3v	Aquæ Destillatæ	3vj

It may be used by cutaneous inunction, as in the unguentum creosoti or the following :—

R Creosoti	℥lxx	Adipis	
Lanolini		Olei Olivæ	ââ3vj

Or it may be exhibited by intratracheal injection, dissolved in oil (10 to 50 per cent). It is doubtful in this, as in all intratracheal injections, how far the agent reaches. There can be no question that by means of intratracheal injection the patient is frequently benefited. Conspicuous symptoms yield, cough and expectoration are lessened, and in many ways he improves. Local tuberculosis of larynx and upper air-passages is certainly helped. It is probable that, so far as the lung lesion is concerned, the drug does not act by immediate contact. But the respiratory passages afford an absorbent surface whence the drug is doubtless carried to different parts, as after absorption from the alimentary tract.

Inhalations of creosote, formerly so much in vogue, are probably of little permanent service. The respirators which used to be worn are positively harmful, as impeding respiration.

Of its congeners, *Guaiacol*, which has the same active principle, is the most important. Its action is essentially the same. It may be prescribed in doses of 2 to 15 min., either in capsule, pill, or in solution.

R Guaiacol	1 part	Water	180 parts
Alcohol (90 per cent)	20 parts		
One to three teaspoonfuls twice or thrice daily.			

Or the *mistura guaiacolis* of Guy's Hospital :—

R Guaiacolis	℥iv	Olei Cinnamomi	℥j
Alcoholis (90 per cent)	℥xl	Aquæ Destillatæ	q.s. ad 3j
Glycerini	℥xxx		

Or it may be given with sherry wine. It is combined pleasantly enough with cod-liver oil.

Or it may be given hypodermically, as in the following :—

R Guaiacol	5 parts	Parolein	100 parts
Iodoform	1 part		

Fifteen to thirty minims once or twice daily.

Where the stomach threatens to be troublesome, or where there is difficulty as to the smell or taste, the same influence may be obtained by the use of carbonate of guaiacol (duotal), a white crystalline powder, without taste or smell, which may be given in pill or cachet to the extent of 5 to 25 gr. thrice daily. A good prescription is as follows :—

R Guaiacolis Carbonatis	gr. iv	Acidi Arseniosi	gr. $\frac{ss}{8}$
Fiat pilula. One to three pills to be taken thrice daily.			

Other derivatives are numerous, but of less importance, e.g., benzoate of guaiacol (benzosol), sparingly soluble (gr. 4 to 12 in cachet or powder); phosphate of guaiacol, and orthosulphoguaiacolate of potassium (thiocol), readily soluble (gr. 5 to 30); cinnamate of guaiacol (styracol), hardly soluble in water (gr. 15). The last named has a considerable reputation. It is a white powder without smell, and not disagreeable to taste, free from noxious influence. It may be exhibited in doses of 15 to 30 gr. three times daily.

Tannin has been considerably used, and is much vaunted by some authorities, both on experimental and clinical grounds. It may be given in doses of 15 gr. three times a day. The writer's experience has been rather unfavourable to its use, owing to the gastric disturbance which sometimes follows.

Menthol has been employed much, both in pulmonary and laryngeal tuberculosis, especially by intratracheal injection. A 20 per cent solution in olive oil is sufficient. Of this, one or more drachms may be injected once or twice daily. The remarks which have been made regarding intratracheal injections of creosote and guaiacol apply here equally. There is no question that symptomatically the patient is generally benefited.

Eucalyptus Oil or *Eucalyptol* is certainly of value. Under its use the patient often improves remarkably. Notably, expectoration is lessened. The oil may be given by the mouth, either in capsule, 5 to 20 min. thrice daily, or in emulsion along with cod-liver oil. Or it may be given subcutaneously, dissolved in liquid vaseline, or intratracheally, in olive or castor oil. *Eucalyptol* should not be used if there be kidney complication.

Iodoform.—Considerable difference of opinion exists as to the value of iodoform. There can be no doubt as to its significance in local (surgical) tuberculosis. On the whole, the evidence points to its value in pulmonary disease. Under its influence, cough and expectoration lessen. There is less tendency to hæmorrhage. In pyretic cases the temperature is sometimes favourably affected. It may be variously exhibited, e.g., in pill, $\frac{1}{2}$ to 3 gr. three times daily, or subcutaneously, dissolved in liquid vaseline (1 to 2 per cent). This has sometimes been combined with guaiacol and eucalyptol. Good results have been reported from its continued subcutaneous use. It has also been used intravenously. Iodoform is contra-indicated in presence of kidney disease. During its exhibition the urine should be examined frequently.

Cinnamic Acid or *Sodium Cinnamate* (*Hetol*) deserves mention. If the strong claims which have been advanced for the specific properties of cinnamic acid cannot be entirely admitted, its continued use is certainly beneficial. Sodium cinnamate may be dissolved in distilled water or normal saline solution, sterilized, and injected subcutaneously or intravenously. It has also been dissolved in oil or glycerin for the same purpose. It may be given internally in doses of 3 to 5 gr., or in the form of oil of cinnamon or oil of cassia (5 to 10 min.), e.g., added to an emulsion of cod-liver oil. Balsam of Peru, which has

been used in various ways with benefit, probably owes its influence to the cinnamic acid it contains.

Camphor is similarly of service symptomatically in the form of camphoric acid, 10 to 20 grains. It has a special influence over night sweating. Camphor has been introduced subcutaneously and intralaryngeally, and even directly into the lung, with benefit. For such purpose it is dissolved in oil.

Formalin.—For cases of lung tuberculosis in which the larynx is involved, inhalation of formalin ($\frac{1}{2}$ to 2 per cent) is to be recommended. It is best exhibited on a light oro-nasal mask made of fine, open-meshed muslin, which does not interfere with respiration, the patient keeping the muslin constantly moist.

There is no end to the list of remedies which have been announced at one time or another as specifics. It would serve no useful purpose to present a long list of these. The following are perhaps worthy of mention at least, viz.: sulphur (including the natural sulphurous waters), mercury, iodine (including iodide of potassium), tar, carbolic acid, and other tar products (izal, cyllin, etc.).

Artificial Pneumothorax.—The production of pneumothorax, or collapse-therapy, as it is sometimes termed, has become a favourite line with many. The method is simple and relatively safe. It is especially applicable in unilateral pulmonary tuberculosis without complications, running a comparatively slow course. It may be serviceable even in acute progressive affections, when limited to one side. Bilateral tuberculosis—when of chronic, non-aggressive type—may be assisted. It can be of little value if the second lung is in a state of advanced disease. On the other hand, a slighter degree of disturbance of the second lung is frequently benefited by the induction of pneumothorax on one side.

Other forms of surgical interference have been utilized as means of effecting a direct attack on the disease. More superficially-lying vomicae have been opened and drained. The results have been, however, less encouraging than might be wished. They hardly justify recommendation of the procedure, as at present realizable.

III.—TO MEET SYMPTOMS AND COMPLICATIONS.

The symptomatic treatment of pulmonary tuberculosis is often made the chief, and sometimes the only, treatment. This is a great mistake. In proportion as the larger indications have been followed, there is little scope for symptomatic measures. Still, from time to time, symptoms must be met.

Cough.—The cause of the cough should be determined. This varies in different cases. We must see that it is not produced artificially, as by the condition of bedroom or residence. It is remarkable how an obstinate cough yields under conditions of hyperaeration day and night. Cough is sometimes maintained by certain agents used for inhalation, e.g., terebene, eucalyptus, or by the use of unphysiological respirators. It is frequently the expression of such a simple cause as smoking, especially cigarette smoking. Sometimes the patient keeps it up voluntarily. He thinks he should cough. He certainly coughs more than is needful for purposes of expectoration. In such cases it is well to explain to the patient that every cough tends to injury, by putting undue strain on the delicate lung tissue, and by forcibly spreading disease. Much can be done by training the patient to hold his breath, and by means of simple demulcent and sedative pastilles.

The routine use of expectorants in presence of cough is to be deprecated. They are seldom necessary, and tend to spoil the appetite, disturb the stomach, and generally derange the patient. Where the cough is irritating and resultless,

sedatives, e.g., dilute hydrocyanic acid in glycerin, are useful, as in the following :—

R Acidi Nitrici Diluti	℥ij-ʒ	Glycerini	℥j
Acidi Hydrocyanici Diluti	℥xlviij	Infusi Quassiae (1 per cent) q.s. ad	℥vj

One tablespoonful to be taken thrice daily, immediately before meals.

Or small doses of morphine ($\frac{1}{12}$ to $\frac{1}{8}$ gr.); or better, as causing less disturbance of gastro-intestinal functions, codeine $\frac{1}{2}$ to 1 gr., dionin $\frac{1}{4}$ to $\frac{1}{2}$ gr., or diacetylmorphine hydrochloride $\frac{1}{16}$ to $\frac{1}{12}$ gr. One or other of these may be conveniently given at bedtime and the first thing in the morning, in effervescent citrate of potash or soda-water. Of milder sedatives, hyoseyamus and belladonna may be mentioned.

When cough is due to irritation about the pharynx, it may be relieved by a menthol and cocaine pastille or by a spray of menthol in parolein (10 to 20 per cent). A similar spray is of value in irritation about the larynx or trachea. Or counter-irritation may be used, e.g., a blister over the manubrium sterni.

Expectoration.—Morning expectoration, which supervenes after the rest of night, may be rendered easier by the use of warm drinks, especially warm alkaline drinks. Boiling milk, to which an equal amount of one of the natural alkaline waters has been added, is often serviceable; or a tumblerful of warm milk with 2 to 4 teaspoonfuls of rum.

When expectoration is attended with difficulty, it may be eased by small quantities of ipecacuanha ($\frac{1}{4}$ to 1 gr.). With this may be advantageously combined 5 to 10 gr. of chloride of ammonium. When expectoration tends to be excessive, benefit is derived from terpene hydrate (2 to 5 gr.), or from 5 to 10 min. of terebene or eucalyptol. These may be combined suitably, in conditions of irritation, with codeine, diamorphine hydrochloride, or other sedatives.

Hæmoptysis. (See Special Article.)—For slighter degrees of hæmorrhage, there is no need for special treatment. The infrequency of hæmoptysis is one of the more remarkable results of the open-air treatment of tuberculosis.

Dyspnœa.—This affords urgent call for complete hyperaeration. Some patients, dyspnœic when indoors even with windows freely open, are marvellously relieved when carried outside. In emergencies of the sort, aromatic spirit of ammonia is helpful. It may be given conveniently in 1-drachm doses in lemon-water. Where dyspnœa is associated with lodgement of discharge in the tubes which is not easily expelled, relief may be had by the use of stimulant expectorants, e.g., carbonate of ammonium, senega.

Pain.—The cause of the pain varies, and should be determined where possible. If comparatively slight, and due to recent pleurisy, relief may be had by fixing the affected side by means of broad strips of sticking-plaster. If the pain is greater, counter-irritation by fly blister is most helpful. This is commonly more effective, and in the end less troublesome, than mustard or iodine. When the distress, as often happens, results from strain of the muscles in coughing, sedatives should be used for the cough, and a rubefacient liniment of oil, e.g., aconite, belladonna, and chloroform liniment (B.P.C.), applied locally on spongopiline or lint under oilcloth. Or a more sedative application may be made by means of poppy-head stupe. When pain is due to more widespread congestion, whether of tubes or lungs, a large poultice, to which mustard may be added, is often serviceable.

Pyrexia.—The effect of hyperaeration on pyrexia is striking. It is extraordinary how quickly temperatures which have swung more or less violently for months under the older treatment in more or less confined rooms, become normal in the course of days or weeks or months. It may take months of persistent hyperaeration to attain the effect. Yet patience through long periods is amply rewarded. In such cases, the air supply cannot be too great and direct.

Apart from drug treatment, the cause of pyretic disturbance should be carefully sought, with a view to its exclusion. The tuberculous patient is more highly sensitive to disturbing influences than the normal subject. Thus, fatigue, excitement, gastro-intestinal irritation, and the like, readily affect his temperature. Consequently, the temperature should be carefully taken at least twice daily, and, in more anxious cases, every three hours. Where pyrexia is present, the temperature curve should be carefully analyzed to determine if there be any uniformity in the recurrence of pyrexia, and if there be any relationship with times of exercise, meals, etc.

If pyrexia seem to follow fatigue, the indication is rest. If it be associated with gastro-intestinal disturbance, the dietary should be revised, and in most cases simplified. Thus the patient may be placed on a milk dietary, or, again, on a raw meat dietary (raw meat juice, raw eggs). Or the bowels may require attention. A dose of castor oil may have remarkable effect. Daily repeated 1-dr. doses of castor oil, with a minute quantity of opium, are sometimes serviceable. When there is no evident and removable cause, hydrotherapeutic measures may prove helpful—for example, sponging with cool or cold water, to which may be added eau de Cologne or toilet vinegar. Or the wet pack may be tried, or a cool or cold bath, with care.

For the same purpose, inunction with guaiacol, 1-dr. doses, over the skin of the thorax, may be serviceable. It must be practised with caution, as sometimes grave depression has followed the application. It may be used pure, or in combination with soft soap and olive oil, as in the accompanying prescription:—

R Guaiacolis	3j	Olei Olivæ	q.s. ad 3iij
Saponis Mollis Peroleati	3j		

A tablespoonful to be applied by inunction.

Antipyretic drugs should be used with some caution. It is easy enough to lower temperature by such means: it is more difficult to say to what extent the patient has benefited. Quinine is largely used, but there exists doubt as to the degree of efficacy. In lesser pyrexia, small doses of, say 2 gr., dissolved in dilute acid, are sometimes helpful. In more persistent pyrexia, quinine is of less service. The old-fashioned combination of quinine (1 gr.), digitalis ($\frac{1}{2}$ gr.), along with a small quantity of opium, may assist. Some stubborn cases yield to the regular exhibition of strychnine—e.g., liquor strychninæ hydrochlor. (1 per cent) 3 min. every four hours. Or quinine, digitalis, and strychnine may be combined. In obstinate cases, where the cause of the pyrexia cannot always be determined, cryogenin (meta-benzamine-semicarbazide) has proved of signal service. It may be given in doses of 5 to 10 gr., twice or thrice daily, conveniently an hour or so before the expected rise of temperature. In the same way maretin, another coal-tar derivative, may be serviceable (3 to 5 gr.). Or antipyrin in 5- to 10-gr. doses twice or thrice daily may be tried, especially when there is attendant discomfort, headache, and other irritability. Phenacetin in similar doses may prove helpful, or pyramidon (5 gr.). It is not advisable to prolong the use of such antipyretics for many days. They should be stopped in any case when gastro-intestinal disability ensues.

The administration of alcohol offers distinct advantages in the pyrexia of advanced disease. If exhibited an hour or so before the temperature tends to rise, it frequently prevents this, while at the same time it lessens tissue waste in patients unable to take sufficient nourishment. As to form, pure spirit (whisky, brandy) is usually wisest, diluted with milk, or mixed with eggs and milk as egg flip, or in alkaline water.

Gastro-Intestinal Disturbance.—As already indicated, digestive troubles are remarkably lessened under the open-air régime. This is so striking, that it is

almost useless to speak of treating them under other conditions. If they fail to yield to this, the diet sheet and prescriptions should be revised. We must make sure that the disturbance is not maintained from without. Simpler diet and the exclusion of drugs may make a vast difference. Thus, limitation to raw meat or to a milk diet for a few days, may prove sufficient.

Loss of appetite is sometimes removed by the use of ordinary bitters taken half an hour before food, while the patient is resting, or by a little dilute acid. Some patients do better with a corresponding dose of alkali before food. The application of an ice-bag over the stomach half an hour before meals has sometimes a remarkable effect on the appetite.

A feeling of fullness and discomfort about the stomach, with a tendency to sickness, is often best relieved by a mild alkaline drink, e.g., bicarbonate of sodium, 5 gr. in hot water, shortly before meals; or by a glass of boiling water taken sip by sip, half an hour before meals or, it may be, two or three hours after food. The occasional use—perhaps every second or third day—of minute doses of grey powder ($\frac{1}{2}$ to 1 gr.) is sometimes effectual. A drop or two of creosote or of weak tincture of iodine (B.P.), diluted and taken after food, is similarly helpful. Or 10 to 15 gr. of bismuth may be given with meals.

Where vomiting occurs as the result of cough (*toux émétiante*) it may be prevented by small doses of a sedative, e.g., morphine, codeine, diacetyl-morphine hydrochloride, just before meals. Creosote taken with meals seems likewise helpful. A mustard poultice over the epigastric region has similar value. It is sometimes serviceable to anticipate this variety of vomiting by making the patient sick the first thing in the morning, by tickling the throat or by other simple means. This generally saves his being sick after meals.

Diarrhœa.—This may be due to a variety of causes. Some judgement is required in determining the point. Thus, it may depend on a dietetic error or drug, on simple or tuberculous enteritis, or on waxy disease of intestine.

A dose of castor oil (and it is the safest purgative) may be needed to remove existing irritation. Thereafter a simple milk dietary for some days, or the adoption of more or less strict zomotherapy, may prove of the utmost service. In most cases, one or other form of bismuth is helpful. In simpler cases, 10 to 20 gr. of subnitrate of bismuth with each meal may be sufficient, while in more pronounced cases, with offensive stools, salicylate of bismuth (5 to 15 gr.) is more serviceable. Where pain accompanies the diarrhœa, or where the latter is excessive, the addition of a small quantity of morphine is indicated. Of other drugs, liquor calcis saccharatus B.P., (1 dr.) or other chalk preparation may be tried. Of vegetable astringents, logwood (e.g., $\frac{1}{2}$ oz. of decoctum) is perhaps the best.

Where the condition is more certainly due to tuberculous involvement of the bowel, the diarrhœa calls for the strictest attention dietetically on the lines already indicated, and salicylate of bismuth with morphine will generally prove of much assistance. It is often necessary, however, to alternate among a variety of antiseptic and astringent drugs, of which may be cited, in addition to those already mentioned, salol, tannin, tannoform, sulphate of copper, acetate of lead, and oxide of zinc. The continued use of creosote sometimes proves more helpful than anything else. In milder cases, petroleum emulsion does good service.

Night Sweating.—This classic symptom, as it used to be considered, hardly ever occurs where hyperaeration is sufficiently achieved. The rapidity with which persons who have been persistent night sweaters, and have suffered in consequence from broken sleep and corresponding depression, have lost the symptom under physiological treatment, is one of the most striking facts in clinical medicine. If, for any reason, open-air methods cannot be efficiently carried out, or the tendency persists notwithstanding such measures, the clothing, night-dresses, and bedclothes should be looked to. They must be as light as is

compatible with comfort. At bedtime, the patients should be freely sponged with acidulated, or sometimes with alkaline, wash, and this may be followed by dry-rubbing. Thereafter the surfaces may be freely dusted with tannoform powder. Irritating external applications should be avoided at bedtime. Internal drugs will be seldom necessary. Of these may be mentioned atropine ($\frac{1}{100}$ gr.), extract of belladonna ($\frac{1}{8}$ gr.), camphoric acid (10 to 20 gr.), picrotoxin ($\frac{1}{100}$ to $\frac{1}{50}$ gr.), and agaricin ($\frac{1}{8}$ to $\frac{1}{4}$ gr.). The writer's experience is that, with proper attention to the physiological requirements, the need for special drug treatment for night sweating is quite exceptional.

Insomnia.—Bad sleepers, even without tuberculosis, usually sleep better in the open air. This is emphatically true of the tuberculous subject. If the open air prove insufficient, sleeplessness is often averted by some such simple means as a warm drink at bedtime, e.g., of dilute milk, malted milk, thin soup, or dilute toddy. The lessening of the evening meal proves beneficial to some persons. Constipation, flatulence, and other gastro-intestinal disturbances should be looked to. Painful conditions must of course be excluded. Irritating applications should be avoided at bedtime. If iodine is used it had better be applied in the morning rather than at night, and at bedtime the surface be dusted over with a soothing powder. If irritating cough be present, a slight sedative may be added to the warm drink, e.g., codeine, dionin, or morphine. Of hypnotics proper, perhaps the most valuable are paraldehyde (1 to $1\frac{1}{2}$ dr.), sulphonal (15 to 20 gr.) dissolved in hot fluid, and trional (10 to 15 gr.).

Anæmia.—Arsenic is of greatest service in the treatment of the anæmia of tuberculosis. It is to be preferred to iron, which in most cases is of doubtful value. Arsenic should be used for prolonged periods. Raw-meat feeding is often most serviceable.

The treatment of other complications—laryngeal, peritoneal, and genito-urinary—is considered under several appropriate headings.

R. W. Philip.

PURPURA.—The widespread effects of sepsis are well shown in connection with the various forms of purpura. So commonly does it underlie conditions of severe purpura, that the latter may be regarded as merely an important symptom of so-called "latent" ("cryptogenetic") sepsis—the latent and cryptic character of which is a measure of the oversight of the various sources of septic infection described in the article on ANÆMIA.

The condition termed "purpura" is not a disease, but a symptom. The conditions with which it is associated, and of which it is a manifestation, are nearly always of an infective, and most usually of a septic, nature, with or without arthritic manifestations of the same infective processes, e.g. :—

1. Obscure septicæmia, pyæmia, malignant endocarditis, scarlet fever, small-pox (obviously septic).

2. So-called "cachectic" purpura, met with in cancer, tuberculosis, Hodgkin's disease, Bright's disease, scurvy, debility of old age (probably due to super-added sepsis).

3. So-called "arthritic"—often termed "rheumatic" purpura (although the evidence on which this view is based is not conclusive). A rheumatic history can only be got in less than one-third of the cases.

- a. One variety—"purpura simplex"—is a mild form seen most commonly in children, not infrequently associated with diarrhœa, loss of appetite, and slight anæmia, the arthritis present being less than in the ordinary rheumatism of children (probably the result of intestinal sepsis).

- b. Another variety—so-called "purpura rheumatica" (peliosis, "Schönlein's disease")—is characterized by multiple arthritis, an eruption, sometimes purpuric, sometimes urticarial, which not infrequently sets in with sore throat

(tonsillitis), slight fever (101° – 103° F.), and articular pains, and is liable to relapse (probably septic tonsillitic infection).

c. A third variety is the purpura, erythema, and urticaria associated with gastro-intestinal conditions—a variety seen chiefly in children, characterized by relapses or recurrences extending over several years: cutaneous purpura, or erythema, associated with gastro-intestinal disturbances (pain, vomiting, diarrhœa), joint-pains or swellings, often trifling, hæmorrhages from the mucous membranes, enlargement of the spleen, and nephritis—the most common cause of death. The cases with colic and purpura are often termed “Henoch’s purpura.”

d. The fourth variety — “purpura hæmorrhagica” (morbus maculosus Werlhofii)—a form of very severe purpura with hæmorrhages from mucous membranes, very common in young and delicate girls, is probably the result of the severest and most cryptogenetic infection.

The chief indication in all such cases is the removal by appropriate measures (see above) of the infective conditions which underlie them. In the last three cases seen by the writer, the source of the sepsis in two was extreme oral sepsis, and in the third an unrecognized chronic antral suppuration.

Apart from that, the chief indication is the use of tonics, good food, fresh air, with arsenic in full doses in simple purpura, and salicylate of soda in so-called rheumatic purpura; in all cases correction of the possible sepsis of the alimentary tract by intestinal antiseptics, best of all some form of mercury (hydrarg. c. creta, hydrarg. perchlor.), or oil of turpentine, 10 to 15 min. three or four times per day.

For the blood condition the best remedies are lactate of calcium in 20-gr. doses four times daily for three or four days, to correct the diminished coagulability, and liq. potassii arsenitis and tinct. ferri chloridi as tonics. Polyvalent anti-streptococcic serum has been used successfully in some severe cases of purpura. It may be given by the rectum, 10 to 20 c.c. being injected the first day, and half that quantity the next three or four days.

William Hunter.

PYÆMIA.—(See SEPTICÆMIA.)

PYELITIS and PYONEPHROSIS.—Suppurative inflammation of the pelvis of the kidney is very seldom of primary origin in the pelvis, but is usually due to the spread of infection from below. It is, however, occasionally seen as a complication of certain infective disorders, the most common of which is enteric fever, and in this connection should be mentioned the condition known as the pyelitis of pregnancy. In this type of pyelitis the kidney substance proper usually escapes. The inflammation of the renal pelvis commences in the later months of gestation, and is almost invariably due to infection by the *Bacillus coli communis*, which can be recovered from the urine in pure cultures. The termination of the pregnancy is usually followed by a rapid disappearance of the pyelitis, but in some instances the symptoms are so severe that labour must be artificially induced to save the life both of mother and child.

Pyelitis may be either acute or chronic, severe or very mild, in character.

TREATMENT.—This is *palliative* and *operative*.

Palliative Treatment.—In acute cases the patient must be kept absolutely at rest in bed, upon a fluid diet of milk, eggs, chicken, veal and fish broths, jellies, and the like. The bowels should be fully moved daily, and a free diuresis induced by means of Vichy, Contrexéville, or Wildungen waters. Urinary antiseptics combined with diuretics should be given; of the former, various preparations which set free formaldehyde, such as hexamethylenamine, cystamin, helmitol, and cystopurin, are probably the most valuable, in doses of 5 to 15 gr. three times

a day, whilst bicarbonate and citrate of potassium, acetate of ammonium, and nitrous spirit of ether may be employed for their diuretic effect.

Large hot poultices to the affected loin should be frequently applied, and dry cupping is sometimes of considerable value.

If the condition is mild and more chronic in character, the patient may be allowed up, but avoidance of undue exertion and fatigue should be insisted upon, and when possible, winter residence in a dry, warm climate is advisable.

As a rule these cases tend to improve slowly, and eventually a complete cure may be anticipated.

Operative Treatment.—In some instances, however, the condition does not clear up beyond a certain point. The urine still remains somewhat cloudy, and on standing deposits a small sediment of pus, broken epithelium, and occasionally a few blood cells. In such cases the writer has on several occasions hastened a cure by the instillation of small quantities of silver nitrate solution into the infected pelvis by means of the ureteric catheter.

But when the free exit of the pus-laden urine from the pelvis is impeded, the condition becomes very much more serious, and to it is applied the name of pyonephrosis. The most common cause of this condition is blockage of the ureter by a calculus, with infection of the resulting hydronephrosis. Removal of the stone or other obstruction should be undertaken without delay, and the pelvis of the kidney should be freely drained through the usual oblique incision in the loin. If operation is deferred too long, the substance of the kidney itself will be infected, and total removal of the organ will become necessary. (See also HYDRONEPHROSIS.)

John George Pardoe.

PYELONEPHRITIS.—By this is implied a suppurative inflammation of the whole kidney, both the pelvis and the secreting substance of the kidney being implicated. To this condition the term "surgical kidney" is sometimes applied, and inasmuch as the condition undoubtedly follows infection of the bladder by unpurified instruments, the term is not in some cases a misnomer. Pyelonephritis is most common in cases where long-standing obstruction has caused dilatation of the ureters and pelves of the kidneys, and is particularly liable to occur in chronic retentions and difficult micturition due to enlargement of the prostate and old-standing stricture of the urethra. It is also very easily induced in cases of atony of the bladder dependent upon diseases and injuries of the central nervous system, such as locomotor ataxia, spastic paraplegia, disseminated sclerosis, and in complete transverse myelitis due to injury of the spinal cord. Indeed, in the latter class of case, however careful the medical attendant may be, and however strictly the catheter may be sterilized, cystitis and rapid extension of septic infection to the ureters and kidneys not infrequently terminates the patient's life. It is therefore essential to take the very strictest precautions in employing the necessary catheterism in these cases. But in laying stress upon the supreme need for asepsis in the catheterism of patients suffering from nervous diseases, the writer must insist that there is no excuse for the passage of unsterilized instruments into the bladder of any patient whatsoever.

Pyelonephritis may be acute or very insidious in its onset.

In the acute type the disease is marked by acute rise of temperature with rigors, a scanty secretion of urine, sometimes terminating in suppression, lumbar aching, a dry tongue and skin, and indeed all the phenomena of an acute septic infection combined with the particular renal symptoms. If unilateral, an immediate nephrectomy is the one chance of life for the patient, but only too often the infection is bilateral, and these cases are of necessity quite hopeless.

The chronic cases are most usually seen in those patients who have for some time lived a catheter life without paying due regard to the necessary aseptic

precautions. The phenomena witnessed are those of chronic sepsis, and unfortunately surgery is powerless to aid these cases when the disease is well advanced. Progressive emaciation, combined with an irregular pyrexia, constant dull lumbar aching, a dry skin, marked thirst, and a cachectic appearance, combined with the local signs of urinary trouble, form a picture which is not difficult to recognize.

John George Pardoe.

PYLORIC STENOSIS OR SPASM.—(See CONGENITAL PYLORIC STENOSIS.)

PYONEPHROSIS.—(See PYELITIS.)

PYORRHŒA ALVEOLARIS.

The disease begins as a marginal gingivitis, localized or more or less general. Later, the edges of the alveolar bone of the jaws become carious. There follows progressive bone destruction, resulting in the formation of pockets between the gum and the tooth. In very chronic cases, bone destruction is accompanied by recession of the gum, and pockets are only formed late in the disease. The toothward sides of the gum are in a state of chronic ulceration which, together with the bone-caries, gives rise to a more or less obvious discharge of pus. The alveolar-dental membrane is thickened, and the bone round the tooth is absorbed to make room for deposits of granulation tissue. In very slow cases the bone reaction is sclerotic, but such cases eventually merge into the less chronic form. The débris accumulated in the pockets undergoes putrid decomposition. The edge of the gum may be inflamed and swollen, bleeding readily when touched; or in more chronic cases it may shrink *pari passu* with bone destruction, and expose the neck of the tooth. Gradually the teeth become tender on pressure and loosened, and abscesses along the side of a denuded root, in the pocket between it and the gum, become frequent. There is generally more or less tartar.

As regards effects on the general health, the extent of the ulceration and the amount of discharge, as indicating the possibilities of absorption of germs and toxins, and the existence of putrid decomposition, are the important points. Resistance varies greatly in different individuals, but, in general, systemic infection is only a question of time: the disease ultimately leads to a more general infection, showing itself in some part of the body.

Pyorrhœa alveolaris originates in the stagnation of germs in the periodontal sulci round the necks of the teeth. The addition of sticky food-débris (fine ground flour) increases their power for evil by providing a suitable food. Overlapping edges and rough surfaces of stoppings, ill-fitting crowns, gold caps, and bridges, and unclean plates add to the natural possibilities of stagnation. The disease is of local origin, and is to be found in persons as young as ten years of age. A marginal gingivitis in childhood eventuates in a few years in a fully developed pyorrhœa alveolaris.

Any deviation from the normal pale-pink, thin-edged condition of the gums is a dangerous sign, whether in the direction of hypertrophic or of destructive inflammation. Minute examination for pockets must be made with fine steel probes. X rays are of great service in showing the extent of bone destruction. Pus and decomposing food are to be sought for by expression, and by mopping out the pockets with cotton-wool twisted round the end of a fine steel probe. What is expressed must be actually smelled; the smell will be made more evident on warming.

PREVENTION.—The disease is of local origin, and can be prevented by cleanliness. The one important part to clean is the neck of the tooth. Adequate cleaning must be begun in childhood.

TREATMENT.—1. Extraction, the only permanent cure.

2. Alternate extraction, which aims at isolating teeth in order to facilitate drainage and cleansing.

When teeth are retained:—

3. Destruction of pockets, by cutting away gum and drilling away bone till every part of the tooth not united by vital attachment to the bone is laid bare and made cleansable.

4. Removal of all tartar and artefact stagnation-areas, e.g., rough fillings, faulty crowns.

5. Permanent cleanliness.

In early cases, thorough scaling and proper daily cleaning will effect a practical cure. Teeth which have lost the major part of their attachment are better extracted. Multi-rooted teeth between whose roots bone-destruction has extended should be extracted, since drainage is impossible.

In determining treatment, the general health must be the first consideration. This is far more seriously affected by sepsis than by absence of teeth. Vaccines are often of great use in relieving the general effects of the disease, such as the various forms of "rheumatism," but in the writer's experience are of no service in curing the local condition. They cannot prevent re-accumulation of germs and débris, or decomposition, and the patient's efforts at cleaning far too often fall very short of the requisite standard. Hence extraction is to be recommended when there is any serious general infection, or when local treatment fails to relieve the remote condition.

Ionic medication is of doubtful value. If all that is claimed for it be true, it can still be only of temporary value: in the absence of destruction of pockets and daily cleaning, reinfection must occur. In the writer's opinion it is merely an elaborate method of mopping out the pockets.

After excision of gum the exposed roots are often very sensitive. Rubbing with powdered nitrate of silver will relieve the tenderness, but will stain the part black. Weak tincture of iodine (B.P.) applied to the necks of the teeth and edges of the gums, every other day, diminishes the activity of bacterial growth. The sum total of treatment is—*clean, render cleansable, and maintain cleanliness.*

Joseph Geo. Turner.

QUINSY.—(See ABSCESS; TONSILLITIS.)

RABIES.

Prophylaxis.—The sanitary measures adopted in England from April, 1897, to December, 1901, viz., muzzling of dogs in infected areas, lengthy quarantine for imported dogs, and the destruction of stray animals, have effectually stamped out hydrophobia in this country. Pasteur's treatment by vaccination, which has been largely adopted elsewhere, has reduced the mortality to about 0·5 per cent—a result pretty constant all over the world. This figure cannot be taken as absolute, for undoubtedly patients are treated who might not have taken hydrophobia or who were bitten by an animal not actually proved to have been rabid.

Immediate Treatment.—The wound should be immediately and thoroughly cauterized with the actual or thermo-cautery. Antiseptic solutions are of secondary value. Such treatment is probably useless unless applied within twenty-four hours of the bite. (It must be remembered that the slightest abrasion of the skin about the finger-nails, the slightest fissure in a lip, may suffice to admit the virus.)

In cases of doubt the suspected animal should be killed and an emulsion of its medulla injected into rabbits. If the animal has been rabid, the rabbits will develop rabies in two to three weeks.

Immunization or Preventive Inoculation.—This is based on Pasteur's discovery that, by a process of desiccation, the virus in the spinal cords of rabbits that had died of rabies could be so attenuated that its activity disappeared completely in thirteen to fifteen days. By injecting an increasingly strong dilution of virus, an animal—or man—may be immunized against the development of rabies. The incubation period of rabies—the time it takes for the virus to pass from the periphery to the great nervous centres (Roux)—is fortunately a long one, and varies in adults from one to two months.

In the Pasteur Institute of Paris there are three formulæ of treatment,

depending upon the gravity of the bite, its site and character, the length of time that has elapsed, and the consequent necessity for intensifying and hastening the immunization. A fragment of about 3 mm. of a cord that has been drying for fourteen days is mixed in a mortar with 1 c.c. of sterile salt solution or bouillon, and injected. This is repeated daily until an emulsion of a three days' cord is used. In bad cases, for example, of bites on the face, or multiple bites of the limbs unprotected by clothing, the *intensive* formula is used: Four injections are given the first day with cords of 14, 13, 12, and 11 days' desiccation, on the second day with cords of 10, 9, 8, and 7 days' preparation, on the third day two injections of 6 days' cord, and so on. Treatment lasts from fifteen to twenty-one days, and appears free from danger, although it often causes depression, loss of appetite, and malaise.

These formulæ of treatment vary in different institutes. Högyès found Pasteur's method of desiccation uncertain, and introduced that of dilution of one gram of nerve substance of a rabbit, suitably inoculated, with 100 parts of physiological solution. He was then able to study the results of inoculation of dilutions of this standard 1 per cent solution, $\frac{1}{10000}$ not proving fatal to a rabbit and $\frac{1}{5000}$ not giving it rabies with certainty. Thus, for a bite on the head, Högyès would give, the first day, four injections of 3 c.c. each of $\frac{1}{10000}$, $\frac{1}{8000}$, $\frac{1}{6000}$ and $\frac{1}{5000}$ dilution, and one injection of 2 c.c. $\frac{1}{2000}$ dilution.

In spite of the completeness of Pasteur's work, there are not a few problems in rabies still unsolved. The micro-organism is still to be isolated, and a vaccine capable of curing patients in whom hydrophobia has actually developed is still to be found. A scientific scheme of dosage that would establish protection and replace the uncertain method of desiccation would be of immense value.

The Pasteur treatment cannot be obtained in England. In France it is carried out at the Institut Pasteur in Paris (25, Rue Dutot), and also at Lyons, Marseilles, Lille, Bordeaux, and Montpellier. Amongst other places where treatment can be obtained are Algiers, Tunis, Berlin, Buda-Pesth, St. Petersburg, Moscow, Kiev, Karkoff, Odessa, Tiflis, Constantinople, Bucharest, Athens, Turin, Milan, Naples, Bologna, Palermo, Malta, Barcelona, Lisbon, Madrid, New York, Chicago, Baltimore, Rio de Janeiro, Buenos Aires, Kasauli, and Coonoor. A. A. Warden.

RADIOTHERAPEUTICS.

The fundamental principle involved in the use of the x rays in therapeutics is that, after a certain minimum exposure to their influence, changes take place in the living tissues. If the exposure has been short, the changes may not be observable to ordinary inspection, yet it is within the knowledge of all who have had an extensive experience of this subject, that cases of long standing will get well under the influence of a series of such exposures without any visible reaction at any time. This is an ideal state of affairs, but unfortunately not practicable in a large number of cases. As a rule, our aim is to get as near a definite reaction as possible, and this may be done in a single application or may be distributed over several; much depends on the nature of the condition with which we are dealing.

If the dose of the rays has been sufficient to bring about a definite reaction, the change observed is, roughly, a cellular degeneration affecting the epithelium of the surface and the glands, and, to a less degree, the endothelial lining of the blood-vessels. As the degeneration proceeds, inflammatory reaction comes on, the vessels are dilated, and there is marked migration of leucocytes and red corpuscles. The active leucocytosis is one of the essential features of the reaction, and probably the most important agent in bringing about any resulting cure. The changes in the blood-vessels do not occur to any appreciable extent when the milder doses are given; but when the irradiation has been severe, the intima is thickened and swollen, there is proliferation of the endothelium, and the lumen is narrowed and may be completely blocked. In these changes we have some explanation of the extreme chronicity of the severe x-ray burn; it is a case of starvation of the part through loss of blood-supply. The same thickening of the intima is seen after a series of mild doses carried on for a considerable time, and the use of this property in treatment will be referred to later.

The degeneration of epithelium may be looked upon as the result of injury through over-stimulation. The amount of such over-stimulation that any particular type of cell will stand without getting beyond the power of recovery bears a direct proportion to its vitality. If we expose an area made up of normal and abnormal cells to this form of irradiation, and so regulate the dose that the normal cells are still able to recover more or less completely, it will be found that, after healing has taken place, the abnormal cells have disappeared. On account of their lower vitality they have succumbed to a degree of over-stimulation insufficient to destroy normal cells. It is sometimes said that the abnormal cell is more easily destroyed because the x -rays have what is called a "selective action." This is attributing to the rays a faculty more or less human in character, and savours of over-enthusiasm. If true, how is it that normal tissues can be inflamed, and even destroyed, with the administration of doses of the x rays not greatly in excess of those regularly used in treatment? The lower resisting power of the abnormal cell is the more likely explanation; it certainly puts less strain on the imagination.

In the foregoing remarks we have, quite briefly, the histological basis of the philosophy of x -ray treatment so far as it is understood at present. But from observations made there appears to be more in it than this. When a patient with psoriasis has one or two patches irradiated, it has been noticed that other patches, not so treated, get better almost as quickly. The same has been observed in the treatment of chronic acne vulgaris, and other conditions of a kindred nature. With our present knowledge we must be careful not to dogmatize on the matter, but it looks very much as if the irradiation was instrumental in causing the formation of antibodies, or vaccines, and that these have an importance in the curing process equal to any other factor. If such should prove to be the case, the value of the x rays as a therapeutic agent will be very much enhanced, and be a great gain to medical science. It will be seen how the establishment of such a theory will do much to rob x -ray treatment of many of its risks, though under modern conditions of working these have been almost eliminated, especially in the hands of the experienced radiologist.

Apparatus.—With an x -ray outfit for diagnosis, few accessories are needed for carrying out proper x -ray treatment. If an outfit has to be obtained for therapeutic purposes only, it may be less powerful and less elaborate in nearly every way. A coil giving an eight-inch spark of good volume is sufficient, and the interrupter may with advantage be of a very simple type. It is inadvisable to use one that gives a very high rate of interruption, and therefore the old-fashioned "dipper" pattern is as useful as any. Many of the high-speed breaks can be set to run comparatively slowly, and so answer our purpose. The disadvantages of high-speed breaks are that they very readily bring about an overheating of the x -ray tube and alter its vacuum, which, in turn, alters the character of the rays given out by it.

The tube-stand should be so made that the tube may be adjusted and secured in any convenient position. The tube must be enclosed in an x -ray-proof shield, fitted with an opening opposite the point from which the rays are given off, and through which the rays must pass to the part under treatment. To this opening nozzles of lead glass can be attached, and as these are of different sizes and shapes, we can confine the action of the rays to any desired area. The rest of the patient's body, and the operator, are fully protected from any injurious influence of the x rays. Protective devices of the most elaborate kind have been designed at various times, principally on behalf of those who have been so unfortunate as to contract chronic x -ray dermatitis. For such as these no protective device or precaution can be too elaborate; but it may be pointed out that, for those who are taking up this work for the first time, or who have not suffered from over-exposure in any way, a tube-stand, as above referred to, is quite sufficient so long as a few common-sense rules are observed. No radiologist should ever get within the active field of an x -ray tube unless absolutely necessary, and then only for the shortest possible time, which seldom need exceed a few seconds. He should always stand behind the plane of the antikathode, and if possible at a distance of two metres from the tube. When it is necessary to go into the active field, protective gloves should be worn, and if the fluorescent screen is used, it must be faced with a

sheet of lead glass. It is quite possible for the operator to do a morning's work without coming within the active field of the tube even for a moment, while keeping every part of the apparatus, as well as the patients, under full observation. With our present knowledge and available appliances there should be no occurrence of further cases of chronic x -ray dermatitis; if any arise they will be due entirely to the carelessness and negligence of the victim himself. The unfortunate experiences of the past make it necessary to be very explicit on this point.

Dosage.—The measurement of the dose of the x rays is a subject that has engaged the attention of some of the greatest authorities in physical science, but the result is far from satisfactory. As yet, the means at our disposal depend on the action of the rays on certain inorganic substances, and while these answer our purpose up to a certain point, the fact remains that the effects on organic living tissues and on inorganic dead material do not run on strictly parallel lines. On the other hand, by making ourselves thoroughly familiar with one or other of the methods that have been elaborated for x -ray measurement, we find that the standard dose can be fractionally divided, or, when large doses are required, can be multiplied, with results that are fairly satisfactory in practice.

It would be outside the scope of this article to attempt to describe even a small proportion of the various methods that have been recommended; such may be found in some of the large works devoted entirely to these branches of science. The method advised is that described by Sabouraud and Noire, which depends on the property possessed by platino-cyanide of barium of changing colour under the influence of the x rays. This is the method very largely employed in the treatment of ringworm, and, used according to the directions, the standard dose represents just so much as the skin will bear without an active dermatitis following, but sufficient to cause the hairs to fall out.

Latterly we have been able to obtain x -ray tubes specially designed for therapeutic work, and the advantage of these is that the vacuum can be adjusted to almost any degree, and by means of an automatic regulator can be kept practically constant for any length of time needed in practice. The standard Sabouraud dose requires that the "hardness" of the tube should correspond to No. 7 Benoist scale. The tube holder is so arranged that the area under treatment is kept at a distance of 15 cm. from the antikathode, and the small pastille is suitably placed exactly midway between. This must be protected from ordinary light during the application. When the full dose has been given, its colour will have changed from a greenish-yellow to an orange tint. With each set of pastilles is provided a standard tint with which the one in use is compared from time to time until the two exactly match. Using a current through the tube of about one milliampère, this will take from seven to fifteen minutes, but a great deal depends on the apparatus and the person in charge of it. The comparison of the pastille must be made with the minimum exposure to ordinary light, which changes the colour back to the original one, and this especially applies to daylight. If the comparison is made by electric light (metal filament lamps), the tint is arrived at sooner than when the comparison is made in good daylight. Latterly the instructions have directed daylight to be used, so when the full pastille dose is not desired, we may compare the tints by artificial light. This gives us a fair margin of safety, and is useful where we want to give repeated doses over an extended period.

When fractional doses are desired, we must arrange for our apparatus to work always under exactly the same conditions, and then note the time it takes to give the full pastille dose. If this should be sixteen minutes, a half dose could be given in eight minutes, and so on. Fractional doses may be given

two or three times a week until a slight erythema occurs, but if the full pastille dose is given, it should not be repeated under fourteen days, and not then if there is any definite reaction.

Whatever type of *x*-ray tube is used, a certain amount of difficulty will be encountered in getting it to work evenly, especially when new. If the current through it is below a certain strength, the tube will become gradually harder; if above, it will get softer through overheating. When the current is right for any particular tube, it will work for a long time without altering to any serious degree. This latter is the critical current, and should be ascertained at the earliest possible moment; having found it, the tube, if very soft, as most new tubes are, should be worked with a current very slightly less, until it has become as hard as we require. This may take minutes or hours to accomplish, but it is always worth doing, since the tube thereby acquires a state of stability that gives more even and certain results.

It must be remembered that the pastille dose given under the conditions described above is the one used for treating ringworm, and is just sufficient to cause epilation but not permanent baldness. This we have spoken of as a standard dose. As we advance into the subject of radiotherapeutics, it will be found that radical departures from this standard must be made if we are to attack in a proper manner the various conditions that come to us for treatment.

We have referred to "hard" and "soft" tubes: the peculiarities of the "soft" variety are a low vacuum and a low resistance; the rays from them have slight penetrating power, and, being absorbed by the superficial layers of the skin, readily set up radio-dermatitis: the action of a soft tube on the tissues is superficial but very intense. The rays from a "hard" tube are more penetrating, but less active in producing reaction or dermatitis. Consequently, we must select our tube to suit the conditions present: if we want to reach a deeply seated part, a hard tube must be used, the distance from the surface must be increased, and the exposure varied as the square of the distance; this gives a more even irradiation of the deeper tissues. It is doubtful whether the pastille is quite reliable in this particular class of work, and it becomes less so when we resort to the use of filters for cutting out the less penetrating rays, or for making the pencil of rays more homogeneous.

When stating the peculiarities of soft and hard tubes, it should have been mentioned that rays of every degree of penetrating power come at the same time from every tube that is in a condition to give out *x* rays. The difference in the output of tubes of different degrees of hardness is, that in the case of a soft tube, for instance, the rays of low penetrating power predominate, but a few highly penetrating rays also are given off. Conversely, a hard tube gives off a preponderance of highly penetrating rays, and but few rays of low penetrability. When treating deeply seated parts, the rays of low penetrating power are not only not required, but are at times very inconvenient through setting up dermatitis, perhaps long before we have given the case as much treatment as we think advisable.

It was to meet this difficulty that the first attempts were made to interpose in the path of the rays some substance which would have the effect of absorbing the soft rays and yet have little or no influence upon the passage of the hard rays. Various substances have been tried, but the only popular one is sheet aluminium. Very useful thicknesses for general purposes are 0.25 mm. and 0.33 mm.: the proportion absorbed by any given sheet of metal depends on the hardness of the tube. The softer the tube the greater the proportion that is filtered out. With a tube having a hardness of No. 7 Benoist, a sheet of aluminium of 0.33 mm. thickness will absorb approximately one-half of the

output. Thus, if we use such a tube and a pastille properly placed, and interpose this thickness of aluminium, by the time the pastille has changed to tint B a half-pastille dose will have been given.

It should be remembered that the rays most prone to produce surface reaction are most easily absorbed by a filter, and for this reason it is possible to give a series of half-pastille doses at short intervals without danger; but half-pastille doses without filtration would be dangerous and unjustifiable.

The various modifications in dosage that may be carried out are very numerous, and would require too much space to describe in detail. The *x-ray filter* is of special use in the treatment of diseases of bone, leukaemia, and deeply seated tumours, such as fibromata. For very deep lesions the filter may be as thick as 5 mm. with advantage, but it will take about an hour to give an ordinary dose. The primary reaction that frequently follows a few hours after the application to a sensitive part, such as the face, may be prevented by interposing an aluminium filter only 0.1 mm. thick. On account of secondary radiation from the metal, the filter should not be placed too near the skin; midway between the tube and the skin surface is a good position.

It must be carefully remembered that the harder the tube the less active, therapeutically, are the rays from it; also that, when we use a filter, the rays most easily stopped by it are the more active ones. Consequently, in treating deeply seated lesions, exposures have to be very long, and the wear and tear on tubes is considerable.

It will be gathered from the foregoing that there are numerous difficulties to be overcome in learning the successful practice of *x-ray* therapeutics, and that many of them can be mastered only after considerable experience. Though it is possible to carry out some of the milder forms of *x-ray* treatment without much practice, such treatment is bound to be of the rough-and-ready type and not without risk. Anyone wishing to take the matter up seriously should attend a place where such work is carried on along proper lines and on a more or less extensive scale. The experience gained under such conditions will prove invaluable.

Practical Application.—The suitability of any particular case for treatment by radiotherapeutics will depend on several circumstances, the chief of which is its anatomical relation to the surface of the body. It may be taken as an axiom that the more superficial the lesion, the more likely is it to be favourably influenced by the *x* rays. It thus happens that it is in the treatment of diseases of the skin that it finds its greatest field of usefulness, and it is fortunate that it is among these conditions, usually very resistant to the more ordinary methods of treatment, that its effects are the most striking.

As an instance of this, take the case of *acne vulgaris*: the way this can be made to clear up under a course of *x-ray* treatment is at times quite remarkable, and sometimes we find parts untreated getting well almost as soon as those that have been treated. It is this that has suggested the possibility of antibodies being set free and acting as vaccines. Another condition that responds very well is *psoriasis*. This disease is not permanently cured, but it rapidly clears up, even in patches that have not been directly exposed, and it is easily kept in hand by a few applications at intervals of a few months. As *x-ray* treatment does away with the use of the messy ointments usually prescribed, patients are very appreciative. *Chronic eczema* also is a disease that at times responds excellently. In all these we may give nearly full pastille doses at intervals of two or three weeks, or smaller doses may be given more frequently; but care must be taken not to carry on the treatment too long or to set up *x-ray* dermatitis. The technique for the treatment of *ringworm* is described under its proper heading, and need not be repeated here.

With regard to *lupus vulgaris* the x rays are most useful in clearing the more active and ulcerative forms up to a certain point, when the improvement frequently fails to go further. At this stage the Finsen method comes in, and if thoroughly done, a cure follows as a rule.

For *rodent ulcer*, pastille doses are given every two or three weeks and are very successful; before each treatment the surface must be thoroughly cleaned with a small spoon.

Pruritus and *nervous itching of the skin* are relieved by x -ray applications; the effect is due apparently to some influence on the nerve endings. This relief of pain was one of the first things noticed in the treatment of painful cancers, and it has been tried in neuralgia with much success. Some writers have claimed good results in that very troublesome form of *nævus* known as the *port-wine stain*. In the milder cases it may answer, but it must be remembered that, if several more or less severe applications have to be given, there is a danger of telangiectases forming some months after which might be quite as unsightly as the original mark. The effect produced upon the inner coat of the small blood-vessels—thickening of the intima and narrowing of the lumen—is taken advantage of in dealing with *redness of the nose*. This condition is not only unsightly but, being frequently associated with alcoholism, is very distressing to those who suffer from indigestion and seldom if ever touch alcohol in any form—especially ladies. An application of x rays from a hard tube, given two or three times a week for from five to ten minutes to each side, at a distance of about ten inches from the antikathode, is usually very successful. The case requires very close attention, and treatment must be suspended on the slightest sign of reaction.

Many of the first efforts to deal satisfactorily with *hypertrichosis* were not successful; in fact, there were cases where the result was worse than the original condition. There is no reason, however, why this should be so now, and by following out a proper technique a good result can be obtained. If the case is one with a comparatively small number of long and strong hairs, it should be treated by electrolysis, as described under ELECTROTHERAPEUTICS. The cases most suitable for x -ray treatment are those with numerous small hairs on the upper lip and chin of female patients. Electrolysis would be too tedious and would leave a large amount of scar tissue behind, so altering the texture of the part that we should get little thanks for all our trouble. Noire has elaborated a technique that in his hands appears to answer well. He gives pastille doses exactly as for epilation, except that he interposes an aluminium screen 0.4 mm. thick between the tube and the part under treatment. This has the effect of filtering out the rays that would otherwise be absorbed by the upper layers of the skin, and the brunt of the attack is borne by the hair follicles. The application is repeated at intervals of a fortnight at first, and later on, of a month. From eight to ten applications are required, and the result is said to be permanent. The whole process must be carried out with care and skill if the result is to be satisfactory. Good results can also be obtained by giving fractional doses two or three times a week, using a suitable filter. This is based upon the permanent epilation that follows treatment for other conditions, such as lymphadenoma, where no reaction has occurred at any time, owing to the use of filters made by soaking lint in a saturated solution of sodium tungstate and drying on a horizontal flat surface to keep the distribution even. This was one of the earliest filters used, and answered quite well, but sheet aluminium of known and definite thickness is more scientific and satisfactory.

The same technique may be used in the treatment of *hyperidrosis*, with excellent results. When the condition is accompanied by an offensive smell,

it is very distressing, especially for ladies: and until the *x*-ray method was employed no treatment had proved of much value.

Various forms of *neuralgia* are frequently relieved by a few applications of the *x* rays. Hard tubes are best, and the dose depends on the depth of the lesion, this also determining the thickness of the filter. Cases ranging in depth from a trigeminal neuralgia to sciatica are very frequently relieved—sometimes after a single application.

The enlarged thyroid gland that accompanies *exophthalmic goitre* responds to *x*-ray treatment very satisfactorily as a rule. A medium hard tube is used, with a filter of about 0.5 mm. of aluminium. The application is from one-third to one-half of a pastille dose, and may be given twice weekly at first. After a month or so shrinking is perceptible, and the gland gradually returns to about normal dimensions in favourable cases. The *exophthalmos*, *dyspnœa*, and palpitation also improve concurrently, and the patient returns to a more normal state.

Another condition that has been successfully dealt with is that of *tuberculous glands of the neck*. We must be careful to avoid anything like dermatitis, but treatment should be more or less bold. If it is carried out properly, a large proportion of cases can be cured to all intents and purposes, and operation avoided.

Deeper conditions, such as *tuberculous periostitis*, also respond well at times, but here we must use harder tubes and thicker filters, so that the lesion receives full treatment before the skin begins to suffer.

The method has likewise been found useful in *enlarged prostate*, bringing about a shrinkage of the gland and relief of symptoms. It is advisable to expose the testicles also in elderly subjects; this causes atrophy and a physiological castration, with its attendant benefit in this condition.

The *x* rays have been much employed in the treatment of *leukæmia*, and if the only trouble in this disease were due to the presence of an excess of leucocytes in the blood, the method would be entirely satisfactory. It is a matter of common experience in the *x*-ray treatment of such cases that the blood-count is brought to normal or nearly so, and kept there by exposures at intervals, yet the patients are not by any means cured, though many of them appear to be benefited in a marked degree. It frequently happens that they die quite suddenly and for no apparent reason, the blood-count being practically normal at the time of death. Still, we know of nothing that has better results, and as the patient is often made to feel more comfortable, it may be worth trying in a proportion of cases. Most treatment has been applied to the spleen area, and after that to the ends of the long bones and the sternum. The spleen sometimes diminishes very rapidly in size, but the *x*-ray doses must not be heavy at first. Owing to the breaking up of a large number of cells, symptoms of severe toxin poisoning have followed vigorous applications. Many observers are now of opinion that the effect is chiefly on the blood itself, and that the treatment may be applied to any part of the body with equally good results, and there is much to be said in support of this view.

The *x*-ray treatment of certain forms of *uterine myoma* has now attained a recognized place in therapeutics. Diminution and arrest of hæmorrhage, relief of pain, and shrinkage of the growth have been observed so frequently that the method is gaining a popularity that seems to be deserved. The technique varies according to different authorities, but all use very hard tubes with a filter of 3 mm. of aluminium. Each application may be 1.5 Sabouraud, and nine of these may be given during the inter-menstrual period. This process may have to be repeated twice or three times before the relief is complete. The applications are to be made from as many different points as possible, on the "cross-fire" principle, to save the skin from possible dermatitis.

With regard to the question of *malignant disease*, sarcoma and carcinoma, there is no evidence as yet to show that the *x*-rays can be considered in the light of a *cure* for either; certainly not at the stage when such cases reach the hands of the radiologist. The cells that make up a malignant growth are, by virtue of their lower vitality, more easily destroyed by the rays than are normal cells, and if we could efficiently apply the rays to the spreading margin of the growth, we might achieve a considerable measure of success. Unfortunately, we can apply them only through the main mass of the tumour, and all the rays likely to do much good are filtered out by the overlying tissue before the growing margin is reached. For this reason the *x*-ray treatment of cases of malignant disease that have been pronounced inoperable is more or less futile, so far as any chance of cure is concerned. On the other hand, it seems to be fairly certain that the rays have an inhibitory effect on the spread of the disease; the growth frequently shrinks to some extent, and almost always there is relief of pain when present; this latter is among the most constant of the effects of a course of *x*-ray treatment. It should also be mentioned that the way some malignant growths, especially sarcomata, disappear under the rays is quite remarkable, though of course a cure does not necessarily follow; the rule is for dissemination to set in sooner or later, and the case comes to an end.

To state the matter briefly, *x*-ray treatment is of distinct benefit to the subjects of inoperable malignant disease; they can be made more comfortable, and life is frequently prolonged to a considerable extent; more than this one cannot say. There seems little doubt that operable cases should undergo a course of *x*-ray treatment as soon as possible after the operation. If this were done as a matter of routine, there would in all probability be fewer recurrences.

The *x* rays have been employed in numerous other diseases with varying success, but enough has been said to show that the method not only has a real value, but has established itself as an important factor in the treatment of many diseases. (See also RADIUM THERAPY.)

Reginald Morton.

RADIUM THERAPY.

TECHNIQUE.

Form of Radium Employed.—Radium is employed, in the treatment of disease, either in the form of radium salts or radium emanation.

Radium salts are used in two ways, as follows :—

1. Distributed over flat, varnished applicators, rectangular, square, and circular, the superficial area of the various applicators ranging from 1 to 30 sq. cms. These may be :—

a. Full strength, containing an amount of radium sulphate equivalent to 10 mgrams of radium bromide to each square centimetre.

b. Half strength, containing an amount equivalent to 5 mgrams.

c. Quarter strength, containing an amount equivalent to 2.5 mgrams.

2. In capillary glass tubes, filled with radium sulphate, closely packed so as to prevent any movement of the salt.

Radium emanation is also employed in two ways, thus :—

1. Collected in glass tubes or metal containers, and used with appropriate screens, exactly as the radium salts themselves are used—due regard being paid to the gradual fall in radio-activity resulting from the decay of the emanation.

2. Dissolved in distilled water, or in a weak saline solution, and administered by drinking or injection.

Screens.—The screens employed as filters for the different rays are :—

1. *Aluminium*, 0.01, 0.02, 0.04, 0.08 mm. thick. These are principally used with short exposures in the treatment of capillary naevi, pruritus, neuro-dermatitis, and superficial skin lesions.

2. *Silver*, 0.5 and 1 mm. thick. These are most useful as shields for the glass tubes of radium when introduced into tumours, and also in the treatment of keloid and vicious cicatrices.

3. *Lead*, 0.1, 0.2, 0.4, 0.5, 1, 1.5, and 2 mm. thick. Screens less than 0.5 mm. in thickness are valuable in the treatment of flat superficial epitheliomata, leucoplakia, fibromata, and granulomata.

Those exceeding 0.5 mm. are used when it is desired to employ the hard *beta* and *gamma* rays only, and to give prolonged applications without causing any surface irritation.

Duration of Applications (Exposures).—1. *Very short exposures* of half a minute to three minutes' duration, according to the age of the patient and the character of the lesion. Principally used in the treatment of superficial skin troubles. The apparatus is applied without any screen beyond that afforded by a covering of thin rubber sheeting.

2. *Short exposures* of five minutes to one hour's duration. Most frequently resorted to when treating warts, senile keratoma, some forms of *nævi*, shallow ulcers, lupus erythematosus, etc. The screening in these exposures rarely exceeds 0.04 mm. of aluminium.

3. *Moderately long exposures* of one to eight hours, adopted when it is desired to obtain the destructive action of the rays. Used in cases of rodent ulcer, rapidly growing epithelioma, lupus vulgaris, etc. No screening beyond thin rubber sheeting is employed, and a total exposure of three to eight hours is extended over two, three, or four days.

4. *Prolonged exposures* of twelve to one hundred hours, or longer. These are employed in the treatment of deep-seated malignant growths, in cancer of the rectum, uterus, breast, etc. Lead screens are always employed, usually of 2 mm. thickness. Exposures are given in periods of six to twelve hours, with an interval of at least twelve hours between successive exposures.

Screens, Appliances, and Methods of Application.—A varnished applicator is always covered with a thin layer of rubber sheeting, thus effectively protecting it from contact with any excretions or moisture, and avoiding the necessity of repeatedly cleaning the apparatus.

When silver or lead screens are used, the passage of the gamma rays through these metals gives rise to secondary rays which are very irritating, though their action is superficial only, and it becomes necessary to absorb these rays. With this object, from six to twenty-four sheets of black photographic paper and one or two layers of lint are interposed between the metal screen and the outer rubber covering. When tubes shielded with lead or silver screens are introduced into the vagina, rectum, uterus, etc., they are enveloped in rubber tubing of 3 mm. thickness for the same purpose. These secondary rays vary greatly in amount, according to the nature of the metal and the thickness of the screen employed.

The lesion to be treated is gently cleaned and dried, and all crusts or flakes of secretion are removed. The healthy skin and tissues surrounding the lesion must be carefully protected by a layer of lead-rubber sheeting—similar to that used in x-ray work—an aperture being cut in the sheeting the exact size and shape of the lesion. For external lesions, the apparatus is best fixed in position with some non-irritant adhesive rubber plaster.

To retain tubes in the vagina or uterus, the employment of a tampon is generally necessary. In the rectum, and nasal and buccal cavities, the apparatus is attached to a handle of thick silver wire, which can easily be bent and fastened to the gluteal fold, cheek, or ear by adhesive plaster.

The Reaction.—All tissues when treated with radium respond in some

manner, but the nature and extent of this response vary very greatly, and depend upon :—

1. *The apparatus, screening, and dosage employed.*

2. *The nature of the tissue treated.*

3. *The condition of the tissue treated.* If x -rays, ionization, CO_2 snow, etc., have been previously used in the attempts to bring about a cure, the reaction is frequently atypical, and repair is exceedingly slow.

4. *The extent of the area treated.* The reaction is dependent, not only upon the strength of the applicator, but also upon its superficial area. For example, the reaction from an applicator of half strength applied over an area of 4 sq. cm. is often not more intense in degree than that obtained with an applicator of quarter strength over a surface area of 16 sq. cm.

5. *Personal idiosyncrasy.* This is most important, and often productive of curiously puzzling results. In this respect, factors to be considered are age, sex, and temperament, susceptibility to actinic rays generally—e.g., in persons who suffer much from freckling or solar eczema—hyperidrosis, exalted vasomotor sensibility, etc.

Nature of Reaction.—The reaction usually appears between the seventh and fifteenth days, and may vary in character from a slight erythema to a destructive ulceration.

Four degrees may be clearly distinguished :—

(1) Simple erythema ; (2) Erythema followed by desquamation ; (3) Vesication with superficial ulceration ; (4) Deep ulceration, sometimes accompanied by the production of an eschar.

With some patients the time of reaction is much delayed, while with others the response is exceedingly prompt, and it is difficult, if not impossible, to say why this difference should be. It is particularly noticeable in the treatment of capillary naevi, and cases have been seen in which, instead of the reaction appearing on about the seventh or eighth day, it has been evident three days after the exposure ; in others a period of four weeks has elapsed before any effect has been perceptible ; though in all of these cases the applicators employed, the screening, and the times of exposure have been identical.

The increased susceptibility to changes of temperature over areas that have been treated with radium is very remarkable, and many patients who have had rodent ulcers and superficial skin lesions cured with radium state that they experience great discomfort at the site of the old lesion when very cold or very warm air plays upon it. This susceptibility, however, gradually returns to the normal in two or three months.

A very marked condition of lethargy is frequently, it might almost be said invariably, noted in patients receiving prolonged exposures with large quantities of heavily screened radium. It generally makes its appearance about the fourth day of the treatment, and passes off within a few days of the cessation of the exposures.

THE TREATMENT OF DISEASE.

Carcinomata.

Squamous-celled Carcinoma (Epithelioma) of the Skin.

Very different results are obtained with epitheliomata affecting the glabrous skin as opposed to those involving mucous surfaces.

Epitheliomata of the face, trunk, or extremities, if flat and superficial, and accompanied by little or no ulceration, give satisfactory results when treated with quarter- or half-strength apparatus, screened with 0.2 mm. of lead, the exposures varying from six to twelve hours' duration, spread over a period of three or four days. The retrogression of the growth is quickly brought about, and little or no scarring results.

Ulcerating epitheliomata, without much subjacent infiltration, require treatment with quarter- or half-strength apparatus applied unscreened, for a total exposure of two to six or eight hours, spread over a period of four or five days, and repeated after an interval of six weeks if necessary. A destructive reaction follows, but the result is usually quite good, and there is but little cicatricial contraction.

Ulcerated epitheliomata, with great infiltration, require prolonged treatment with heavily-screened apparatus emitting "ultra-penetrating" rays. Exposures of thirty to sixty hours, given during one week, and repeated in five or six weeks' time, are best; but if the growth show signs of rapid extension, the borders should be given a vigorous treatment with unscreened apparatus.

Epitheliomata in Association with Mucous Membranes.—Epitheliomata of the tongue, and of the buccal, gingival, and pharyngeal mucous membranes, are almost uniformly disappointing in their ultimate response to radium therapy. Temporary improvement is not infrequently seen, and this sometimes goes as far as disappearance of the original lesion; but the treatment has practically no effect in preventing or delaying the appearance of metastatic deposits in the cervical glands and elsewhere.

The rate of growth of the infected glands can often be retarded by the prolonged and persistent use of the "ultra-penetrating" rays. If the dose given be a large one, the glands sometimes break down and discharge a milky-white fluid through a small sinus, and it is remarkable that ulceration of glands thus treated rarely occurs.

Considerable difficulty is experienced in giving satisfactory exposures within the oral cavity, as patients are often unable to tolerate the presence of applicators in their mouth for the necessary length of time, and should the reaction be at all pronounced, the congestion of the tissues occasions great discomfort. There is the further danger that a severe reaction may act as a stimulus to the original growth, increase its size, and hasten metastasis.

A method of treatment has recently been introduced which is well worth a trial in suitable cases of cancer of the tongue; it consists in burying within the carcinomatous nodule a small, but intensely powerful, radium emanation tube, possessing an initial activity equivalent to 80 or 100 mgrams of radium bromide, enveloped in a screen of 1 mm. of silver or 0.4 mm. of platinum, and giving an exposure of twenty-four hours' duration. A fairly severe reaction results, and in some cases the nodule ceases to grow, and becomes replaced by dense fibrous tissue.

Epitheliomata of the Vaginal and Uterine Mucosa.—These conditions are more amenable to the action of radium, and some distinctly encouraging results have been obtained.

Small primary growths of the vaginal mucosa, unaccompanied by much deep infiltration of the vaginal tissues, may be completely eradicated by treatment with full-strength or half-strength apparatus, with an unscreened exposure of one to three hours.

With larger ulcerated and deeply infiltrating growths, radium is best applied heavily screened, and with prolonged exposures of from thirty to sixty hours, healing over a week or ten days. This frequently checks the rate of growth, heals the ulceration, and lessens the amount of infiltration.

Secondary non-ulcerated deposits in the cellular tissue of the vagina often respond extremely well to treatment with the "ultra-penetrating" rays, and in some instances the deposits completely disappear.

Carcinoma of the Uterus.—In cases of inoperable malignant disease in this situation, radium will often bring about results which cannot be attained by any other known method of treatment. The hæmorrhage is arrested, the

discharge is diminished in amount and rendered inoffensive in character, the ulceration is healed, and the pain is greatly relieved. The rate of growth is checked, and sometimes completely arrested; and the surrounding infiltration and induration are so much lessened that, in a few instances, cases previously declared to be inoperable become operable.

The treatment is best carried out by the introduction of a tube containing 50 to 100 mgrams of radium, screened with 2 mm. of lead and 3 mm. of rubber, into the cervical canal, or, if this be not practicable, into the posterior fornix, a large flat strong applicator screened with 2 mm. of lead being placed on the abdominal wall over the fundus of the uterus. The exposure should be prolonged, and should be from thirty to sixty hours' duration, spread over a period of from five to ten days. The series of exposures should be repeated at intervals of not less than six weeks.

The action of radium is, however, only local, and though it may, and often does, check the rate of growth, yet, in most cases, dissemination will sooner or later occur, and the disease spread to parts beyond the effective range of radium.

Great caution must always be observed in treating recurrence in the vagina within six months of the performance of a Wertheim's hysterectomy. The extensive and elaborate dissection which is unavoidably associated with the performance of this operation appears seriously to impair—for some few months at least—the functions of the trophic nerves of the pelvic contents; and a treatment within the vagina, of a strength and duration which might quite safely be given under ordinary conditions, may be followed by an intense and severe destructive reaction. It is, therefore, inadvisable to use more than 50 mgrams of radium bromide; and the exposure should not exceed twenty hours' duration, which should be spaced over four or five days. A lead screen, 2 mm. in thickness, should be employed, and the non-affected portions of the vaginal wall carefully protected with gauze packing.

Carcinoma of the Rectum and Intestine.—Radium therapy not infrequently proves of considerable value in the treatment of these carcinomata, but it is extremely difficult to say what are the factors which determine, or contribute to, the success of the treatment.

Speaking in general terms, the application of radium results in the arrest of hæmorrhage, the healing, partial or complete, of any ulcerated surface, a diminution of the amount of the discharge, less pain, and a retardation of the rate of progress. In some instances more striking changes manifest themselves. The growth shrinks in size, undergoes a fibrous transformation, and becomes much less fixed to the underlying tissues; so that a carcinoma, which before radium treatment was regarded as inoperable, can be easily and completely removed.

A few patients manifest an unusual degree of susceptibility to radium when applied within the rectum, and a relatively short treatment of eighteen to twenty-four hours with heavily screened radium is followed by a severe, though transient, proctitis.

The cases which are most favourable for radium treatment are those in which the growth is annular in type, and situated in the upper half of the rectum; though a successful result, in these instances, means the production of a fibrous stricture at the site of the original growth.

The routine method of treatment in rectal cases is the introduction—through an operating sigmoidoscope, if necessary—of 50 to 100 mgrams of radium, screened in 2 mm. of lead and 3 mm. of rubber. It is maintained in position by a stem of soft silver wire, which is bent at an acute angle at the anal orifice, and fastened by strapping and a T bandage in the fold between the buttocks.

Each exposure is from six to twelve hours in duration, and is repeated daily until a total treatment of thirty to sixty hours has been given. The series should be repeated after an interval of six weeks.

Carcinoma of the Stomach.—Inoperable cases of cancer of the stomach may be treated with radium, not in the hope of cure, but with the object of checking the growth and alleviating the symptoms.

Some slight degree of benefit usually results from the application of powerful apparatus, screened with 2 mm. of lead, over the gastric region, the pain being lessened, the frequency of vomiting decreased, and the general health improved.

Carcinoma of the Breast.—The results of radium therapy in the treatment of cancer of the breast are, on the whole, encouraging; and this is especially the case when the primary growth is of the sclerotic rather than of the medullary type, and when the secondary deposits occur in the skin lymphatics and lymphatic glands, and there are no internal metastases.

Radium should never be used as a substitute for operative interference; but when the case is inoperable, it will do much to relieve pain, promote the healing of ulcerated surfaces, and check the growth of the secondary deposits. In not a few cases it will bring about the almost complete absorption of superficial carcinomatous nodules and infected glands. Instances have been noted in which the physical signs were strongly suggestive, if not positively indicative, of carcinomatous deposits in the lungs; and the prolonged application of from thirty to forty hours of a large quantity of radium, screened through 2 mm. of lead, has brought about an apparent resolution. In rapidly growing cancers of the encephaloid type, radium can do little but relieve pain. The post-operative lymphatic engorgement of the arm on the affected side is sometimes distinctively benefited by the application of a heavily screened tube of 50 to 100 mgrams of radium, placed at the apex of the axillary cavity, an exposure of twenty-four to thirty hours, spread over five days, being given.

Page's Disease.—The external lesion of this condition is generally rapidly healed by radium, an hour's exposure to a half-strength applicator, unscreened, usually producing the desired effect. The disappearance of the skin lesion must not, however, be regarded as an indication of the cure of the disease, which will steadily progress to a fatal termination unless operative interference—or, if this is impracticable, heavy dosage with screened radium rays—be adopted.

Rodent Ulcer.—This is, of all forms of malignant disease, the one which is most amenable to the action of radium. Untreated rodent ulcers, not exceeding 2 cm. in diameter, and not affecting mucous membrane, cartilage, or bone, almost invariably yield to one exposure of one to three hours' duration with a full-strength unscreened applicator.

If the ulcer occupy a large superficial area—say, 20 sq. cm. and upwards—an unscreened application over the whole area, at the same time, is inadvisable, in view of the severe systemic disturbance which would follow such a procedure; and the lesion should be treated by two, three, or four applications, applied in rotation to different parts of its surface, at intervals of three weeks or a month.

When a mucous membrane is affected, rodent ulcers prove much more refractory; though an exception should, perhaps, be made in regard to the palpebral mucosa, as small rodent ulcers in this situation often respond well to exposures of strong unscreened apparatus, of fifteen to twenty minutes' duration, given consecutively for three days.

If the rodent ulcer has attacked bone or cartilage, great care must be exercised not to give too heavy an exposure, or a very acute, painful, and prolonged inflammation may be produced.

When the extent, position, or character of the ulcer precludes the possibility

of strong unscreened exposures, the best results will probably be attained by prolonged exposures with heavily-screened apparatus, using the "ultra-penetrating" rays only. This method is followed by little or no active inflammatory change, and, in addition, often alleviates the pain of the ulcer in a very definite manner. The action of radium in these cases can be greatly aided by judicious skin-grafting as soon as the base of the ulcer has assumed a healthy appearance.

Many of those ulcers which have received treatment extending over a period of many years with x rays, zinc ionization, CO_2 , etc., respond badly to radium treatment; and it is unwise to attempt to make any pronouncement as to the probable result. Quite frequently the previously treated tissues break down to an extent which far exceeds the existing ulceration, and repair is very slow and imperfect.

For the purpose of prognosis rodent ulcers may be classified into two well-marked clinical types:—

1. The nodular and hypertrophic form, with but slight and superficial ulceration. This responds well to radium treatment, and yields the most satisfactory results.

2. The excavated form, with undermined and overhanging edges and a gelatinous base. This is always difficult to cure, and not infrequently proves intractable to all methods of radium therapy.

Sarcomata.—Whenever possible, sarcomata are best treated by the insertion into their centre of a tube containing 50 to 100 mgrams of radium, with a screen of 0.5 or 1 mm. of silver; it is left in position for twenty or thirty hours; the application is repeated after a month. This frequently proves most effective; the tumour steadily shrinks in size, and becomes replaced by a dense fibrous nodule which shows little or no tendency to grow.

If this method be impracticable, prolonged exposures with flat applicators, screened with 1 or 2 mm. of lead, and placed so as to cover as great an extent of the growth as possible, and to produce a "cross-fire" action of the rays, will often do much to check the growth; but this procedure is not nearly so promising as the preceding one. In either case, it is essential to give as vigorous a treatment as possible, as the great vascularity of these growths, and their rapid and wide dissemination by the blood-stream, are factors which militate very strongly against the chances of success.

Nævi.

Flat Superficial Nævi (Capillary Nævi, "Port-wine" Stains).—These are the most difficult of all nævi to treat, and much care and patience must be exercised in order to bring about a satisfactory result.

The factor of personal idiosyncrasy is always prominent, and it is exceedingly difficult to lay down any definite rules as to strength and duration of exposure. It is best to proceed with great caution, giving a short, unscreened exposure, and, if necessary, gradually increasing the same until a satisfactory reaction has been obtained. As a general rule, apparatus of quarter or half strength should be used, the screening should not exceed 0.02 mm. aluminium, and the exposures should range from ten to sixty minutes' duration.

The best results can be looked for when the nævus is quite superficial and shows no tendency to infiltration. If much infiltration exist, the treatment will have to be much more vigorous, and a destructive reaction of slight degree produced. A smooth, supple, and white scar will be left.

Cavernous Nævi.—These lesions are frequently particularly suitable for "cross-fire" treatment, and in such cases good results can generally be expected.

Half-strength applicators should be used, with screens of 0.1 mm. lead, and exposures of from twenty minutes to one hour's duration, given daily for three consecutive days, and the series repeated in a month's time. Under this

method of treatment, the nævus slowly and steadily shrinks, and the process is unaccompanied by any surface irritation.

Keloid.—The results obtained with radium in the treatment of this condition are admirable. Keloids of recent formation, and occurring in young subjects, are the most easily cured. Applicators of half strength should be employed, with screens of 1 mm. of silver, and an exposure of from fifteen to twenty hours given, extended over three successive days. The series should be repeated at intervals of one month. By this method of treatment a steady and gradual return of the tissues to the normal is produced, without any surface irritation.

Small elevated and rapidly growing keloids may be safely treated by a single exposure of one to one and a half hours' duration, with a half-strength unscreened apparatus. The resultant scar is usually quite smooth and supple, and shows no tendency to further keloidal formation.

Parotid Tumours.—These growths appear to be peculiarly susceptible to radium, and in almost every instance distinct improvement, frequently going on to apparent cure, is observed. The treatment must, however, be lengthy, and much patience and perseverance are needed to bring about a successful result. Applicators of half or full strength should be employed, and screened with 2 mm. of lead; the tumour should, if possible, be covered over its whole extent, and the exposures should be of not less than thirty hours' duration, extended over five days. The series of exposures should be repeated at intervals of four to six weeks as long as is necessary.

Fibroid Disease of the Uterus.—The symptoms of this condition—menorrhagia and metrorrhagia—are almost invariably greatly improved by radium treatment, and this improvement is sometimes supplemented by distinct diminution in the size of the uterus. The best results are seen when a "cross-fire" irradiation is resorted to, a 100 mgrams tube, screened with 2 mm. of lead, being placed on the posterior vaginal fornix, and a plate containing 100 to 150 mgrams of radium, screened in similar fashion, on the abdominal wall over the fundus uteri. Thirty hours' exposure should be given, spaced over four or five days, and the series repeated in six or eight weeks.

Lichenification of Skin.—This peculiarly intractable form of skin lesion is quickly cured by short exposures to half-strength applicators, unscreened, or screened with the thinnest aluminium; the relief afforded to the intolerable irritation is often marked within twenty-four hours. Cases so treated show little or no tendency to relapse.

Pruritus.—Radium is undoubtedly of great use in this condition, especially if it be of long standing and associated with leucoplakia or hyperkeratosis. When no actual lesion exists, and the trouble is purely nervous in character, the results are not so satisfactory, and often but little benefit follows from the application.

No definite rules can be laid down for treatment, as the local conditions vary so greatly; but the screening and exposures must be adjusted in relation to the character of the lesion.

Chronic Eczema, Psoriasis.—These conditions generally yield readily to short unscreened exposures with quarter-strength apparatus, applied for two or three minutes on three successive days, the exposure being repeated after a week or fortnight if necessary.

With chronic eczema the cure may be permanent; but in psoriasis the patches tend to recur sooner or later, and require further treatment.

Lupus Vulgaris.—Treatment with Finsen light is to be preferred to radium in this disease, and it should always be adopted whenever possible.

If radium be used, however, half-strength or full-strength applicators should be employed, without screen, and a destructive reaction produced.

Lupus Erythematosus.—This very intractable condition, which so often defies all treatment, is usually greatly improved by radium. Care must be taken not to give too strong a dose, and the best results usually follow the use of a quarter- or half-strength applicator, sufficiently large to reach well beyond the borders of the lesion, unscreened or screened with 0.01 mm. aluminium, and an exposure of forty to sixty minutes' duration.

Arthritis Deformans.—This extremely obstinate, progressive, and crippling malady is not infrequently strikingly benefited by the daily drinking of 250 c.c. of radium emanation solution, of a strength of 1 to 2 millicuries per litre. The treatment must, however, be persisted in for quite a long time, and at least six weeks are likely to elapse before any change is noted. In a favourable case the articular and muscular pains are lessened, or disappear; the movements of the affected joints become much freer, and are accompanied by less grating; the muscles controlling the joints regain much of their lost tone; and the general health of the patient is greatly improved. With the majority of the patients the emanation solution produces a definite diuresis, and with a few it acts as a slight laxative, though free purgation has never been noted.

In cases with a markedly gouty history, the first effect is often to cause an acute exacerbation of symptoms; but this is not to be regarded as a contra-indication to treatment, and the taking of the solution must be steadily persevered with.

It is difficult to predict with certainty which patients will derive the greatest benefit; but relief is most likely to be obtained when the patient is under fifty, and when the disease is poly-articular in distribution, and peri-articular in character. Ankylosis, the presence of osteophytes, or osseous changes of any kind, militate very strongly against successful treatment, and but little good is to be expected.

Post-operative Prophylactic Irradiation is now often resorted to by many surgeons when the patients have suffered from extensive, severe, and rapidly progressive malignant disease and the probability of their remaining free from recurrence for more than a few months has been but slight. The results so far noted do much to justify the routine adoption of post-operative irradiation, especially in those cases of malignant growth where it has been found impossible to operate well beyond the appreciable area of the disease.

A. E. Hayward Pinch.

RANULA.—This is a name given to a cyst found on the floor of the mouth, apparently due to blocking of a salivary duct, or a duct of one of the smaller glands, such as those of Nuhn and Blandin, or even of one of the mucous glands.

In treating the condition, it is necessary to perform some operation which will prevent a recurrence. If the cyst is simply dissected out and the wound closed, the condition is almost certain to recur, for the minute duct of the affected gland will still be left without an opening. The same result will follow if the cyst be opened and scraped and allowed to granulate up. The simplest method is to remove the whole of the anterior wall of the cyst, and then to suture the floor of the cyst to the surrounding mucous membrane of the floor of the mouth. By this means the floor of the cyst forms a part of the floor of the mouth, and on to it will open the duct of the affected gland.

Albert J. Walton.

RAYNAUD'S DISEASE.—(See also CHILBLAINS, ELECTROTHERAPEUTICS, GANGRENE, and BLACKWATER FEVER.)

1. Preventive Treatment.—The patient should avoid undue exposure to cold. In severe cases it may be necessary for him to winter abroad, or at any rate to remain indoors during cold weather; he should be warmly clothed in flannel, and wear wide, stout boots, and loose, warm gloves; he should wash

only in water at blood heat. The dietary should be abundant and contain plenty of fat. From time to time a course of tonics, especially cod-liver oil and iron, is beneficial.

2. Medicinal Treatment.—Quinine should be given if there be a history of malaria, in doses of 10 to 20 gr. per day. Opium is to be specially recommended in middle-aged or elderly persons who suffer from daily painful paroxysms with a tendency to gangrene. It may be given in doses of $\frac{1}{2}$ or $\frac{1}{4}$ gr. in pill thrice daily, or $\frac{1}{4}$ gr. of the extract may be given with 2 gr. of extract of hyoscyamus. If there be any suspicion of a syphilitic taint, iodides should be given a fair trial.

3. Electrical Treatment.—Galvanic treatment, preferably by means of a local bath, is of great value as a local vascular tonic. For the details of its application, see **ELECTROTHERAPEUTICS**.

4. Local Measures.—During a paroxysm the affected parts should be covered with cotton-wool; friction or gentle massage with the aid of a stimulating liniment (e.g., lin. camphoræ) is very useful when it can be tolerated. The application of a tourniquet to the affected limb for one or two minutes twice daily has recently been strongly recommended. It seems to act by inducing a temporary loss of vasomotor control (see *Med. Ann.*, 1905, p. 429).

Robert Hutchison.

RECTUM, DISEASES OF. (See also PROCTITIS.)

Cancer of the Rectum.—The only treatment which will materially prolong life is excision of the rectum at the earliest possible opportunity. This operation has been greatly improved within recent years, and most satisfactory results can now be obtained, providing the cases are seen early enough. The position of the growth in the rectum does not now affect the question of removal, as any growth can be removed providing it is not too densely adherent to surrounding structures. Growths that cannot even be felt per rectum can be quite successfully removed.

The contra-indications to excision are : (1) The presence of secondary deposits in the liver or abdominal glands ; (2) Dense adhesions to important structures, such as the bladder ; (3) Fixation of the growth to the pelvic fascia, if high up ; (4) Bad general condition of the patient, great obesity, bronchitis, etc.

The best results are obtained from the modern methods of excision of the entire rectum by the perineal or abdomino-perineal routes. In these operations, after excision, some part of the sigmoid flexure is brought down and stitched to the skin of the anus after repairing the anal sphincter. Though in some cases it is necessary to leave the patient with a permanent colotomy opening, the possibility of restoring the bowel depends upon the amount of the pelvic colon which has to be removed and the length of the pelvic mesocolon.

The rectum, growth, and glands in the hollow of the sacrum are removed together. It is possible by modern methods of excision to obtain aseptic healing of the wound, and to almost entirely restore the normal function of the bowel. The operation, however, is one of the most formidable procedures of modern surgery.

The Results of Excision of the Rectum.—After a successful operation, in which the bowel has been restored, complete functional control is obtained in the normal way, and except for some slight difficulty at first in emptying the bowel, the patient suffers but little inconvenience from the removal of the rectum. Stricture will not result, providing there is not free suppuration of the wound or sloughing of the bowel after operation. If the sphincters have to be removed, functional control cannot be expected, and the patient is more comfortable with a colotomy opening and no opening in the perineum. The percentage of recurrences of the growth after rectal excision is still high as compared, for instance, with the results of operation for cancer of the breast ; but better results

are to be expected from the present improved methods of operating, and the patient's life is prolonged for two or three years even in those cases in which recurrence occurs.

Colotomy.—(See COLOTOMY.)—This is indicated when there is commencing obstruction, or for the relief of diarrhœa and tenesmus. Colotomy, if performed early and before obstruction or secondary septic complications have occurred, will often materially prolong the patient's life; under these circumstances it can usually be reckoned that life will be prolonged by at least six months. It is therefore always well worth considering in inoperable cases.

Curetting.—When the growth cannot be removed, and is low down in the rectum, great temporary benefit follows curetting or cauterizing the ulcerated portion of the growth; but growths on the anterior rectal wall should not be curetted, as there is risk of going into the bladder.

Palliative Treatment in Inoperable Cases.—With proper care the patient may be made much more comfortable and saved much pain. Opium should be avoided, if possible, in the early stages, and the pain relieved with acetyl-salicylic acid in 10-gr. doses, or by phenacetin, antipyrin, etc. Later, opium and belladonna suppositories should be given sufficiently frequently to allay all severe pain, and the dose increased if necessary, or hypodermic injections of morphia may be used. Iron, in the form of tinct. ferri perchlor., by the mouth, is often beneficial in relieving pain and discomfort, and great relief is afforded by irrigation of the rectum with weak antiseptics or astringents. An occasional dose of castor oil, 1 oz., to which 7 min. of tinct. opii have been added, will also be found beneficial in getting rid of fæcal accumulations and preventing congestion of the parts. No form of electrical or x-ray treatment is of any value. Radium has been a good deal used in inoperable cases recently, but is not of much value. It seems to delay the progress of the growth for a time, but the author knows of no case in which permanent benefit has resulted. Such treatment more often seriously aggravates the condition and increases the pain. Much better results can be obtained by care in keeping the growth clean and preventing secondary septic infection and ulceration. Anæsthesin ointment introduced through a rectal pipe will often relieve the pain and tenesmus most effectually.

A guarded prognosis should always be given as regards the prolongation of life in cases of inoperable cancer of the rectum. The author has known two patients who lived in fair health for over five years.

Polypi of the Rectum.—The two common forms of rectal polypi are the myxomatous and the fibromatous. The former is the most common, and is often seen in children. Polypi often cause bleeding or prolapse, and should be removed. The sphincter should be stretched under anæsthesia, and the polypi either twisted off, or cut off after ligaturing their base with silk.

Prolapse of the Rectum (Procidencia).—It is important to distinguish between prolapsus recti and prolapsus ani. The latter is a condition commonly associated with piles, and the mucous membrane only is involved, while in the former the whole of the rectal wall comes down, and in the severe degrees of procidencia the peritoneum may form part of the prolapsing mass. Prolapse of the rectum in children is also a very different thing from the same condition in adults. In children prolapse is common and very amenable to treatment, while in adults it is not so common, and treatment is often unsatisfactory.

Prolapsus ani requires no special treatment apart from that necessary for hæmorrhoids (which see).

Prolapse of the Rectum in Children.—Treatment should be directed to improving the child's general health, correcting the dietary, regulating the bowels, correcting nasal obstruction, if present, and administering iron and strychnine in small doses to improve the muscular tone. The child must not be allowed to sit on a

chamber for the purpose of evacuating the bowel, but should perform this act lying in bed or in a squatting position over a shallow receptacle or newspaper. This is all that is required in most cases, but if not effectual the buttocks should be strapped together with a broad piece of strapping, the front edge of which passes just behind the anus. In a few cases operation is necessary. This usually consists of linear cauterization of the prolapsing bowel, the object being to obtain adhesions between the mucous membrane and the muscular coats of the bowel. From three to five shallow grooves, two to three inches long, are made in the rectal wall with a Paquelin's cautery blade. The child is kept in bed for a week, and made to pass all stools lying down for at least a month.

Treatment in Adults.—Nothing but operative treatment is of the slightest use. The simplest operations are linear cauterization of the prolapse, as already advised for children, and ligature of the slack mucous membrane in two or three places. A slack fold of the rectal mucosa is seized with forceps, and a silk ligature tied tightly round its base. This is done in two or three places at different levels. It is practically the same operation as that for piles (see HEMORRHOIDS). These operations are not likely to be more than temporarily successful, except in slight cases.

Other operations are : (1) Rectopexy, which is done by making an incision behind the anus and anchoring the bowel into the hollow of the sacrum ; (2) Restoring the pelvic floor by a plastic operation somewhat similar to that for ruptured perineum ; (3) Excision of the prolapse ; (4) Sigmoidopexy. This consists in dragging up the bowel through an abdominal incision, and fixing it to the anterior abdominal wall.

It is often advisable to combine two of these operations in the same case. The author's operation has given very good results in these cases, and has the advantage of being very simple and involving the minimum of risk, while up to the present there has been no case of recurrence. It consists of making an incision behind the anus, and opening up the posterior pelvi-rectal space with the finger and blunt dissection. This space is then lightly packed with gauze. The gauze packing is removed daily and replaced until the wound has healed from the bottom. This leaves dense adhesions between the posterior rectal wall and the sacrum, and prevents a recurrence of the prolapse. With the exception of the ligature and cautery methods, these operations should not be attempted by anyone not thoroughly accustomed to the performance of difficult surgical operations, as they often involve unexpected difficulties, and the peritoneal cavity may be opened in dealing with the prolapse.

Prolonged rest in the recumbent position is essential after any operation for prolapse.

Stricture of the Rectum (for *Malignant Stricture* see CANCER OF RECTUM, *supra*).—In treating any stricture of the rectum of old standing it must never be forgotten that there is more than likely to be ulceration of the bowel above the stricture. The treatment of fibrous stricture of the rectum will depend very much upon its situation and density, and also upon the degree and extent of ulceration above it. It is therefore very important to make a thorough examination with the sigmoidoscope before proceeding to treat the case. In slight or recent stricture where there is no very dense induration, gradual dilatation with bougies will sometimes effect a cure. The dilatation must be very carefully and gradually performed, and after the stricture has been fully dilated the patient should himself pass the largest bougie which can be inserted, and should continue to do so daily for some months. Unfortunately, in most cases the stricture recurs rapidly in spite of the continuous use of bougies.

Good results have been obtained by posterior proctotomy, by which the stricture and all the tissues are divided straight backwards to the coccyx,

the anus being also laid open in the same cut. Division of the stricture alone is not satisfactory, and is often dangerous from septic periproctitis. At the present day by far the best method of treating a bad stricture is to excise the affected portion of bowel, including the whole of the stricture. The healthy bowel above is then brought down and stitched to the anus: the operation is similar to that of excision of the rectum for cancer.

The results of excision are most satisfactory, and it is the only way in which a complete and permanent cure of the condition can be obtained. In cases of stricture at the anal orifice or within two inches of it, such as are sometimes seen after a badly performed operation for piles, the proper treatment is to dissect out all the fibrous tissue and free the rectal mucous membrane. Most excellent results can be thus obtained, but it is essential to success that the wound should heal by primary union and not by granulation. Often the easiest way of removing the fibrous tissue is to excise the last two inches of the mucous membrane, then bringing down the stump.

In bad cases of stricture, accompanied by severe and intractable ulceration, the proper treatment is a left inguinal colotomy, and this should be most strongly urged. Such patients are far more comfortable with a good colotomy, and it is the only way to get the ulceration to heal. It may be possible later to excise the stricture and close the colotomy, and on the other hand chronic ulceration above a rectal stricture is apt in time to become malignant.

Ulceration of Rectum (see also ANUS).—Rest in bed, combined with frequent irrigation of the rectum with some mild astringent lotion, is the best treatment at first. Later, local applications of pure ichthyol, or nitrate of silver 10 gr. to the ounce, may be made by means of a speculum. Good results have followed from the use of zinc ionization (see PROCTITIS, CHRONIC). The diet should be as bland as possible, and the bowels should be kept acting loosely. In severe cases, stretching the sphincters so as to obtain free drainage is often necessary; and in very bad cases a colotomy may be needed in order to deflect the faecal current.

J. P. Lockhart Mummery.

RELAPSING FEVER.—In this form of fever the treatment must be mainly directed to the relief of symptoms and complications, of which pneumonia and hyperpyrexia are the most important. These must be treated on ordinary lines.

The disease is most debilitating, and stimulants are usually required towards the end of each pyrexial period, and during the crisis, which is the period of greatest danger. Hot bottles, sinapisms to the cardiac region, and injections of strychnine may be required. The results of treatment with Ehrlich's salvarsan and neosalvarsan show that that drug has a specific action, and are most satisfactory.

RETENTION OF URINE.—(See URINE, RETENTION OF.)

RETROPHARYNGEAL ABSCESS.—(See PHARYNGITIS.)

RHEUMATISM, ACUTE.

I.—ARTICULAR RHEUMATISM.

A sharp attack of articular rheumatism with cardiac dilatation occurring in an adult is the most generally recognized of all forms of rheumatism, and most of the chief methods and problems that concern the treatment of acute rheumatism centre round it.

The indications for treatment are to :—

1. Alleviate the pain and distress.
2. Control so far as possible the rheumatic processes.
3. Encourage the great natural resistance to the disease.
4. Conduct the patient safely through the stage of convalescence.

The first step towards alleviating the pain and distress is *rest in bed*. This rest must be absolute. The bedstead should be a convenient one in height and breadth for nursing purposes, and should, if possible, consist of a good hair mattress on a modern woven-wire foundation. It is a great boon to the patient to avoid all unnecessary movement, and for this reason it is advisable to have powerful nurses who can manage the heavy lifting. Much importance is generally attached to the necessity of lying between blankets, but in my opinion there is less need for this since the introduction of skilled nursing, and it is most uncomfortable for those with sensitive skins. There are exceedingly soft, light blankets to be obtained which are a great comfort, but failing these, if there is a good nurse, the patient may lie upon a blanket and be covered by a cotton sheet and more blankets. The nightdress should be loose and made of the best soft flannel. It should be opened down the front for its whole length, and also along the sleeves. A light woollen shawl for the shoulders can be used in addition. By these arrangements it is easy for a nurse to dry the patient gently and rapidly from time to time, and thus prevent his lying in a steamy, sour bath of his own perspiration.

Diet.—During the acute stage this should be fluid and consist chiefly of milk. There is good reason to believe that during the acute illness the function of the kidneys is impaired, and therefore strong meat essences are not advisable. Milk diluted with water or Salutaris water should be given, and 10 gr. of citrate of soda may be added to every half-pint of milk. In addition, a home-made lemonade, to which bicarbonate of potash has been added in the proportion of 20 gr. to the pint, may be placed beside the patient. He should take about three or four pints of the milk and water in the twenty-four hours and the lemonade between. The citrate of soda renders the milk more digestible, and thirst is relieved by the lemonade. At the present time the condition of "acidity of the blood" that was supposed to exist in acute rheumatism is not literally accepted, for there is no evidence in its support. Nevertheless, it is a most interesting and remarkable fact that the diplococcus of rheumatism possesses powerful acid-producing properties. The alkaline treatment of acute rheumatism is thus quite as clearly indicated now as in the days of Dr. Fuller. Stimulants are seldom needed for acute articular rheumatism: the indications for their use in rheumatic fever will be given in the section on cardiac rheumatism. While on the question of diet, I would add that in my opinion there is no justification for a rigid rule prohibiting meat. In countries where, of necessity, meat is taken in excess, the disease occurs and is recovered from. In countries where the diet is practically meat-free, it also occurs, and may be fatal. Each case must be judged on its merits. If the type of the attack is sthenic, or the kidneys are affected, meat must not be given except with great caution. On the other hand, the asthenic cardiac type of childhood is often much benefited by a liberal diet.

The Condition of the Bowels.—It may be looked upon as a rule of practice that the bowels should be well opened before a severe course of treatment by the salicylates is commenced. Two grains of calomel in cachet, followed by a saline aperient, will usually answer the purpose. When once the bowels have acted thoroughly, mild aperients, such as liquorice, cascara, confection of senna, or a saline, can be used.

Local Applications.—Numerous local applications to the inflamed joints have been advocated, but in the majority of cases hot wool, skilfully applied, is

sufficient. The limbs should be kept at rest, and if necessary all weight taken off them by means of a cradle. There are exceptional cases in which the arthritis is exquisitely painful and unusually obstinate. The limb should then be placed upon a splint, and thus absolute immobility of all the tissues that may act upon the articulation be secured. Fuller's alkaline and opium lotion can also be applied on lint. The formula of this lotion is:—

R Potassii Bicarbonatis	℥ss	Glycerini	℥ij
Tincturæ Opii	℥v	Aquæ Rosæ	q.s. ad ℥xij

Ft. lotio. To be applied warm.

Blisters are, in my experience, more effectual in the chronic types of painful arthritis. There are certain forms of application which are believed to produce anodyne effects by withdrawing fluid from the tissues, thus reducing the heat and swelling. Other forms, more applicable I think to the subacute phases of painful arthritis, are the oil of wintergreen preparations. Thus methyl salicylate, a colourless liquid with strong odour, is spread on the skin and covered by some impermeable tissue. Mesotan, a methoxyl-methyl ester of salicylic acid, which has not so strong an odour, is used in solution in olive oil in the proportion of one part of the mesotan to two of olive oil. This mixture is gently rubbed into the affected part; but it should be used cautiously, for troublesome and irritable cutaneous eruptions (erythematous and papular in character) have followed its use. An elegant preparation is a compound gaultheria liniment containing methyl salicylate, gaultheria, and terebene: two or three drachms to be lightly rubbed into the affected parts. Spirosal is another recent preparation of this order.

Medicinal Treatment.—The salicyl compounds are at the present time very extensively used, and yet authorities of mature judgment and wide experience are still at variance as to the best way in which to employ them.

Many physicians believe that these drugs are directly antidotal to acute rheumatism, and some have gone even further, and have looked upon them as tests of the presence of the disease. We must, however, remember that the proof of specificity rests entirely upon clinical observation, and that observations upon the results of treatment are notoriously difficult, and are rendered more so from the tendency of our profession to run in a circle upon an insecure platform of fact. Thus it is stated: "Salicylates are antidotes to rheumatism"; following this we are told: "What does not yield to salicylates is not rheumatic." It only remains for some one in an authoritative position to emphasize these two dicta, and any real advance in our knowledge is at once checked. The fatal weakness of such a position lies in the fact that we are in complete ignorance of the nature of the poison or poisons that are formed in acute rheumatism. I think that the whole question of the specific action of these drugs is still an open one. Certain important facts, however, have been ascertained. In the first place, no drugs ease the pain and lower the temperature in acute articular rheumatism with such constancy as these do. Secondly, none of the other rheumatic manifestations react to these drugs in a manner comparable to the articular lesions. On the other hand, certain points are still in dispute:—

1. Is the lack of success with salicylates in other than the articular lesions the result of insufficient dosage?
2. Can large doses be given without producing ill effects?
3. If large doses are given, are the results superior to those obtained by other methods of treatment?

Dr. D. B. Lees has shown conclusively that children and adults can take very large doses of the best preparations of sodium salicylate. His conclusions favour the view that large doses, if they are given *early* in the disease, are antidotes to all rheumatic manifestations. If, however, we consider the possible danger from large doses, we find again there is general agreement that some individuals show an intolerance to these drugs, and in some cases, if large doses are pushed, very grave and even fatal results may ensue. In such cases the vision becomes dim, there are buzzing in the ears, deafness, and giddiness. Sometimes there is headache, and more often vomiting, which is sometimes difficult to control. Of greater importance are the cardiac symptoms: the pulse becomes slow, irregular, and small in volume, and the cardiac sounds are enfeebled. The extremities become cold and clammy, and the aspect of the patient

is one of intense depression. In rare cases, a very remarkable series of symptoms arises, in which slow and deep breathing develops, much urine is passed, coma supervenes, and the patient dies in a condition strikingly suggestive of diabetic coma.

Granting this idiosyncrasy, there is dispute as to whether or not in other cases the drugs are depressant. This would seem easy to settle considering the great number of observations that are made; but the rheumatic poisons are in themselves intensely depressant, especially to the heart. Thus one observer will attribute the symptoms to the disease, and another to the drugs. The last question to be answered is, whether better results are obtained by large doses of salicylates than by other forms of treatment? Here again, opinions entirely differ; but in rheumatic cardiac lesions I cannot myself believe that large doses of salicylate of soda produce such good results as do other methods of treatment.

As there is this diversity of opinion, I shall first consider the medicinal treatment with salicylate of soda used only as an aid in subduing rheumatic arthritis and rheumatic pains—the method to which I personally incline—and then the treatment as carried out by those who believe the drug to be a specific antidote (see p. 874).

For a strong adult the following prescription may be given:—

R Sodii Salicylatis	gr. xx	Syrupi Zingiberis	3 ^{ss}
Sodii Bicarbonatis	gr. xv	Aquæ Chloroformi	q.s. ad 3j

Ft. mist. Two tablespoonfuls every two hours for six doses, every three hours for four doses, and then every four hours.

The result, if favourable, will be a fall in the temperature and marked relief to the articular pains, together with a striking improvement in the general comfort of the patient. In some cases, when the pain is exceptionally severe, it is advisable to add to the evening dose 10 min. of nepenthe, or to give a cachet containing 10 gr. of Dover's powder. If there is much nervousness and anxiety, bromide of potassium is indicated. Here it may be repeated, that the bowels should be well opened at the commencement of the illness. If the patient is easily depressed, sal volatile should be added to the salicylate mixture.

A child of ten years, of robust constitution, can be given 10 gr. of salicylate of soda at a dose; but frequently, when the drug is being used to control the arthritic pains, 6 gr. will be sufficient. For a delicate child, salicin may be prescribed. This can be given in warm milk thus:—

R Salicini	gr. x	Sodii Bicarbonatis	gr. v
------------	-------	--------------------	-------

Ft. pulv. Mitte tales xñ. Take one in milk as directed.

When the temperature has fallen, and improvement is clearly indicated, the dose of salicylate of soda or salicin is gradually diminished, but these drugs are not entirely discontinued until at least a fortnight has elapsed from the day that the temperature reached normal. In many cases, at the end of this time a change can be made to salicylate of quinine, and a week later to a simple quinine tonic, which for adults can be prescribed in an effervescing alkaline draught.

R Saloquininæ Salicylatis (Rheumatin)	gr. x
---------------------------------------	-------

Ft. cachet. Mitte xii. Take one three times a day.

Children will take this drug well if it is given in 5-gr. doses suspended in syrup and water.

EFFERVESCING QUININE MIXTURE.

R Sodii Bicarbonatis	gr. xx	Aquæ Chloroformi	q.s. ad 3j
----------------------	--------	------------------	------------

Ft. mist. alkalina.

R Acidi Citrici	gr. xvij	Aquæ Destillatæ	q.s. ad 3 ^{ss}
Quininæ Sulphatis	gr. ij		

Ft. mist. acida. To two tablespoonfuls of the alkaline add one of the acid mixture, and take as a draught three times a day.

For children at this stage of the illness, the following prescription is useful:—

R Quininæ Sulphatis		Mucilaginis Tragacanthæ	3j
Ammonii Carbonatis	āā gr. ss	Syrupi Aurantii	3 ^{ss}
Potassii Bicarbonatis	gr. v	Aquæ Chloroformi	q.s. ad 3ij

Ft. mist. Mitte 3iv. Two teaspoonfuls three times a day after meals.

The *convalescence* from articular rheumatism, in spite of every care, is frequently retarded by relapses. Many attribute these to an over-hasty return to solid food. I would, however, point out that the diplococcus has prolonged vitality, and we have no evidence that any drugs can destroy it in the tissues, neither can we gauge how completely the resistance of the tissues has done its work. What then is more likely than that there should be these relapses? There seems little doubt that premature exertion is detrimental, and on this account it is advisable that the tender joints and stiffened ligaments should be skilfully massaged for a week before the patient attempts to bear his weight upon them or make voluntary movements. The massage should include passive movements of the limbs. If the effusion has been more than usually copious, and the softened capsule thereby stretched, it is advisable to strap the joint firmly as soon as the effusion has disappeared. Hydropathy in those cases in which there are left much pain and stiffness, coupled with considerable muscular wasting, is of great service. In this stage there can be no doubt of the value of this treatment. The combination of radiant-heat baths and massage is also very useful. Stimulating liniments, such as the compound mustard or camphor liniment, are also helpful, and a prescription on the following lines will sometimes give relief:—

R. Liquoris Potassii Arsenitis	℥iij	Syrupi Zingiberis	℥ss
Potassii Iodidi	gr. v	Aquæ Chloroformi	q.s. ad ℥ss
Sodii Salicylatis	gr. x		

Ft. mist. Mitte ℥vj. One tablespoonful, in an equal quantity of water, three times a day after meals.

Should there be, in addition to pain, swelling of the joints after movement, blisters should be applied above them. Occasionally cases are met with, resembling those of acute articular rheumatism, *which do not respond at all to treatment with salicylate of sodium*. These some authorities consider to be examples of a special disease they term acute rheumatoid arthritis. I am not convinced of the truth of this opinion. In such cases it may be advisable to push the drug for a few days, but if there is no improvement, then to abandon this method and turn to the alkaline quinine mixture; or, if the pain is severe, to the acid solution of quinine, to which liquor morphinæ hydrochloratis (1 per cent) can be added. Another difficulty which sometimes confronts us is finding that most of the joints react to treatment with salicylate of sodium, but that one remains obstinate, very painful, and drifts into a condition of arthritis deformans. We must be on our guard for such an occurrence when there is great œdema and peri-articular swelling. The limb should be placed on a splint, and, if (though this is exceptional) there is much intra-articular fluid, it is advisable to aspirate the joint very slowly and with strict antiseptic precautions. A film of the exudation should be examined, and if the diplococcus is present in numbers, the joint cavity should be washed out with a 1 per cent carbolic solution. In any case, after aspiration the joint should be carefully strapped with Scott's dressing, or Bier's method of passive congestion be tried. I do not think that the free opening and drainage of the joints in acute rheumatic arthritis is indicated in the present state of our knowledge. I have made no allusion to the treatment of acute dilatation of the heart, for the necessary rest in bed and proper care during convalescence will generally put this right. After an attack of rheumatic fever, the winter and spring are better spent out of England. Thus, a winter in Egypt may complete the recovery. As regards our own climate, we badly need a careful investigation and report upon the incidence of acute rheumatism in all its ordinary types in various localities. In general terms, a dry gravel soil and liberal amount of sun are advisable, and inland is preferable to seaside.

Bee-stings in Rheumatism.—I feel I ought to devote a few lines to the treatment

of rheumatism by bee-stings, because I am partly responsible for its recent development. So far as I understand, it rests upon two somewhat slender supports. The first is an empirical one, viz., the observation that bee-keepers, who undoubtedly become to a great degree immune to bee-stings, are accredited with freedom from rheumatism. The second is more scientific. Triboulet, Paine, and I pointed out that the diplococcus was strongly acid-producing in culture, and Triboulet discovered this acidity was in part due to the formation of formic acid. Ainley Walker and Ryffel further showed the presence of a considerable quantity of this acid both in culture and in the micrococci themselves. As the sting of a bee is greatly dependent upon the presence of formic acid, it does not require a great stretch of imagination to picture the painful results of rheumatism as largely due to this acid. If then the hardened bee-keeper becomes immune to bee-stings, which I believe is certainly the rule, and if, as there is some medical and lay evidence to show, such people are also thereby protected against rheumatism, why not sting the rheumatic with bee-stings? This method has been chiefly applied in stubborn rheumatic arthritis, and a special apparatus has been devised by Burton for holding the bees. Some good results have been recorded, and it is a method which attracts the layman's imagination. We must not forget, however, that the micrococcus forms various acids in different media, and as yet we have no reliable data upon the occurrence of formic acid in the human tissues in rheumatism. We need, too, many more facts about the immunity of bee-keepers from rheumatism. In acute rheumatism I suspect we should need a good swarm of bees, and as regards the local forms of this disease, I believe we may safely trust that those who undergo this treatment will eventually give a decided opinion.

II.—CARDIAC RHEUMATISM.

The second clinical type is a severe attack of acute cardiac rheumatism. This is most frequent in childhood, and on this account the outlines of treatment are mapped out for the child, but can be modified for the adult.

The chief therapeutic indications are :—

1. To relieve pain and distress by immediate and complete rest, coupled with suitable remedies.
2. To feed the patient skilfully.
3. To spare the heart all avoidable strain, and to endeavour to strengthen it.
4. To guide the patient through the convalescence. The child should be kept in bed, and trained nurses are advisable, for much depends upon the nursing in difficult cases. For easing the pain and distress there is no better remedy than the *ice-bag*, which has been so warmly advocated by Dr. D. B. Lees. The details of this treatment are as follows :—

The præcordial area is marked out with an aniline pencil as a guide to the nurse. If possible, two ice-bags should be in use, so that one can be substituted at once when the other is exhausted, and hot-water bottles should be placed in the bed to keep the lower extremities warm. The bag must not press heavily upon the chest, and if there is much præcordial pain it should be suspended from a cradle. For fixation in position on the chest—a point of much importance—a domette vest should be made with armholes, and, in addition, with a third hole over the cardiac region through which the neck of the ice-bag is slipped. The vest is fixed above by a tape passing round the neck, below by a safety-pin. The ice should be carefully pounded, and the top of the bag must be screwed down on the washer. Nothing should intervene between the bag and the skin, although cotton-wool should be packed round the bag to absorb the moisture which tends to condense upon its surface. The most convenient arrangement is to refill the bag every two hours, at which time the temperature and the rate of the pulse should be taken. The continuous application is the most satisfactory, although in the early morning hours it may be advisable to intermit the treatment.

If skilled nursing cannot be obtained, the ice-bag may still be used during

the day. Some delicate children find the cold too depressing, and in spite of stimulants may show signs of collapse. In such cases, the application of belladonna liniment or warmed pine wool is preferable. When there is considerable distress consequent upon dilatation of the right side of the heart, four leeches applied to the præcordial region give relief, but I do not personally favour the use of leeches as a routine method. It is for the dilatation of the heart rather than for the pain that they are indicated. In these cases, if there is arthritis or much muscular pain, let 5 gr. of salicylate of sodium be given to a *child of seven* with the object of controlling these pains. For the præcordial distress and sleeplessness, opium may be given, the bowels having been previously opened by aperients.

FOR INSOMNIA AND RESTLESSNESS.

R Nephenthe	℥iv	Glycerini	℥xx
Potassii Bromidi	gr. v	Aquæ Chloroformi	q.s. ad ℥ss
Misce. Mitte ℥vj. Two teaspoonfuls to be given at night or every six hours for a child of seven.			

I do not advocate the free use of salicylate of sodium, although the details of this method will be given later for the guidance of those who favour the theory of its specific action.

In many cases there is no special necessity for relieving pain, and then a prescription containing small doses of quinine is serviceable; children dislike it less in simple than effervescing solution. Regarding stimulants, alcohol, in the form of sound brandy, is useful when the temperature is low, the pulse feeble, the appetite poor, and the rest disturbed. It is not advisable for routine use in rheumatic heart disease, and quite wrong to persist with it longer than is absolutely necessary. The same discretion is needed in the employment of direct cardiac stimulants. There is nothing to be gained by plying an excited heart with strychnine during the early stage of acute pericarditis, for the rapidity of the heart is thereby increased, and its force may be exhausted prematurely. Should the cardiac excitement be the prominent feature, and there be no unusual effusion, digitalis is more useful.

R Tincturæ Digitalis	℥vi	Glycerini	℥xv
Potassii Bromidi	gr. v	Aquæ Chloroformi	q.s. ad ℥ss
Ft. mist. Mitte ℥iv. Two teaspoonfuls every six hours for a child of seven.			

It is when the strength of the heart is failing that strychnine is of great use. It can at first be given by the mouth in combination with digitalis, and later hypodermically, in doses of $\frac{1}{30}$ gr. every six hours to a child of seven. When the heart, after the outbreak of pericarditis has died down, is left feeble and dilated, I have observed good effects from the use of formate of soda.

R Sodii Formatis	gr. v	Aquæ Chloroformi	q.s. ad ℥ss
Syrupi Aurantii	℥ss		
Ft. mist. Mitte ℥viiij. A tablespoonful every six hours for a child of nine.			

It is a very grave event when, in an attack of acute pericarditis, vomiting, restlessness, and livid pallor supervene. It is all important to cope with the sickness at once. Such drugs as digitalis and strophanthus should be discarded, and recourse had to hypodermic injections of strychnine. The drugs given by the mouth should be those which assist in arresting the vomiting. The milk should be peptonized, or citrate of sodium added in the proportion of 2 gr. to the ounce of milk, or ass's milk obtained. Patent meat-juice is sometimes of great value, and well-made beef, chicken, or veal tea may be used in place of milk. A stomachic mixture containing bismuth and soda with 3 min. of dilute hydrocyanic acid will help to arrest the sickness. If in spite of these measures the vomiting is persistent and urgent, all food by the mouth should be stopped and recourse

had to rectal injections. For the lividity, oxygen is of some value, and for the restlessness, the bromide and opium mixture already mentioned. Brandy and dry champagne are the most useful stimulants. Allusion has been made to the early application of leeches in pericarditis. It is, however, in the later stages, especially in cases when there has been old valvular disease, that their use will be most frequently required. When the right heart is beating forcibly in the epigastrium, when the pulse at the wrist is small and feeble, the colour ashen, and the child in great distress, five leeches applied over the liver may give great relief, and even if this be only temporary, it is some gain. The leeching should be followed up by free stimulation of the heart. Should the rare event occur of embarrassment of the heart from a large pericardial effusion, it will be found that the impulse becomes diffuse and wavy, the cardiac sounds more and more muffled, and the præcordial dullness wooden in character. If then, after most careful deliberation, it is thought advisable, paracentesis should be done by introducing the needle of the syringe at the extreme limit of the cardiac dullness in the left axilla over the region of the apex. The operator must be prepared to find that flakes of lymph may block the syringe, and on this account deliberate incision of the pericardium by a skilled surgeon is preferable.

The convalescence after an acute carditis is prolonged. Six months of the greatest care is not a day too much. This time should not, however, be spent in passive rest, but be employed in cautiously preparing the heart for the return to everyday life. The methods at our disposal are :—

1. Rest, fresh air, and sun.
2. Massage of the limbs.
3. Passive and resisted movements.

There can be little doubt that it is a mistake to keep children at rest for long periods and then allow them to plunge suddenly into ordinary life. When once the temperature and pulse are steady, and have remained so for an interval of three weeks, massage of the limbs should be commenced.

I know no condition in which more satisfaction may be obtained from a prolonged convalescence than a severe carditis in childhood. We cannot at present control the lesions to any great extent, but may add many years of peace and happiness by this caution. Here, as elsewhere, I would beg for the founding of special convalescent homes for the poorer children who have fallen victims.

Cod-liver oil and malt is a remedy of value in the convalescent stage, particularly during the winter months. Among the poor, the anæmic, delicate children, damaged by previous rheumatism, frequently derive great benefit from this old-fashioned prescription.

III.—ACUTE RHEUMATISM WITH HYPERPYREXIA (CEREBRAL RHEUMATISM).

This most dangerous condition is probably the result of an acute rheumatic toxæmia, for local lesions are the exception, and recent observers have found great and general degeneration of the nerve cells in the brain. It is fortunately rare, although it may supervene in what is apparently a mild attack of rheumatism, and not only in the severe forms. The onset is as a rule in the third and fourth week of the active disease. Warning symptoms are headache, delirium, and vomiting. Importance has been attached to the sudden disappearance of the arthritic pains without any corresponding improvement in the general condition of the patient. In other cases, cutaneous hyperæsthesia has been noted. Graver signs are spasmodic twitchings, irregular breathing, and a lapse into semi-consciousness. The temperature may rise with great

rapidity to the height of 107°, 108°, or even 110° F. It must, however, be remembered that grave nervous symptoms may arise with a temperature of about 105° F., and that such symptoms must be looked upon as pointing to cerebral rheumatism, unless there should be evidence of severe pericarditis.

The most successful method of treatment is the use of the cold bath. Some advise that the bath be at first warm (about 90° F.), then rapidly cooled down by ice; others, that it be only tepid (75° F.), and the ice added. I think that those who advocate the latter and more drastic treatment are more likely to be successful, for, as they point out, the element of nervous shock is in itself of some value. There is undoubted danger of collapse; but with the slower method the patient must remain longer in the bath. In either case no time should be lost. Collapse can only be anticipated by watchfulness and the use of stimulants. The temperature is taken repeatedly while the patient is in the bath, and it is important to remember that the fall in the temperature will continue after the patient has been removed. Thus, if the initial temperature is 106° F., the patient should be taken out when it has fallen to 102°. Twenty minutes is the average time required.

It must sometimes happen that there is no convenience for giving a bath. In such cases a sheet can be wrung out in cold water and wrapped round the patient, who is then rubbed over with smooth blocks of ice. This again is a great shock, and the utmost watchfulness is requisite.

Should the temperature rise again, the bath must be repeated. No drugs appear to control the fever. Salicylate of sodium is powerless, although when once the temperature has been lowered, both salicylates and quinine may aid in keeping it down. Drugs of the nature of antipyrin or phenacetin are ineffectual alone, and too depressant if combined with the cold-bath treatment. The physician must be prepared to find that all efforts are useless; for the cold bath, though the best remedy at present known, is far from infallible.

IV.—OTHER RHEUMATIC MANIFESTATIONS.

The greater number of rheumatic symptoms not dealt with already in this article are treated upon general principles. There are, however, a few points in connection with them that are worthy of mention.

Rheumatic Pleurisy is essentially plastic in type, and seldom gives rise to much effusion. Should it, however, complicate cardiac dilatation and tricuspid regurgitation, then fluid may accumulate rapidly, and increase the dyspnoea. In such cases the fluid should be drawn off before there is any great accumulation, particularly should it occur on the right side, embarrassing the right chambers of the heart. In one case I was compelled to tap the chest on account of an extensive active effusion, but this is quite exceptional.

Unusually high pyrexia in acute rheumatism, apart from the cerebral type, should suggest a patch of **Pneumonia**. This usually subsides rapidly, with no special treatment. The type of rheumatic pneumonia is the broncho-pneumonic.

Acute Pulmonary Œdema—a rare occurrence—commences, as in renal disease, with the appearance of numerous fine râles in the upper lobes of the lungs. There is also a rapidly-increasing dyspnoea. All depressing remedies should at once be stopped, and such cardiac stimulants as strychnine and strophanthus employed.

Alimentary Disorders.—The possibility that the rheumatic infection may attack the abdominal viscera seems worthy of more attention than is perhaps given to it. We find, not infrequently, that children complain of abdominal pains at the commencement of and during an attack of acute rheumatism. Sometimes it would seem that the pain is muscular in origin, while in other

cases it is clearly due to intestinal disturbances, as shown by vomiting or the passing of much mucus. In adults, acute dilatation of the stomach may occur, and sometimes severe pain in the region of the colon, while in children mucous colitis is not infrequent. These attacks of colitis may replace, or occur simultaneously with, a rheumatic attack.

The question of a rheumatic appendicitis has reached a new stage since, with Dr. Paine, I have been able to show that the diplococcus intravenously injected may cause an appendicitis in rabbits indistinguishable in its morbid anatomy from that of some cases of human appendicitis. It is significant also that in a child suffering from appendicitis and tonsillitis, a strepto-diplococcus isolated from both lesions reproduced in rabbits appendicitis, arthritis, and carditis.

The chief indications as to treatment that result from these investigations are the particular care of tonsillar affections in the rheumatic, the realization that appendicitis may result from a blood infection, and the need for careful attention to the alimentary canal. Another point worth attention is the occurrence in the rheumatic of attacks of nausea with a coated tongue, offensive breath, and pale motions. Here again, it is interesting to find that the diplococcus can be isolated from the bile of infected rabbits, and that a gall-stone has been found by us in the gall-bladder after a protracted infection. These results may throw light on the difficulty there may be in giving strong iron preparations to the rheumatic, and may explain in part the remarkable intolerance to salicylate of soda that sometimes occurs in children and adults.

Renal Disease.—I am of opinion, with others, that rheumatic renal disease is not uncommon. The treatment is conducted on general principles, and the subject is mentioned here as a warning of the tendency in the rheumatic to develop this serious condition.

Erythema Nodosum is looked upon by many as a special disease. Rest in bed and soothing lotions are indicated for the painful swellings. These are most commonly met with over the shins, but may also occur on the upper extremities and trunk. Salicylate of sodium relieves the articular pains, but does not appear to control the course of the disease. Gargles should be freely used for the sore throat which is not infrequently present.

Rheumatic Tonsillitis shows no very special clinical features. In most instances there is a general and diffuse redness, spreading over the tonsils and uvula. On the other hand, it may be more severe, and I think that some cases of rheumatic tonsillitis are mistaken for diphtheria. The sore throat is frequently very transitory, but hardly sufficient attention has been directed to this manifestation. Children who are rheumatic, or inherit the tendency, should be taught to gargle early in life, and much attention should be paid to their throats. They can safely use a gargle of oxymel (B.P.), borax, and water. Adults can use a gargle containing salicylate of sodium, or formalin, or chlorate of potassium. Some rheumatic children have large diseased tonsils, with deep pockets of unhealthy exudation. At the present time I am following the advice of my colleague, Mr. Waugh, and advise such tonsils to be *enucleated* in the quiescent period between rheumatic attacks. Dr. Paine and I have shown recently that cultures obtained from the depth of these tonsils enucleated in the quiescent stage contain strepto-diplococci which will produce experimentally both arthritis and carditis. I am now in the position to make some definite statements of practical use upon this question of operations on the throats of the rheumatic.

1. Operations in the acute phase may precipitate an acute attack of rheumatism.

2. In the quiescent stage there is no such danger, and if the tonsils are large and unhealthy there will be marked improvement in the general health.

3. Attacks of rheumatism may occur again, however, although the tonsils have been enucleated.

V.—OTHER METHODS OF TREATMENT.

Treatment by Sodium Salicylate used as a Specific.—In the description of this method, I cannot do better than follow the rules laid down by Dr. D. B. Lees in his monograph upon "The Treatment of some Acute Visceral Inflammations," for there can be no doubt that if the drug is specific, the logical procedure must be to push it in the more severe types of the disease. For an adult, 20 gr. of salicylate of sodium are given, combined with 40 gr. of sodium bicarbonate, every two hours during the day and every four during the night. Dr. Lees emphasizes the necessity for the addition of a quantity of bicarbonate of sodium double that of the salicylate, for this combination tends to prevent the supervention of that dangerous form of dyspnoea already described. In proportion, children require large doses. Thus, a child from six to ten years will commence with 10 gr. of the salicylate and 20 gr. of the bicarbonate every two hours in the day and every four hours at night. In two days' time the doses are raised to 15 and 30 gr. respectively, and later, even to 20 and 40 gr. This treatment is persisted with until the symptoms of the acute disease are overcome, and then the doses are cautiously diminished. For rheumatic chorea the same line is adopted. The objections to the method by those who do not agree with it have already been enumerated.

Surgical Treatment of Rheumatic Arthritis.—O'Connor and others have advocated the free opening of the joints in severe cases of acute articular rheumatism, on the principle that the process is an infective one, and that the heart may be infected from the local lesions. Vernon Shaw has, in fact, experimentally proved that the *Diplococcus rheumaticus*, when injected into the knee-joint of a rabbit, will cause not only arthritis but endocarditis. Granted that these reasons, so far as they go, are sound, I cannot believe that in the majority of cases there is any necessity for such drastic measures. Moreover, as the diplococci are located especially in the synovial membranes, and not in the articular fluid, this treatment, though drastic, is not radical; further, it cannot prevent a primary infection of the heart, which clinical experience leads one to believe is a frequent event.

Serum Treatment.—It is in some such direction as this that we look for help in the future, though we do so with feelings chastened by a remembrance of repeated failures in serum therapy. The difficulties are numerous. The diplococcus, though tenacious of life, soon loses its virulence, and the virulence is not as a rule very high. An antibacterial serum is notoriously uncertain in its action, and such sera cannot as yet be standardized. At the present time no specific serum has established itself, and should one appear, let us hope that it will fall into the hands of those who realize how great a natural tendency there is to recovery in acute rheumatism. Those who do not believe the micro-organism is specific have employed sera made from several varieties of the streptococcus. This method I have myself used without success, but the polyvalent sera are apparently improving in efficacy, and their value is still *sub judice*.

The serum which has attracted most attention is Menzer's. The cultures from which this serum is made are taken from the upper air-passages of patients suffering from rheumatic angina faucium, and I need hardly point out that such a method assumes that rheumatism is not a specific disease, for such cultures could hardly be pure. This serum produces certain very decided effects. In four to six hours from an inoculation, heat and swelling occur in the joints which have been affected by the rheumatism. For a while the cardiac symptoms

may be increased. Fever and pains in the neck and head, swelling of the lymphatic glands, and sore throat, are all occasional events. Later there is a fall of temperature by lysis, and then should follow a natural course towards cure. The serum has not been standardized. The test dose used by Menzer was 5 to 10 c.c., but as much as 200 c.c. has been used for a single case. He is of opinion that it prevents relapses and the development of endocarditis. The dangers and weaknesses of this method should be thoroughly realized. The dangers are the local reactions described by Menzer; for since we cannot standardize the serum, we have no complete control over these reactions. The weaknesses are the assumption that rheumatism is not specific, and that in the present state of our knowledge cultures from the throat are to be relied upon as a basis of treatment.

For the last six years I have attempted in carefully chosen cases to use a serum made from the diplococcus, but up to the present time I can report no really satisfactory results.

Vaccine Treatment.—This is a method which would seem to promise much, particularly in the obstinate relapsing cases of rheumatism in childhood. Unfortunately we are almost invariably driven to use a "stock vaccine," for it is difficult to isolate the micrococcus except from cases of severe pericarditis. I feel strongly that this fact opens up several contingencies. It may be thought, for example, advisable to withdraw fluid from the joints, or even from the pericardium, with a view to obtaining an "auto-vaccine." Upon this method I would accordingly venture to express myself very clearly. It must be remembered that the micrococci lie primarily in the tissues and not in the fluids, and as I have always maintained, and Professor Beattie has recently supported, there is no apparent relation between the number of the micrococci and the severity of the reaction. I am convinced, then, that there will be many failures to isolate the micrococcus, and all evidence with regard to arthritis has pointed to this conclusion. Accordingly, in the present state of our knowledge, we take a considerable responsibility in attempting to obtain a vaccine by such undertakings. With increasing knowledge of the streptococci, utilization of the throat seems a more hopeful line, but at present the difficulty here lies in the fact that we rely upon experimental data to assist us in the differentiation of the micrococcus, and when it has been passed through animals it may be altered in character, and the original culture, pending experimental results, may lose potency. Lastly, with all deference to the opinions of others, I am still of opinion that in vaccine therapy there is a vast amount of promise in comparison with the actual basis of fact upon which it rests, and I can see in it but one (a valuable one, doubtless) possibility in the complex problem of immunity. Working with a stock vaccine made for me by Messrs. Burroughs and Wellcome, I have not, up to the time of writing, convinced myself of its value, but much more work and time will be needed before reports of real value can be expected. I have had no evil results.

Phylacogen Treatment.—Among the more recent developments in treatment has been the rheumatic phylacogen of Schafer, which has been widely used for rheumatism in general in the United States, and more recently in this country. Phylacogens are described as sterile aqueous solutions of metabolic derivatives generated by bacteria when grown in artificial media, and are neither "vaccines" nor "sera." The rheumatic phylacogen consists of equal parts of a filtrate obtained from the rheumatic micrococcus and a mixed-infection phylacogen. I am not prepared to agree with Schafer's statement that all infections are essentially mixed infections, for this has not been the experience of Dr. Paine and myself with regard to rheumatism. Numerous cases have been recorded, more or less completely, in which wonderful results have been obtained with

this treatment. The phylacogen has been given subcutaneously and intravenously, but of the latter I have no personal experience. No one should use this method of treatment without being acquainted with the systemic reactions, which are recognized to be of frequent occurrence. When they are marked they are startling, and we may well ask ourselves whether the subsequent results justify their occurrence, and whether they are to be explained as a phase in the curative process, or as a gallant effort by Nature to overcome a fresh poison imposed upon it in addition to the sufficiently grave rheumatic ones. In a severe case there is a rigor which may last an hour, a swift uprise of the temperature, profuse sweating, a rapid heart, headache, and general malaise. The strongest supporters of this treatment advise that the first dose should be given subcutaneously. This is generally stated as ranging from 2 c.c. to 10 c.c., the quantity being gradually increased from the initial one. If it is well borne it may be administered daily, but if there is some reaction a delay for forty-eight hours is advisable. The intravenous dosage ranges from 0.5 c.c. to 5 c.c. Six successive doses may be given, and many more have been administered in the chronic forms of rheumatism. After experience, I have found in childhood an initial dose of 5 min. advisable, gradually increasing at each injection (1 c.c. is equivalent to 16.2 min.). In this way severe reactions are avoided. If it is held that without reactions of severity the treatment loses its value, I advise against its use at this age. In the lingering cases, it has seemed to be helpful in lowering temperature, and possibly in shortening the duration of chorea.

The results in rheumatoid arthritis are beyond the scope of this article.

Radium Treatment.—Treatment by water impregnated with radium emanations has been advocated, particularly in chronic arthritic affections. It is too early as yet to state whether this is of any value in the acute forms of rheumatism; the method seems purely empirical, and the effect accordingly to be judged only by prolonged and careful clinical observation. This can be stated, that no startling result has been observed up to the present.

F. J. Poynton.

RHEUMATISM, CHRONIC (FIBROSITIS).—The essential pathological changes in chronic rheumatism take place in the white fibrous tissue of muscle-sheaths, tendons, aponeuroses, ligaments, periosteum, fascia, and nerve sheaths. The lesion consists in inflammatory overgrowth of the connective tissue, this being the result of a local reaction against microbes, or possibly toxins conveyed by way of the blood-vessels. The irritant gives rise to proliferation of fibrous tissue locally, with serous exudation, and the whole may resolve without treatment, or may become fibrous and permanent. When once formed, these fibrous indurations are usually more or less defined and circumscribed, and, as felt through the skin, they vary in size from a split pea to an almond, or they may be in comparatively large masses, or spread out as an inelastic layer under the skin. They may occur after acute rheumatism, rheumatic colds, influenza, gonorrhœa, rheumatoid arthritis, and local injuries such as a sprain, and from mucous colitis. They are therefore sequelæ of many morbid conditions. Many have nerve-twigs passing through them, the fibrous-tissue sheaths of which are in a condition of interstitial neuritis which renders them very tender to pressure. In an individual with these lesions, exposure to cold and wet, muscular exertion, a chill, indigestion, and other exciting causes produce swelling of the fibrous tissue, with consequent pressure on nerves, and this gives rise to the series of symptoms which are characteristic of "chronic rheumatism," namely, stiffness, aching, pain, a feeling of fatigue, and often neuralgia. These fibrous indurations may occur in any part, but they are most frequently found in the back, thighs, legs, neck, shoulders, and joints. According to the part

specially affected, we use the terms lumbago, stiff neck, pleurodynia, sciatica, etc. The subcutaneous fibrous tissue is very often the seat of similar lesions, and fat tends to be deposited in larger or smaller masses around them ("panniculitis," "chronic subcutaneous fibrosis"). The swellings can be most readily made out by smearing the skin with oil or vaseline, and then passing the thumb or tips of the fingers over the part with firm, gentle pressure. They are usually tender on pressure, and can be felt as ill-defined, doughy swellings. The larger ones, and those in the panniculus adiposus can be readily grasped by the fingers.

TREATMENT.—When the indurations are quite recent, they can be resolved comparatively quickly by massage; hence, after an attack of acute rheumatism or influenza any painful local spots should be efficiently massaged for ten days or a fortnight. A course of treatment at a spa, with hot baths and rubbing, is a great aid to complete recovery. During an acute exacerbation occurring in a chronic case, when the fibrous indurations swell and cause pain or severe aching, general treatment may be necessary. The treatment is that of a slight feverish attack, and improvement takes place in a few days. Sodium salicylate, acetyl-salicylic acid, or salicin, alone or with phenacetin, greatly relieves the pain; or a hot bath followed by a copious perspiration, or a Turkish bath, may cut short the attack. If the pains are widely spread, rest in bed, light diet, saline purgation, and mild diaphoretics and diuretics hasten recovery, and give ease to the patient.

Very often the chief site of the pain is localized in the lumbar region, or in the shoulder, neck, or chest wall. If so, a few thorough applications of massage may give complete relief. The parts are usually very tender, and the manipulations must be begun very gently by stroking, so as to get rid of the exudation and relieve tension, but gradually more severe pressure can be borne, until finally the fist or knuckles may be forcibly applied. Dry cupping, hot applications, mustard, methyl salicylate, menthol, A. B. C. liniment, etc., are all of great value in relieving the local pain, and may be used in addition to the massage.

To obtain permanent cure and complete relief from recurrent attacks, the fibrous indurations must be got rid of, and this is always a tedious and troublesome affair.

Massage.—The most important agent at our command is massage aided by appropriate exercises. General massage as ordinarily applied is of no use, as treatment must be specially directed to the nodules and indurations which can be felt, and to those parts which are painful on pressure or movement. In carrying out the massage, the muscles of the part should be relaxed, and the skin (shaved if necessary) be well smeared with vaseline, oil, lard, or liquid paraffin. To begin with, the rubbing should not be too severe, as it is apt to irritate unduly the indurations and so cause sharp pain, followed by aching and stiffness. It requires a good deal of tact and experience to determine how much pain must necessarily be caused, and how much the patient may reasonably be expected to put up with. Different individuals vary very much in these respects, and also in the feeling of fatigue following the massage. If the manipulations are properly carried out, the pain is severe only during the actual rubbing. After a few days of treatment the fibrous thickenings become harder and more defined, and only then are many of them detected. After treatment for ten to fourteen days they begin to shrink in size and become more callous, and then more and more pressure may be applied to them, until even the knuckles may be used. The massage must be carried out daily for an hour, about fifteen minutes being devoted to each part treated. If expense is no object, two masseurs may be employed. If the indurations are numerous and widespread over the body,

the best plan is to select three or four regions for treatment (e.g., the back and thighs), and to continue with them until a cure is effected, before proceeding to deal with other parts. At the beginning of each treatment gentle effleurage should be given for two or three minutes to remove serous engorgement and to make the subsequent manipulations less painful. For a thoroughly satisfactory result the indurations must be completely dispersed, otherwise the pain and aching recur. The length of time required for this varies very much. Recent soft thickenings can be removed in two or three weeks, or less. In old-standing cases, three to six or twelve months are required. The rapidity of dispersion depends greatly upon their anatomical situation. If the nodules can be compressed against a bony part, such as the sacrum or humerus, the massage is much more effective than when they lie in the fleshy mass of the thigh or alongside the spinal column, where they are difficult to get at. Deeply placed nodules in the heel and elsewhere can seldom be removed.

Exercises.—Appropriate exercises which stretch the joints, aponeuroses, and muscles involved, are a great aid to the treatment just described. They can be readily devised, and can be carried out without any apparatus, or with the aid of dumb-bells, Indian clubs, a stick, and an indiarubber exerciser. Two periods of ten minutes daily are sufficient for the purpose.

Faradism.—The faradic current is of some assistance also, especially if neuritis is present.

Drugs.—No remedies are known which cause absorption of the fibrous indurations. Locally, blisters and iodine sometimes do good, but very often they have no effect, probably because many of the indurations are beyond the reach of their action. Where the periosteum or joints are affected superficially (close to the skin), the results are better than in other cases.

Where intestinal indigestion is present, a small dose of rhubarb and grey powder at night, with a saline purgative in the morning, often lessens the aching. The salicylates of sodium, of methyl, and of quinine, and other salicyl compounds, such as acetyl-salicylic acid, salicin, salol, etc., often give relief to pain, but their value is merely that of a temporary palliative. The same is true of phenacetin, phenazone, quinine, and similar substances. In very recent cases potassium iodide has a limited value, but it is quite incapable of dispersing old indurations.

Diet.—Dietetic treatment is, *per se*, of no specific value. The broad rule is to avoid gastro-intestinal fermentation, and this is best done by a sufficient but simple ordinary diet. It is very important that digestion should be perfect.

Spa Treatment.—In recent cases, where the fibrous thickenings are newly formed and still plastic, cure is often rapidly brought about by a course of bathing, or hot-air treatment, combined with massage. Even in chronic cases a good deal of relief from the stiffness and aching is obtained. The indurations remain, however, and, after a longer or shorter time, again give rise to symptoms.

Climate.—During a sojourn in a dry, stimulating climate rheumatic people find that their sufferings are much lessened or even entirely abolished. In some cases the indurations appear to be absorbed.

Surgical Treatment.—Single nodules, if they are well-defined, may be excised. The operation is not always an easy one, as the small mass of fibrous tissue may lie deep, and is then very difficult to find.

Chromic Acid.—If the nodule is sharply defined and can be accurately penetrated by a hypodermic needle, the injection of 5 to 8 min. of a 1 per cent solution of chromic acid often causes it to shrink, and greatly relieves muscle

and nerve pain. The small piece of fibrous tissue is, however, very easily missed, and the treatment is only occasionally suitable.

Prophylaxis.—Rheumatic patients should avoid damp, draughts, and over-exertion; but on the other hand they should lead active out-of-door lives as far as is possible, and take plenty of muscular exercise. Sore throats, muscular colds, and indigestion should always be carefully and immediately treated.

Prognosis.—Under such methods of treatment as have been indicated, the prognosis is good in most cases of ordinary severity, but time and perseverance are necessary. In very severe cases, where there are large and numerous indurations, and the patient is very stiff and crippled, recovery is hopeless, but by stretching, massage, and manipulations, more freedom of movement may be obtained. When the subcutaneous tissue is brawny and much thickened over a large area, such as the lumbar region, any very substantial improvement is rare except after very prolonged and continuous treatment. *Ralph Stockman.*

RHEUMATOID ARTHRITIS.—Within the last few years the views of physicians as to the value of treatment in checking the progress of rheumatoid disease have undergone considerable modification. Formerly it was believed that treatment was of little or no avail, but now it is held that our efforts may be rewarded not only with great alleviation, but possibly in some cases with cure, if the condition be treated in its earliest stage. It is therefore essential to recognize the disease early, and to persist in a carefully thought-out plan of treatment, possibly for many weary months. Consequently, the patient's co-operation and help are of prime importance.

Rheumatoid arthritis is essentially dependent on agencies which lower the general health, and any line of treatment not based upon this fact is foredoomed to failure. Recently, too, it has been admitted that the actual cause of the disease is, in all probability, a bacterial or toxic poison affecting the entire system as well as the joint structures. It is therefore essential to make a most careful scrutiny of the patient's past history, to discover the offending organ or function through which the poison has obtained entrance, and, by correcting any local disturbance, prevent further developments of the mischief. For instance, it is important to remember that in many cases the disease follows some chronic lesion of the mucous membranes, some local discharge, some ovarian or uterine disorder, or it may come on subsequent to some general infection, such as influenza, etc. Local lesions must, in the first instance, be remedied as far as possible; in the second place, vaccines can in some cases be profitably employed, and in all it is possible to increase the resisting power of the patient by overcoming general debility; and in the third place, the organism must be assisted by drugs, baths, etc., to eliminate the poison. With these objects in view the principal elements of treatment may be subdivided into four sections: (1) Diet, clothing, exercise, climate, etc.; (2) Vaccines; (3) Drugs; and (4) Thermal, electric, and surgical treatment.

I.—DIET, CLOTHING, EXERCISE, AND CLIMATE.

1. *Diet.*—Following what has already been said, the diet must be of a nourishing and sustaining character, but it must not be too rich. It is fatal to place a patient on a low diet on the supposition that it is a gouty condition; any restricted dietary is almost certain to do harm. It should be varied, and contain plenty of nitrogenous food. Fats are important, and cod-liver oil in many cases must form a staple article of diet. Vegetables and fruit are necessary; abundance of milk, butter, and cream are indicated. Should there be fever, the food must be given in a liquid form. Stimulants are often of service, especially

good sound wine ; but each case must be considered separately, and should the stimulant increase the pains, it must be discontinued. Food should be taken regularly, and its quantity determined by the patient's condition and increase or loss of weight. Although no hard and fast rules can be laid down, the following is a good diet list :—

Soups.—Mutton, chicken, oyster, turtle, barley, rice, pea, bean.

Fish.—All that agree—boiled, baked, stewed, or broiled—not salt fish.

Meats.—Beef, broiled or roast ; lamb, roast or broiled ; mutton, roast or broiled ; poultry, roast or broiled ; game ; sweetbreads ; predigested meats (beef peptonoids, sarco-peptonoids, peptonized beef tea, beef jelly, etc.).

Eggs.—Raw, poached, or boiled.

Vegetables.—Greens, lettuce, celery, spinach, asparagus, cresses, cauliflowers, onions, tomatoes, green peas, beans, lentils, and other leguminous vegetables ; rice, well cooked, sparingly ; potatoes, more sparingly.

Bread.—Wheat and gluten bread, toast, milk-bread toast. Bread should be at least one day old, and only a small quantity should be taken.

Fruits, etc.—Oranges, lemons, pears, apricots, peaches, grapes, green figs, and dates ; apples baked, but not raw ; walnuts, and other nuts, sparingly.

Drinks.—Fresh water, but Apollinaris and other carbonated waters sparingly ; hot milk, cream, egg-nog, lemonade, sherbet, alcoholic drinks as prescribed (whisky, wines, and malt liquors) ; malt preparations, coffee, tea, cocoa, chocolate more sparingly.

2. *Clothing.*—Too much clothing does harm, yet it is essential that the body should be encased in woollen garments worn next the skin. Some patients find it desirable to wear a piece of wash-leather next the skin and over the affected joints, but often this plan leads to abuse, and in the majority of cases is unnecessary. Many rheumatoid cases feel cold and damp to a much greater extent than ordinary rheumatics, and this has to be taken into account. They are also particularly sensitive to changes in the wind, cold easterly and north-easterly winds being more especially felt.

3. *Exercise.*—In acute cases, where there are fever and great pain, the patient must be confined to bed, but on no account should this be continued a day longer than necessary, and everything must be done to encourage the patient to move and use the joints as much as possible. Half the battle is to induce the patient not to give up doing things, for once a joint is allowed to stiffen and become useless, many months of treatment will be required before it becomes usable again. If the pain be very severe, a light splint may sometimes be used for short periods, but as soon as possible gentle passive movements and massage must be begun. In the more chronic cases, rest in bed is a mistake, and the patient should be ordered a moderate amount of exercise. If unable to walk out-of-doors, fresh air should be obtained by carriage driving or in a Bath chair, and, as the case becomes less acute, graduated gymnastics, special movements, passive exercises, and the use of Zander machines and of pulleys and weights are all of great help. In no circumstances is force or violence to be used or recommended ; everything must be done gently and progressively, and with as little pain as possible.

4. *Climate.*—As far as possible no rheumatoid patient should be allowed to live in a damp, cold climate, on heavy clay, or at the bottom of a valley. The ideal climate is bright, sunny, and dry, and the soil should be sand or gravel, with no subsoil water. In this country this is hard to find. The seaside is not suitable, but these cases often do well on a high moorland, where the moisture runs off quickly—especially in summer. Wherever possible the patient should winter in a dry, warm atmosphere, as for example in Egypt (Assouan for preference), or at Biskra in Algeria. As a rule the northern Mediterranean seaboard is not advisable. Some cases do very well at Seville, a place where the disease is practically unknown amongst the natives. But it must be borne in mind that rheumatoid patients require comfort and good food, and therefore it

is better to live at home than go where these cannot be obtained. Many have found benefit from a visit to the dry Karoo of South Africa, or to some of the dry places in Western America, but these are not available to the ordinary patient. As a rule a sea voyage is not desirable, but the mere rest and absence of worry may do good. Plenty of fresh air and sunshine are of the utmost importance.

II. VACCINES.

We know no specific vaccine for this disease. Looking upon it as an infective condition, the question of a general antitoxin or vaccine naturally arises. So far such has not been found, but within the last few years the writer has succeeded in having a micro-organism isolated from the blood of certain acute cases, and in having a vaccine prepared which when injected has been found to give very great relief from pain and a marked improvement in the joint condition. The cases so treated have been comparatively few in number, and this line of treatment is mentioned here only to draw attention to what may materially help in certain of the more acute cases. Painter, of Boston, has also used a vaccine in joint conditions resembling rheumatoid arthritis, but he used it as a stock vaccine, and did not isolate the individual micro-organism in each case; hence, probably, his disappointing results. A few other cases corresponding apparently to typically acute rheumatoid arthritis have been benefited, and the disease apparently arrested, by the injection of the polyvalent antistreptococcic serum. Warren Crowe has reported some cases improved by the use of a vaccine made from a staphyloid coccus isolated from the urine. Cases have also apparently been cured or greatly improved by the use of a vaccine prepared from the streptobacillus found in pyorrhœa alveolaris. Many cases do undoubtedly improve by vaccine treatment where pyorrhœa exists, but there are many cases which give most disappointing results.

For rheumatoid cases the preparation most used is composed of the *Streptococcus rheumaticus* and a basic mixed infection. At present our experience is too limited to do more than record these facts, but as it seems fairly certain that several infections may cause the disease, so we must expect different vaccines to act differently in different cases. It is most important, therefore, to find the individual cause in each case.

III. DRUGS.

Treatment by drugs may be classified under three headings: (1) Those substances which, when administered internally, are antagonistic or antitoxic to the rheumatoid poison, or which enter into conjunction with it and thereby assist in its elimination; (2) Those substances which act by improving the general tone of the body, and those whose action is more or less indefinite, and which have been given empirically and to relieve symptoms; and (3) Those substances which are of use when applied externally.

1. In the first group we know of no substance having any certain antagonistic action, except it be those vaccines or serums already mentioned. We are therefore forced to turn our attention to those drugs which have been found useful owing to their power of entering into conjunction with the rheumatoid poison and thus assisting in its elimination. To this group belong guaiacol carbonate, benzosol, salol, and quinine salicylate. Their action in the first instance seems primarily to be in the intestinal canal, where they decompose with varying rapidity. After being split up into their component parts, they are absorbed, and, in the blood, enter into combination with the toxic albumins, and thus render their elimination easier. The longer the substance takes to decompose, the greater its local action; and, in inverse ratio, the greater the rapidity of

decomposition, the greater the rate of absorption and the eliminative power. Apparently the various substances do not act with certainty or regularity, or they are governed by factors of which at present we are ignorant. Thus, one case will do well on guaiacol carbonate, whereas another will do better with the quinine salt. Cases have occurred which, while unresponsive to one of these drugs, when put on one of the others have been followed by an increase in the amount of urine excreted, which often gives off a volatile matter with an unpleasant odour. This has always been followed by an immediate improvement in the joint condition. It is therefore obvious that, while one salt had not produced an easily excretable combination, the other salt had. The large majority of cases respond best to guaiacol carbonate. It may be administered in doses of 5-10 gr. three times a day in powder, pill, or cachet. It is usually readily taken, with little or no symptom of intolerance. After ingestion it is decomposed throughout the entire length of the small intestine, giving off guaiacol, which is absorbed into the blood, and carbonic acid. The total process of decomposition is slow, but within an hour or so the guaiacol can be traced in the urine, and as only a small quantity exists in the blood at one time, it can never become dangerous.

Benzosol is slightly soluble in the stomach, and more so in the intestines. It splits up into guaiacol and benzoic acid. It is given in doses of 5-10 gr. three times a day, and acts much as does guaiacol carbonate. Salol may be given alone in 10-gr. doses, but it acts better when combined with quinine salicylate, and it may then be given in 5-gr. doses. It splits up in the intestines into phenol and salicylic acid, both of which are rapidly absorbed and form compounds with the toxic products, and so assist their elimination. Quinine salicylate may be given in 4-10-gr. doses, with or without salol. Its action is similar.

2. In the second class are those drugs which have been found useful by improving the general tone of the body—the most important being iron and arsenic. They are best given in conjunction, either in a pill or mixture, probably the best preparation of iron being the syrup of the iodide. Many prefer to combine the iron with quinine. Arsenic may be given as the liquor potassii arsenitis, or as the liquor sodii arsenatis. Iodine and the iodides are commonly supposed to be beneficial, iodide of iron being said to have a special action. As a tonic it is excellent, but beyond that it has no influence. Barr strongly recommends the free use of lime salts, and amongst many other remedies are the alkalies, *actæa racemosa*, *fraxinus excelsior*, *colchicum*, etc., which all have their advocates, but are of little lasting avail. Quinine has already been spoken of. The salicylates may occasionally give relief, but their action does not seem to be curative. Guaiacum has been largely used, and abroad ichthyol is a favourite remedy. For the relief of painful cramps, Dr. Garrod recommends hyoscymus. Morphia is occasionally necessary for the relief of pain. Thyroid extract helps in some cases, more especially where there are marked vasomotor phenomena present, but its use cannot be generally recommended. An extract of thymus and glycerin has been recommended by Dr. Solis-Cohen, and the late Dr. Hyde tried an extract of joint-tissue. Neither remedy has been successful to any great extent. Radium has latterly been strongly recommended, and is most frequently administered in water which has been made strongly radioactive. The reports so far published record satisfactory results. Fibrolysin, injected subcutaneously, helps in many cases in relieving stiffness, but has no apparent effect on pain. It is principally used to prevent the occurrence of deformities. Care has to be taken not to give too many or too frequent injections, as some patients exhibit a marked rise in temperature and a general exacerbation of the joint symptoms from its use.

3. For external use the best drugs are—guaiacol, which should be applied in equal parts with olive oil, or in the proportion of one to six of weak tincture of iodine (B.P.) ; methyl salicylate, either pure or with olive oil, lanolin, or vaseline ; mesotan (deodorized methyl salicylate) one in three, with olive oil or lanolin. After the preparation has been applied to the skin it should be covered over with lint, guttapercha tissue, and a bandage, or else with a glove. The principal objection to guaiacol, and to a less extent to methyl salicylate, is its smell ; in private practice, therefore, mesotan answers best, but it must be remembered some patients exhibit a marked intolerance to it. Oil of cloves masks the smell to a certain extent, but not entirely. When applied externally, they all produce a slight numbness, a sense of coolness, and a feeling of relief. They are absorbed rapidly and can be traced in the urine. They may produce a reddening, and occasionally, if applied too strong, a blistering of the skin ; so care must be taken with the first few applications.

Carbolic acid is used, in the strength of 1 in 30 or 40, as a warm fomentation, renewed every two or three hours, and acts as a local anæsthetic and analgesic. In acutely painful joints it may give great relief.

Menthol may be combined with any of the foregoing, and is often useful. Apart from these, practically every liniment has been tried ; all are more or less unsuccessful in the majority of cases in accomplishing more than the temporary relief of pain. Iodine frequently relieves pain, and may diminish the size of a joint : the writer prefers to combine it with guaiacol or methyl salicylate. A small cantharides blister often markedly relieves pain and lessens a swollen joint, and occasionally much relief may be got by freely and repeatedly blistering the spine as recommended by Dr. Latham. Chaulmugra oil, cod-liver oil, oleate of mercury and morphia, unguentum hydrarg. co. (B.P.), are often useful to rub into a joint, or for strapping. Ordinary strapping is of use in many cases in lessening the size of a joint, and it certainly relieves pain. It is most usefully applied to a knee or wrist.

IV.—ELECTRICAL, THERMAL, AND OTHER SPECIAL TREATMENT.

Electrical Treatment often gives much relief, probably most good being gained from the use of a weak continuous current used twice a day. It should be applied directly to the affected joint. The interrupted current does not give such good results. In no case should electricity be used in acute cases. It is particularly of service where there is much wasting, and the application must be to the individual muscles. The electric bath has also been used, but it does not seem to act otherwise than as a general nerve tonic. Latterly, high-frequency currents, static electricity, and sinusoidal currents have all been used, and occasionally some good may be obtained, but their use is not required as a routine treatment. Cataphoresis helps materially in the more chronic forms in relieving pain and reducing the size of a joint. It is also found useful in relieving stiffness. The drugs mostly used for the ionization are salicylate of soda and iodide of potash.

Thermal Treatment.—The use of hot mineral waters and other accessories is of the utmost use ; but while one can safely say this, it must be remembered that different waters are most advantageously employed in different cases. Many things must be taken into account besides idiosyncrasy, in ordering a patient to a certain spa, and for a certain course of treatment ; but broadly speaking, a spa that is at all lowering is useless in this disease. Unfortunately no fixed rules can be laid down, but undoubtedly hot alkaline, or indifferent strongly radicle-active mineral waters, with douches and massage, act best ; and perhaps next to these, the warm peat baths. In this country Bath and Buxton are probably the most successful. Owing to its situation, Bath is much warmer than Buxton in

winter, and hence, in the majority of cases, is the more suitable. Should it be desirable to try the sulphurous waters of this country, Strathpeffer and Harrogate are of use in summer. At the former spa an excellent form of peat bath is employed. Amongst the other spas in this country are Woodhall (iodine) in Lincolnshire, and Llangammarch (bromine) in Wales, both of service in certain cases. Abroad we have the thermal waters of Aix-les-bains, La Bourboule, Mont Dore, Aachen, Wildbad, Wiesbaden, Töplitz, Homburg, Kissingen, Assouan (Egypt), Hammam R'Irha and Hammam-Meskutine (Algiers), Arkansas, Virginia, and Banff (America). When anæmia and debility are prominent symptoms, the chalybeate waters of Langenschwalbach, Rippoldsau, Spa, and Franzenbad are of use.

Mineral waters are administered both internally and externally. Moreover, the balneological treatment is only part of the cure, as by going away from home many of the daily worries are left behind, and the patient has the advantage of change of air and scene, and superintendence of diet and mode of life.

Why mineral waters should relieve rheumatoid patients is not quite obvious, but that it does so we know from experience, and also that it cannot altogether be replaced by other modes of treatment. To explain it scientifically is difficult, but it is probable that most mineral waters act beneficially on account of their radio-activity, and doubtless partly by causing increased perspiration and expiration of watery fluid from the lungs, with consequent increased imbibition of fluid and flushing of the body channels; also by their sedative action on the nervous system, and by their stimulating effect on the circulation as a whole.

In rheumatoid arthritis, douche massage is the best form in which to administer baths. The massage combined with douching is much more effectual than either remedy alone, although great benefit is derived from additional dry massage on days on which the patient is not bathed. Massage is specially indicated in chronic cases, and where there are much stiffening, fixation of the joints, and muscular wasting. It may be combined with electricity, or with passive or active movements. At first it should be applied very lightly, and principally to the muscles, and then, as it is found the patient can stand it, to the joints, getting more forcible and deeper as the case goes on. Massage *à friction* is the most suitable form to use, but in addition, gentle kneading and squeezing of the tendons and fibrous parts may be practised.

Should douche massage baths not be advisable, ordinary immersion, with or without douches, vapour baths, peat baths, radiant heat or electric baths, are all of use in special circumstances. Plombières douches are often most useful in cases with colitis, and sometimes they seem to not only cure the local condition, but greatly help the general joint condition.

If there be much rubbing of ulcerated cartilages one upon another, with great pain, relief may sometimes be got by extension by weights. This method is particularly useful in the case of the knee-joint. Heavy weights are unnecessary. Again, if there be much tension of a joint from fluid, good may be done by tapping the joint, great care being taken to see that the syringe is aseptic.

The prevention of deformities is of great importance, and this can usually be secured by massage, etc., and the use of light springs which are applied to exert their strength in the opposite direction to that in which the deformity is occurring. In the case of the fingers and hand, the springs are best applied attached to a glove, which may readily be drawn on and off. Should ankylosis occur, it may be desirable to give an anæsthetic and move the joint, or possibly the question of a more drastic operation may arise.

Bier's method of passive congestion by the use of a Martin's bandage may in some cases and for a time greatly relieve pain and swelling, but more than that it does not seem to do.

Surgical Treatment.—Recently surgical treatment of rheumatoid arthritis has received a good deal of attention both on the Continent and in America, and good results have been recorded both for the relief of ankylosis or locking of a joint, and with the view of arresting the spread of the disease. In one class of case the operation can be intended as a local measure only, whereas in the other it is done with a view to eradicating the disease. Data at present do not allow us to speak authoritatively on either question, but it seems to the writer that excision or removal of bony nodules must be a comparatively rare necessity. For one thing, bony ankylosis is very rare in true rheumatoid disease, and although bony excrescences and fibrous adhesions are common in the chronic forms, yet the stiffened joints usually yield to milder forms of treatment, and even if ankylosis has occurred, it is but in few cases one would recommend excision or the formation of a new joint, and only if the ankylosis were the cause of such serious crippling as to affect the general health or wage-earning capacity of the patient. Recent advances in surgical methods have made the question of the formation of new joints one which in some cases must be considered, and the results reported are so good that this method of treatment holds out great hope of benefiting those who are incapacitated from using some of the more important joints. These methods would only be of service when the disease had assumed a quiescent stage, and where one, or at the most two joints were involved. In these cases there is no question of cure, but it is quite otherwise in the acute cases, where excision, incision, and scraping of the joint tissues, or incision only, have been practised, with the idea of arresting the spread of the disease. The operations so far have been confined to one, or at most two joints, and many of the cases have given most encouraging results, as it has been found that by the removal of the diseased cartilages and synovial membranes of one joint, not only is that joint improved, if not cured, but the other affected joints are also improved. As our knowledge at present stands, surgical interference should only be recommended in the chronic cases where real bony ankylosis has occurred, or where there are such rigid fibrous union and locking of the joints as to resist all gentler methods, and where the joint thus fixed seriously interferes with the patient's health (as in the case of the jaws) or his wage-earning capacity; and in the acute cases, only where the disease is so severe and painful as to resist all other methods of treatment, and where the patient is fully informed of the dangers and probabilities of the operation. As a rule, once a stiffened joint has been made to move by massage, passive movements, and baths, the atrophied muscles quickly respond to treatment. Electric and other stimuli soon cause the tissues to regain their tone and usefulness.

To SUMMARIZE.—In the acute stages the patient should be kept quiet and on a light, nutritive diet, being encouraged, if possible, to use the joints gently, and for short periods; but if too painful, the limb may be allowed to rest for a short time in a splint. The use of vaccines must be considered, and where any micro-organism can be isolated, vaccines should be employed. The joints should be painted with guaiacol and olive oil or iodine, or with methyl salicylate or mesotan, or fomented with carbolic acid fomentations. Internally, guaiacol carbonate or salol with quinine should be given, and, as an occasional tonic, iron and arsenic. If sleep be not readily obtained, this must be attended to, as must also be the various functions and organs of the body. If the patient can stand it, light massage and baths, for short periods, may be ordered. As the case becomes more chronic, the thermal treatment must be pushed, increased exercises, electricity, and gymnastics now being also indicated. Internally, the treatment must be as in the acuter stages, with possibly the free use of cod-liver oil and maltine. Above all, there must be persistence and patience.

Gilbert A. Bannatyne.

RHINITIS,

Acute Rhinitis.—The ordinary cold in the head is so familiar that it may be briefly dealt with.

In the *earliest stage*, when the patient has a burning or pricking sensation in the nose or throat, and is feeling feverish and ill, but before any definite symptoms of catarrh have commenced, various remedies have been recommended to cut short the disease. None of these is absolutely reliable, but all are apparently successful at times, and act better in some patients than in others. One of the best is a full dose (10 gr.) of Dover's powder at bedtime. The diaphoretic action of this drug may be increased by taking a hot bath and by some of the other remedies about to be described. Another remedy, successful in some patients, is the administration of a single large dose of quinine, 5 to 10 gr. It should be given in solution; or the ammoniated tincture of quinine (B.P.) may be prescribed in drachm doses every two hours for three doses. Others recommend ten drops of spirit of camphor to be taken as a single dose; essence of cinnamon and carbolic acid in one-grain doses taken every hour for six hours, also have proved successful. Whenever possible the patient should remain in bed one day, and stay in the house another day if the weather is inclement.

In the *second stage*, when the cold has really commenced, the ordinary household remedies should be employed. The patient should have a hot bath in a warm room and go straight to bed. He should take plenty of hot drinks, such as hot lemon, or hot whisky and water. The following mixture is very beneficial:—

R Morphinæ Sulphatis	gr $\frac{1}{10}$		Aquæ Chloroformi	q.s. ad $\bar{3}$ ss
Liquoris Ammonii Acetatis	$\bar{3}$ ij			

One tablespoonful to be taken every two hours for four doses, or until sleep or profuse perspiration is produced.

An alternative mixture having almost identical effects is the following:—

R Tincturæ Opii	℥iij		Aquæ Destillatæ	q.s. ad $\bar{3}$ j
Sodii Bicarbonatis	gr x			

Two tablespoonfuls every two hours for four doses, or until sleep or profuse perspiration is produced.

A hot steam inhalation, made by adding 1 dr. of tincture of benzoin, or 1 dr. of a 10 per cent solution of menthol in spirit, to a pint of water at a temperature of about 130° F., will often alleviate the local discomfort. The patient should inhale the steam through the nose for five to six minutes, and the inhalation may be repeated three or four times a day provided the patient remains in a warm room. If confinement to one room be impossible, the best local application is a soothing ointment, such as plain lanolin or weak boracic ointment, containing 5 gr. of menthol to the ounce. A piece about the size of a pea is inserted up each side of the nose and well smeared over both nostrils. In addition to this treatment the patient's general health should be attended to. The diet should be light and nutritious, and a brisk purge should be given. If these directions can be followed out for two or three days, a cold can generally be cured. This is of importance in the very young, in the aged, and in weakly persons, and it is especially important in singers and other professional voice users. Solution of cocaine as a spray, or ointments containing cocaine, are frequently recommended as local applications in this stage, but their use should be absolutely forbidden. The constant use of cocaine is exceedingly pernicious, and it is at all times a dangerous drug to place in a patient's hands. The use of epinephrin or other of the suprarenal extracts is equally pernicious.

In the *third stage*, when the sneezing and irritation have subsided, when the profuse watery discharge is lessening and becoming more sticky and more

muco-purulent, a simple alkaline nasal lotion such as the following should be prescribed :—

R Sodii Bicarbonatis	Sacchari Albi	gr v
Boracis	Aquæ Destillatæ	q.s. ad ʒj
Sodii Chloridi	āā gr ij	

It is convenient to prescribe this lotion three or four times the above strength, with directions for diluting it sufficiently with warm water before use. It may be sniffed up the nose from the palm of the hand or from a cup or glass, or more conveniently be introduced into the nose with one of the nasal irrigators. In children a small glass syringe should be used and the fluid injected as gently as possible. The nasal douche should never be employed.

The use of the boracic ointment as above described may be continued. As the patient becomes convalescent, the best remedy is a change of air to the country or seaside, together with a suitable tonic. Cod-liver oil may be given to children, perchloride of iron and strychnine to adults.

PROPHYLAXIS.—Much may be done to prevent colds. Children who are particularly prone to nasal catarrh should be examined carefully with a view to the detection and removal of adenoids. In adults any chronic nasal affection should be remedied, especially any cause of nasal obstruction, such as hypertrophy of the inferior turbinates, polypus, and thickening or deviation of the septum. General measures should also be adopted. The clothing should be warm and light. The healthy action of the skin should be promoted by a cold or tepid daily bath, followed by thorough drying and rubbing, or by an occasional Turkish bath. The patient should sleep with open window, should avoid cold draughts when overheated or tired, and should especially avoid hot, stuffy rooms. Ill-nourished children should be put on a fattening diet and cod-liver oil prescribed, and any departure from the normal general health must be corrected.

Fibrinous Rhinitis (Croupous or Membranous Rhinitis).—Whenever fibrinous rhinitis is suspected, the nasal secretion should be examined for the Klebs-Löffler bacillus, both by staining films of the discharge and by taking cultures. If the organisms be found, the patient should be isolated, and must not be allowed to associate with other children until by subsequent examination it has been ascertained that the bacilli have disappeared. The child must be kept quiet, but is usually not sufficiently ill to be confined to bed. Plenty of good food, and a tonic, such as Easton's syrup, should be prescribed. The nose should be frequently washed out with a weak solution of boric acid (10 gr. to the ounce), or with salt and water (1 dr. to the pint) to which Sanitas, an ounce to the pint, has been added. Weak boracic ointment or, better still, dilute nitrate of mercury ointment, prepared according to the following formula, should be applied to the anterior parts of the nose with a brush :—

R Unguenti Hydrargyri Nitratiss	gr xl	Paroleini	q.s. ad ʒj
Olei Amygdalæ	ʒ ss		

Under this treatment the child usually makes a complete recovery in three to six weeks. The disease is never followed by serious sequelæ such as paralysis, and never gives rise to the severer forms of diphtheria in others.

Attempts to remove the membrane should be avoided, as they cause bleeding and discomfort, and the membrane quickly re-forms. The use of antidiphtheritic serum has so far proved useless.

Chronic Rhinitis.—Both local and general treatment are necessary. The general treatment consists chiefly in the correction of any constitutional condition, such as anæmia, dyspepsia, or constipation.

The plethoric, gouty, or alcoholic patient must be carefully treated by regulation of the diet, restriction of alcohol, and regular exercise in the open air. Many men who lead a sedentary life without regular exercise, and eat and

drink too much, are greatly benefited by undergoing an annual "cure" at a health resort, such as Carlsbad, Contrexéville, or Marienbad. If a visit of this kind be impossible, a morning dose of *mistura alba* or of some natural aperient water will be beneficial. An occasional Turkish bath is often useful. Late hours, overheated, ill-ventilated, crowded rooms and other insanitary surroundings, should be avoided.

In the anæmic, thin type of patient the diet should be nourishing and include plenty of fats. Cod-liver oil may be given if the patient can digest it; an iron and strychnine mixture often does good. The patient should live in well-ventilated rooms, take a fair amount of outdoor exercise, and wear suitable clothing. A cold morning bath is useful, provided it is followed by a healthy reaction. In all cases a change of air, especially to a dry, bracing place, is of the greatest benefit.

In old or delicate persons the question of change of climate must be considered. Although the affection is not serious in itself, it may be impossible to cure it if the patient remains in the ordinary English climate during the winter. It may be necessary to send such patients to a health resort in the South of England, or to a warmer climate such as Madeira or Egypt.

Patients who suffer from repeated severe nasal catarrhs, especially those with a tendency to bronchitis or other chest trouble, may be strongly advised to take an annual "cure" at Ems.

The *Local Treatment* depends upon the local condition. If there is no gross abnormality in the nose, such as hypertrophy of the inferior turbinates, the affection will usually yield to simple local measures combined with suitable general treatment. The best is the regular use of an alkaline lotion to cleanse the nose. The lotion should be sniffed up the nose or introduced with a nasal irrigator. It should be used regularly at least twice a day. The following are examples of useful formulæ:—

R Sodii Bicarbonatis		Sacchari Albi	gr v
Boracis	āā gr iij	Aquæ Destillatæ	q.s. ad 3j
Acidi Carbolici	gr j		
R Sodii Bicarbonatis		Sacchari Albi	gr v
Boracis		Aquæ Destillatæ	q.s. ad 3j
Sodii Chloridi	āā gr ij		
R Glycerini Boracis (B.P.)		Aquæ Destillatæ	q.s. ad 3j
Alcoholis	āā ℥x		
R Sodii Bicarbonatis		Eucalyptolis	℥ 1½
Boracis	āā gr iv	Mentholis	gr ½
Sodii Benzoatis	gr ½	Aquæ Destillatæ	q.s. ad 3j

It is convenient to prescribe these lotions four times the above strength, and to direct the patient to add ½ oz. to 1½ oz. of warm water for use. The second and fourth prescriptions may be given in the form of compressed tablets, a great convenience to patients who travel. When one lotion fails, another should be tried.

If this treatment fails, or succeeds only up to a certain point, an oily spray may be used. The following are two of the most useful formulæ:—

R Mentholis	gr v	Olei Amygdalæ	q.s. ad 3j
Olei Eucalypti	℥ xx		
R Unguenti Hydrargyri Nitratis	gr xl	Paroleini	q.s. ad 3j
Olei Amygdalæ	5ss		

To be applied with a small camel's-hair brush or by means of a spray twice daily after using the nasal lotion.

If these methods fail, more active measures must be adopted. In the first place, any cause of nasal obstruction, such as hypertrophy of the inferior turbinates, or deflection or thickening of the nasal septum, must be dealt

with (*vide infra*). If the nasal passages are unduly narrow, it may be necessary to remove portions of the inferior turbinates to make a free air-way through the nose. If the nasal obstruction depends mainly upon congestion of the inferior turbinates, the best treatment is the application of the galvano-cautery. Two or three applications may be necessary, as it is well to do very little each time. Local anæsthesia should be produced by packing pledgets of wool soaked in a 10 per cent solution of cocaine round the anterior half of one inferior turbinate. After ten or fifteen minutes the part will be found completely anæsthetic. The cautery point is then introduced into the nose, heated to a dull red-heat, and two or three horizontal lines are drawn along the inferior turbinate from behind forwards. Care must be taken to avoid burning the septum, and also to prevent the heated wire coming in contact with the skin of the vestibule. Injury to the septum is liable to lead to subsequent adhesions, whilst if the vestibule be burnt the pain is severe. Three or four days later the anterior half of the other inferior turbinate should be cauterized, and if it is necessary, after fourteen days, when these wounds have healed, the posterior ends of the turbinates should be similarly dealt with. These little operations are followed by very slight reaction. For the next few days a small piece of the following ointment may be inserted into the nose two or three times a day :—

R. Mentholis	gr vj		Lanolini	3j
Acidi Borici	gr xx			

A piece the size of a pea may be inserted into each nostril with the finger, or the ointment may be warmed and sprayed into the nose with a De Vilbiss spray. As a rule this ointment alone is sufficient, but if there be much nasal secretion an alkaline lotion (*vide supra*) should also be used.

Linear superficial cauterization as above described is better than puncture with the cautery, inasmuch as it is followed by less reaction and by more shrinking. The latter method consists in plunging the red-hot cautery point deeply into the tissues of the inferior turbinate, without destroying more of the surface epithelium than is absolutely necessary. This is done to avoid the danger of adhesions, but if proper care be taken there is no risk with the ordinary method.

When the electric cautery is not at hand, the application of a chemical caustic may be tried. Caustics act very well, but it is a little more difficult to limit their action. The inferior turbinate is anæsthetized with cocaine as above described, and then chromic acid fused on a probe, or fuming nitric acid on a wooden or glass rod, is applied to it. Any excess of acid is immediately wiped away with wool mops. These applications produce very little pain and are followed by little reaction.

When the nasal passages are excessively narrow, it may be impossible to clear them sufficiently by these methods, and it is often impossible to cure a chronic catarrh without restoring nasal respiration. Thus it may be necessary to remove portions of the inferior turbinates, and anterior turbinectomy, alone or combined with posterior turbinectomy, may be required. Enough tissue should be removed to restore free nasal breathing, but no more of the turbinate should be sacrificed than is absolutely necessary to attain this end ; therefore complete turbinectomy should never be attempted. For the methods of performing these operations see HYPERTROPHIC RHINITIS, *infra*.

To sum up, the treatment of chronic catarrhal rhinitis consists in the use of simple lotions and oily sprays, and, when these are unsuccessful, in the application of the galvano-cautery. Free nasal respiration must be restored by the removal of any deflection or thickening of the nasal septum, of hypertrophy of the inferior turbinate, of adenoids, or of any other cause of nasal obstruction, and even, in

cases of undue narrowness of the nasal passages, by the removal of portions of normal turbinates. At the same time appropriate general treatment must be carried out, and in some few cases, especially in old and delicate patients, or in those suffering from some dyscrasia, climatic treatment is absolutely necessary to obtain a cure.

Hypertrophic Rhinitis.—Hyperplasia of the inferior turbinates is usually associated with, and is merely an advanced stage of, chronic catarrhal rhinitis. If there be not too much hyperplasia, the treatment should be carried out on exactly the same lines as for chronic rhinitis. Simple cleansing lotions should be prescribed, and usually it will be necessary to reduce the enlarged turbinates with the galvano-cautery (see CHRONIC RHINITIS, *supra*). If this treatment fail, if the hyperplasia be excessive, or if the nose be unduly narrow, more active measures must be adopted. If the anterior ends of the inferior turbinates are in contact with the septum, and if this enlargement does not disappear under the application of cocaine, anterior turbinectomy should be performed. If only the posterior ends of the turbinates are hypertrophied, they may be removed with snare or cutting forceps. If the whole of the inferior turbinate is hypertrophied, a strip must be removed from the free border of the entire length of the turbinate, but no more should be removed than is necessary to restore free nasal respiration. These operations may be briefly described.

Anterior Turbinectomy may be carried out under local anæsthesia, or under nitrous oxide gas alone or followed by ether. In some cases it may suffice to

Fig. 64.—Anterior Turbinectomy. The plain lines show the blades of the scissors, the dotted lines the barrel of the snare and the wire loop.

remove portions of the anterior end of the turbinate with punch-forceps or nasal scissors, or it may be possible to snare off a large portion with a strong wire snare. When it is wished to remove a considerable piece of bone, as is necessary when the nose is unduly narrow, the following method will be found convenient: With nasal scissors or shears, or with strong cutting forceps such as Mahu's, the attachment of the inferior turbinate is divided from the outer wall

of the nose. The wire of a stout snare is quickly slipped into the notch thus made, and the anterior end of the turbinate cut through (see Fig. 64). As a rule this operation is followed by little bleeding, which soon ceases. The after-treatment consists in keeping the nose clean with a simple alkaline, or with weak boric acid, lotion, and in applying an ointment such as the menthol and boracic ointment (see CHRONIC RHINITIS).

Posterior Turbinectomy.—The posterior ends of the inferior turbinates may be removed with the cold wire snare. This is introduced through the anterior nares, and the wire loop is guided by sight over the posterior end of the turbinate, or held in position with the tip of the left forefinger introduced through the mouth. With the former method local anæsthesia is sufficient. The inferior meatus is packed with pledgets of wool soaked in a 10 per cent solution of cocaine and suprarenal extract. These are left in position for about half an hour, so as to obtain the maximum shrinkage of the mucous membrane. It is now usually possible to see the posterior end of the turbinate by anterior rhinoscopy. The wire loop of the snare is passed down the inferior meatus and adjusted over the posterior end of the turbinate partly by sight and partly by feel. A strong snare with a fairly thick wire is necessary, as the tissues are

often tough. It is convenient to give the loop a double twist, so that as the wire is tightened up it curves over towards the part to be removed, and thus prevents the tendency to slip off. This double twist is effected by protruding a small loop of wire from the snare and bending it sharply over in the direction in which it is desired that it should subsequently curl. Another quarter of an inch of the loop is then protruded from the snare, and the loop bent sharply back so as to lie in a line with the barrel (see *Fig. 65*). When in position the wire loop should be quickly tightened, so as to obtain a firm hold of the part, and then slowly pulled home, so that the cutting may be done slowly and the vessels obliterated as they are divided. In this way there will be very little bleeding. The after-treatment consists in cleansing the nose two or three times daily with a weak antiseptic lotion, such as boracic acid solution. For the first twenty-four hours all food should be given cold, and the patient should remain quiet, and especially abstain from violent efforts to blow the nose, for fear of re-starting the bleeding.

Fig. 65.—Method of shaping wire loop or snare. The plain line shows the wire loop as introduced into the nose, the dotted lines the positions it successively assumes as it is tightened.

If it is impossible to perform the operation in this way, or if for any other reason, e.g., for the removal of adenoids, a general anæsthetic is given, the operation may be carried out in a similar way with the snare; but the wire loop is guided over the posterior end of the turbinate and held in position by the tip of the left index finger, which is introduced through the post-nasal space (see *Fig. 66*). An easier method is to clip away the posterior ends with punch

forceps, such as Grünwald's or Mahu's, which can be more easily felt and guided by the finger in the post-nasal space.

Fig. 66.—Posterior Turbinectomy. Wire loop of snare held in position by left forefinger.

In rare cases of extreme turbinal hypertrophy or of unduly narrow noses, it may be necessary to remove a slice from the whole length of the turbinate. Successive portions may be removed with the snare, or the free inferior border of the turbinate may be clipped away with a pair of punch-forceps or scissors. With cocaine and adrenalin, with or without general anæsthesia, it is usually possible to see accurately what is being done, and to clip away just sufficient to give a free passage through both nostrils. No more tissue should be removed than is absolutely necessary.

The inferior turbinate is the most valuable structure in the nose, and its total, or too free, removal is apt to result in an intractably dry condition of the nose and whole upper air tract. After any operation on the turbinate, especially when performed under adrenalin, the danger of hæmorrhage four to six hours after the operation must be borne in mind, and the patient never allowed to go beyond reach of his surgeon. He must take the precautions described under anterior turbinectomy, and follow the same after-treatment.

Rhinitis Sicca.—Rhinitis sicca occurs in two distinct conditions: (1) It may depend upon anæmia, and is often associated with indigestion and constipation. The nasal mucous membrane is pale, shrunken, and dry. (2) It occurs in plethoric, gouty, or alcoholic individuals, in whom the mucous membranes will usually be found red, congested, and covered with small black mucous crusts.

A common exciting cause is the inhalation of dust, which alone may suffice to produce the disease. Thus, workers in certain industries, such as brush-makers, metal grinders, millers, and librarians, are liable to get a somewhat severe form of the affection without any predisposing cause.

In the first type the general treatment consists in regulating the bowels, in correcting any dyspepsia, and in the administration of a plentiful nutritious diet, with plenty of fresh air and gentle exercise. Later, tonics, such as iron, are useful. In the second type the patient's diet should be regulated, alcohol strictly limited, and outdoor exercises encouraged. Such patients will be all the better for a daily morning dose of Epsom salts or of some natural aperient water. A regular course of aperient waters at a health resort, such as Carlsbad, is usually beneficial.

The local treatment must also be attended to. The chief indications are to cleanse the nose and to prevent the formation of crusts. The nose should be washed out two or three times daily with an alkaline lotion (see CHRONIC RHINITIS), which after a time may be modified by substituting chloride of sodium or chloride of ammonium (5 gr. of either to the ounce) for the carbolic acid. To prevent the formation of crusts the washing should be followed by spraying the nose with oil. Two of the most useful prescriptions are given under CHRONIC RHINITIS, *supra*.

Sometimes it will be found more efficacious to use plain lanolin; a piece about the size of a pea should be inserted into each nostril twice or three times a day. There is a special tendency for the crusts to collect on the most anterior part of the mucous membrane of the septum. They often cause much irritation, which leads to picking the nose or to violent efforts to detach them. This leads to excoriation and ulceration of the mucous membrane, repeated epistaxis, and ultimately to perforation of the septum. This condition must be met by energetic application of oil or ointment to the anterior part of the septum, and if the patient's occupation entail work in a very dusty atmosphere, it may be necessary to change it, or he may wear wool in the affected nostril and breathe through his mouth whilst at work.

Atrophic Rhinitis.—This disease generally begins in childhood as a purulent rhinitis, but the characteristic symptoms—the crusty discharge and the foetid breath—are more usually delayed until adolescence. As the atrophic changes are progressive, prompt recognition and early treatment are essential to obtain the best results. It must be borne in mind that the crusts and the stench are *secondary* symptoms, depending upon the fact that the discharge is retained in the nose for a long period.

The mucopurulent nasal discharge, sometimes in part derived from one or more of the accessory sinuses, tends to collect in the nose because:—(1) It is unduly tenacious owing to atrophy of the secreting glands and diminished watery secretion; (2) The abnormal width of the nasal passages impairs the power of blowing the nose; and (3) The ciliated epithelium is replaced by squamous cells. The discharge retained in the nose, exposed to the passage of the respiratory air, loses water by evaporation and dries into crusts, and the germs in the air are deposited in the crusts, develop, and cause decomposition of the discharge, with the resultant foetid odour of the breath. Further, the products of decomposition are irritants and set up fresh discharge. These

pathological conditions explain the *rationale* of successful treatment and the intractable nature of the affection.

The nose must be syringed regularly with a mild antiseptic lotion. A solution of ordinary salt, a teaspoonful to the pint, to which a little Sanitas or permanganate of potash is added, a weak boric acid lotion, or any of the mild alkaline lotions (see CHRONIC RHINITIS) may be used. Strong lotions should never be employed. The nose should be syringed; sniffing up is useless, and the nasal douch is not really so effective as syringing, whilst it is more dangerous. Higginson's syringe is the most convenient for the patient's own use. About a pint of fluid should be used each time, and injected in various directions until the nose is absolutely clean. It is advisable for the doctor himself to do the first syringing, and he should always supervise it until he has properly instructed the patient. After syringing, the interior of the nose should be inspected, and any remaining crusts should be removed by directing a stream of water directly on to them, or better still, by gently detaching them with a mop of cotton-wool dipped in a solution of peroxide of hydrogen. When the nose has been thoroughly cleansed, it should be lightly packed with a strip of cyanide gauze about one inch broad and nine to twelve inches long. This prevents the patient breathing through the nose, and also, by setting up a certain amount of irritation, renders the nasal discharge more watery. The packing should be worn day and night, and changed only when the nose is syringed. The patient soon becomes tolerant, but at first the packing may cause considerable discomfort or headache, and may interfere with sleep. At first, also, when the discharge is profuse, it may be necessary to renew the packing two or three times a day. If the packing causes much pain, or if it sticks and causes bleeding on removal, plain sterilized gauze should be used, and should be soaked in oil or ointment, such as the dilute nitrate of mercury (B.P.) or weak boric acid ointment.

The nose should be syringed and packed at least twice daily until the discharge has apparently ceased. After three or six months, as the case may be, the packing should be omitted, at first for a few hours a day, and gradually increasing the time until it is omitted all day and worn only at night. Many patients, however, prefer to continue the packing owing to the great relief it gives them, and such patients may be instructed to pack the inferior meatus only and to leave the middle meatus clear for breathing purposes. When it has been found that the packing may be safely omitted without the return of the worst symptoms, it may be left off altogether, but the daily syringing must be continued. As already pointed out, the nasal passages are unduly wide and are lined by squamous epithelium which possesses no cilia. The nose, therefore, is no longer a self-cleansing apparatus, and any dust or dirt in the air, mixed with dry nasal secretion, collects in the nose and forms small dry mucous crusts all over the mucous membrane. If the patient takes a severe cold, there is apt to be a partial return of the symptoms. It will therefore probably be necessary for the patient to syringe his nose regularly every morning for the rest of his life. At this stage of the disease the patient may also find benefit by spraying the nose with liquefied vaseline or lanolin, or with one of the oils prescribed for the treatment of RHINITIS SICCA, *supra*. It is in the very early cases only, when but slight atrophy has occurred, that the patient can recover sufficiently to be able to abandon all treatment.

In addition to local treatment, the general health must be carefully attended to and the patient's nutrition maintained. The majority of patients are, in the circumstances, in surprisingly good health, but any tendency to anemia should be corrected. In a proportion of cases, variably estimated at from 10 to 20 per cent, complications, such as suppuration in one of the nasal accessory sinuses, are present. The sinuses most frequently affected are the antrum and

the sphenoidal sinus. These complications must be sought for carefully and appropriately treated (see NOSE, ACCESSORY SINUSES OF). The method of packing the nose as above described greatly facilitates the diagnosis of these complications.

Numerous other methods of treatment have been from time to time recommended and abandoned, but some may still serve a useful purpose. Massage of the mucous membrane by rubbing it lightly with small pledgets of wool wrapped on a probe has been recommended as a restorative of the nasal mucous membrane. It undoubtedly causes increased vascularity and discharge at the time, and although it cannot restore the atrophied mucous membrane, it is a useful help in thoroughly cleansing the nose, especially if the wool be soaked in peroxide of hydrogen.

Attempts have been made to restore the atrophied turbinates by submucous injections of melted paraffin wax. The posterior part of the turbinate should be first injected, then the anterior part, and finally a little paraffin may be inserted into the septum also. The technique is the same as for the subcutaneous injections of paraffin, but the paraffin should have a melting point of 105° F. Local anæsthesia suffices. When a fair-sized turbinate is present, the injections are easy, but when the turbinate is represented by a thin ridge along the outer wall of the nose, they may be almost impossible. Some patients seem to experience benefit, but the treatment is of little real advantage.

Rhinitis Caseosa.—In this affection a large mass of semi-solid material, looking like putty, is found in one nostril, usually surrounded by swollen mucous membrane and cedematous granulations. The treatment consists in clearing the nose. Cocaine and suprarenal extract should be applied to anæsthetize, and to reduce the swelling of, the mucous membrane, and then the putty-like mass should be broken up and removed, partly by blunt hooks and scoops, and partly by syringing the fragments away with mild antiseptic lotions, such as a solution of boracic acid or of Sanitas and salt. When the nose has been cleared, which may require two or more sittings, the granulations will usually subside without further treatment. Sometimes the disease involves the accessory sinuses, especially the antrum. Extensive operations are generally required in these cases, as the sinus is usually filled with material similar to that found in the nose, and its walls are often carious. Sometimes extensive necrosis may be present in the nose, and a general anæsthetic will be required to deal with it thoroughly; or a foreign body will be found and must be removed.

H. Lambert Lack.

RHINOLITHS.—(See NOSE, FOREIGN BODIES IN.)

RHIZOTOMY.—(See NERVES, PERIPHERAL, SURGICAL AFFECTIONS OF.)

RICKETS.—The prevention of rickets depends on the maintenance of the mother's health during pregnancy, and on the provision of proper hygienic conditions, and of suitable diet, for the child.

The therapeutic indications to be observed in the case of a child who has rickets may be summed up as follows: (1) He must have more fresh air and sunshine; (2) His digestion must be attended to; (3) His diet regulated; (4) Certain tonic measures must be used; (5) Severe symptoms or complications present are to be treated; and (6) Means are to be taken to prevent or relieve bony and other deformities.

1. Fresh Air and Sunshine.—The child should be taken out of doors twice daily at least, and for as long as possible. In the case of the poor, it is often a good plan to have the baby left in the open air in his perambulator for the greater part of the day, provided the weather be at all suitable. He must, of course, be very warmly clad, because a rickety infant, owing to his excessive sweating

and general debility, is particularly liable to chills. If he cannot be taken out, the window should be kept widely open, night and day, and he should be kept in the sunniest room available. When the parents' circumstances permit of it, a stay at the seaside may be very beneficial.

2. The Digestion.—Before making any great change in the diet, or giving tonics, it is advisable to consider the state of the digestion, and if this is defective, to take means to improve it. A short course of soda, with rhubarb or with nux vomica and gentian, e.g. :—

R Pulveris Rhei	gr j	Syrupi Zingiberis	℥ij
Sodii Bicarbonatis	gr ij	Aquæ Menthæ Piperitæ	q.s. ad 3j
Ammonii Carbonatis	gr ss		

M. Thrice daily half an hour before food.

R Sodii Bicarbonatis	gr iiij	Infusi Gentianæ Compositi (N.F.)	3j
Tincturæ Nucis Vomicae	℥iiss		

M. Thrice daily half an hour before food.

will often so strengthen the digestive powers as greatly to enhance the efficiency of the dietetic treatment. A few doses of grey powder will sometimes be found to facilitate considerably the digestion of the increased fat in the food. Should diarrhœa and vomiting be present, it is of course important to stop them before beginning to give cod-liver oil or otherwise to increase the fat.

3. The Diet.—In all cases, the feeding of the child must be carefully regulated. It is important to see that his meals are reasonable in amount and digestibility, and are given at suitable intervals. The main thing, however, is to ensure that they contain an adequate proportion of fat and protein in such forms as to be easily assimilated.

Should the patient be a young baby on the bottle, a wet-nurse's milk is the ideal treatment for him. Short of this, however, careful modification of cow's milk, so as to make it resemble human milk as nearly as possible, is often very successful. When the child is unable to digest the casein of cow's milk sufficiently for the necessities of his nutrition, the addition of raw meat juice to the bottle is often serviceable.

In the case of children during the second year of life, the first point generally is to see that sufficient milk is being given. Mothers, who are otherwise sensible, will often be found giving their infants less than half a pint of milk in twenty-four hours, instead of one and a half or two pints, as they should. It is also important to see that the child is not having a large excess of bread, potatoes, and other starchy foods, and that his digestion is not being upset by frequent mouthfuls of "whatever is going." Oatflour or well-boiled oatmeal porridge, or some such preparation as Chapman's wheatflour, should be given in preference to arrowroot and cornflour, and a little cream should be given with them. Yolk of egg—providing, as it does, both protein, fat, and organic combination of phosphorus—is almost always good for the child. The regular administration of cod-liver oil in moderate doses is advisable in most cases.

4. Tonic Measures.—Cod-liver oil often seems to act as a tonic as well as a food. The value of alkaline tonics in improving the digestion has already been referred to. Iron is occasionally very useful if anæmia be present.

-----------------	------	---------------	------

Fiat pulv. Thrice daily after food.

Often, however, this only upsets the digestion, and generally it is unnecessary, because the condition of the blood rapidly improves as the rickets passes off.

Uncombined phosphorus has been strongly recommended as a sort of specific for rickets by Jacobi and Kassowitz. Although others have found it less useful, it is certainly sometimes of considerable advantage, if given with care so as not to disturb the digestion. It is usually administered dissolved in cod-liver oil, and it may be given in doses of $\frac{1}{20}$ gr. thrice daily after food.

R. Phosphori	gr $\frac{1}{2}$	Olei Morrhue	\mathfrak{z} iij
	A teaspoonful	thrice daily after food.	

R. Phosphori	gr $\frac{1}{2}$	Sacchari Albi	\mathfrak{z} iv
Olei Amygdalæ	\mathfrak{z} j	Aquæ Destillatæ	\mathfrak{z} iss
Acaciæ	\mathfrak{z} iv		

A teaspoonful thrice daily after food.

Phosphorus combined in the form of mineral phosphates has long been known to be of no value—these salts being passed unchanged in the motions.

Cold douching does a great deal of good in most cases of rickets. Salt water is to be preferred to fresh; and the douche may have a temperature of 70°–75° F. to begin with. The child should be seated in warm water at the time of its administration, and it should be very rapidly and carefully given. Cold douching is specially indicated in cases where there is great muscular feebleness, and where there are any nervous symptoms (facial irritability, laryngismus, tetany, convulsions). It has a strongly tonic effect on the circulatory and nervous systems. The frequent use of cold water in this way has the great advantage that it renders the child much less susceptible to cold, and thus enables him to be more freely exposed to the open air without taking chills.

5. Symptoms and Complications.—It is always to be remembered, with regard to the symptoms and complications of rickets, that their main treatment is that of the diathetic condition, and that the local treatment is only of secondary importance. Thus, we find that profuse sweatings, laryngismus and convulsions, sleeplessness and restlessness, digestive disturbances, loss of appetite, constipation, and bronchial catarrh are generally all rapidly and permanently improved when thorough antirachitic treatment is carried out, even if no special measures are taken.

It is often, however, desirable to make use of local treatment also. If the sweating is severe, it may sometimes be benefited by oxide of zinc (1 to 2 gr.). When laryngismus and convulsions recur, antipyrin (1 to 2 gr. according to age) or bromide of potash may be very useful; and in these cases it is generally well to use cold douching twice a day, as its effect is very markedly beneficial. The ordinary treatment of digestive and respiratory disorders should, of course, not be neglected.

6. Prevention and Relief of Deformities.—We have to remember that, while rickets softens the bones and the ligaments, it does not bend and stretch them. That is done by mechanical forces acting in various directions on the softened parts. While, therefore, we are trying to arrest the rickety processes which are softening the bones, we must not forget to prevent, as far as possible, all postures and actions on the child's part which tend to produce deformities.

The child must not be allowed to sit up for long, for fear of the development of kyphosis. If he is very rickety, he had better, at first, be kept lying on a pillow, and not allowed to sit up at all. His nurse must not carry him always on one arm, lest he develop scoliosis; and any tendency to assume undesirable attitudes habitually must be checked.

It is, of course, very important to prevent the patient's attempting to stand or walk while the bones are still soft. Returning health is apt to bring with it a desire for more active exercise than can be safely allowed; and if care be

not taken, bow-legs, knock-knee, and flat-foot result. The application of lateral wooden splints, reaching from the thigh to four inches below the sole, is very useful, because these entirely prevent the child's standing. No form of steel or other apparatus which permits the child to walk about is of any value in preventing the bending of the limbs.

Rickety deformities of the thorax have a striking tendency to lessen as the child grows older and stronger; and this improvement can be very much increased by the persevering use of dumb-bells, and by various other exercises of the arms and trunk. (See also INFANT FEEDING.) *John Thomson.*

RINGWORM.—Ringworm may be treated from various standpoints. One may aim at the direct destruction of the fungus by the application of antiseptics, which, indeed, is the method commonly used; and the usual prolonged duration of the disease testifies to its inefficiency. But although it does not cure the disease, or at all events does not do so rapidly, it at least has the merit of preventing its spread, and one may describe first how this treatment should be carried out when once it is determined on.

The hair should be cut quite short, so that the patches may be identified. It is probably not necessary to shave the head, but if the patches are few in number it is an excellent plan to clear a little ring round each with epilating forceps. The head should be washed daily, and an antiseptic ointment applied twice a day. It does not matter much what the antiseptic is; it is the method of application which counts. Sulphur, various mercurial or copper salts, resorcin, formalin, and other preparations, all have their advocates. But the important point is that they must be thoroughly rubbed in. The mother or nurse should be instructed to spend twenty minutes over each spot, working the ointment thoroughly into the scalp with the thumbs.

The following are suitable formulæ :—

R Sulphuris Præcipitati	āā 3ss	Lanolini	
Hydrargyri Ammoniaci	gr xx	Vaselini	āā 3ss
Acidi Salicylici			
	Fiat Unguentum.		
R Hydrargyri Oleati	gr xl	Lanolini	
Acidi Salicylici	gr x	Vaselini	āā 3ss
	Fiat Unguentum.		
R Cupri Oleati	3ss	Adipis Benzoati	3j
Lanolini	3j		
	Fiat Unguentum.		

To be thoroughly massaged into the affected spots for at least ten minutes twice daily.

The next method of treatment is that which is often unintentionally carried out, and which may be called the indirect method, as it consists in applying to the affected part something which will produce a reaction, and thus bring about destruction or elimination of the fungus from within. The popular iodine, and the (with the patients) unpopular blistering fluid, are the more characteristic examples of this method; but many so-called antiseptic ointments really act as counter-irritants. If the disease be recent, this method is often successful, but it has the disadvantage that one is unable to follow, under the resulting scab, the progress of the affection.

The third method is that of *epilation*. Dermatologists have long recognized that this was the ideal, but the erosion of the hairs by the fungus made it impossible, even for the most skilful, to remove by the roots more than a small percentage of the diseased hairs. In the depilatory action of the *x*-rays many hoped to have found a solution of the difficulty, and numerous efforts were made, which at first usually resulted in the removal of the healthy surrounding hair,

the diseased ones remaining in the follicles. It was left for the ingenuity of Sabouraud to point out that all that was required was a little longer exposure to the rays, and now, in skilled hands, the *x*-ray treatment is likely to take precedence of all others, since it has reduced the average duration of treatment to about one-eighth of its former length.

This is not the place to give the details of the operation. It is one which should never be undertaken by unskilled persons; indeed, of the many diseases in which *x* rays are used, it is probably the one in which experience is most essential. The disappointment when the hair does not come out, and the regrets when the reaction produced is too severe, are serious troubles to the beginner. It is impossible to lay down hard and fast rules applicable to all the varying mechanisms by which *x* rays are produced, and even then the factor of the tube remains probably the most important of all. As a general rule it may be said that an exposure of twenty minutes at a given distance, which varies with different tubes, should be followed, in from two to three weeks, by a complete loss of hair. The writer now always checks his exposure by the use of Sabouraud's pastilles, and has seen no reason to regret the confidence he has placed in them. If the application has not been quite long enough, the healthy hairs will fall out, and the diseased stumps remain, ready to infect the new growth when it appears some six weeks later. These stumps are loose, and much may be done by the application of a comedo extractor, or even by vigorous scrubbing, to remove them; but if they are left alone, the whole labour has been in vain, and the patient is no better off after all his trouble.

In successful cases, when the hair has fallen, antiseptics should be vigorously applied to the bald scalp. The rays have no effect on the fungus, and it is almost certain that some spores remain in the follicles. These, however, are not only empty but open, and ointments well rubbed in have every chance of reaching and destroying the remaining spores.

When one considers the serious interference with education, and with family life, caused by the occurrence of a case of ringworm in a large family, perhaps the advice will be appreciated that it is more important to treat those children who are unaffected than the one who is. In such cases, all the boys in the family should have their hair cut weekly with clippers, and washed daily with an antiseptic soap. Such advice would probably not be favourably received in the case of the girls, but at least daily washing should be insisted upon, and the utmost rigour of separation from the infected member.

Norman Walker.

RODENT ULCER.—The treatment varies with the stage of development and extent of the disease, and also with its position. It will be convenient to consider three groups of cases.

1. In its earliest stage the rodent ulcer is a small, solid, pinkish tumour. It sometimes starts in a mole, and its commonest sites are the outer and inner canthi, the side of the nose and the alæ, and the cheek and ear. It is important that the nature of the tumour be recognized early, for it is often regarded as a wart, and allowed to develop, or, perhaps, is perfunctorily touched with caustic. If any doubt exist as to the exact nature of any wart-like tumour, especially in an elderly person, it should be treated as if it were malignant.

Complete removal with the knife gives excellent results. Care must be taken that the whole growth is excised, or recurrence is inevitable. The incisions should therefore include a margin of healthy skin. After excision, a series of short exposures to the *x* rays is useful to prevent recurrence. Even in this, the earliest stage, it may be impossible to remove the growth completely, because of its position. This is especially the case when the canthi and eyelids are affected. The removal of a small rodent growth from an eyelid is attended

with great deformity; such deformity should be avoided, if possible, not only for cosmetic reasons, but also on account of the secondary eye troubles which result from ectropion, etc. In such cases I have found the application of radium very useful. The radium salt should be spread on a flat or slightly concave surface and covered with a varnish. A radio-activity of 500,000 units is most serviceable. With apparatus of this strength, applications of two to four hours' duration are usually sufficient to cure a superficial rodent ulcer. An inflammatory reaction is set up, and this may be enough to destroy the tumour. A second and third application may be necessary. It is important to remember that the reaction set up by the radium may not appear for from fourteen to eighteen days after the sitting, so that there should be an interval of at least three weeks between two applications.

Small rodent tumours which cannot be excised can also be successfully treated by paring down the growth with the knife or curette (under anaesthesia) and then applying the x rays in the manner described in the following paragraph. If this preliminary curetting be impracticable, the x rays must be used alone, but a larger dose is required.

2. The commonest stage in which advice is sought is that in which there is an ulcer with a raised beaded margin. If small, and in a suitable position, such an ulcer may be excised, together with the margin and some healthy skin, and the x rays applied to prevent recurrence. But if there be the slightest doubt as to the possibility of complete removal, I strongly advise that the lesion should, if possible, be treated by radium as described above. If that be impracticable, any surgical interference should be limited to paring away the margin by the knife or curette, and after a few days' interval the x rays should be applied. This preliminary curetting removes the mass of the growth and the intact epidermis over it; in fact, converts the whole into an ulcer and thereby considerably shortens the ray treatment. Some cases require only two or three sittings, provided sufficient doses are given. Each worker must estimate the output of x rays from his own apparatus. This is conveniently done by the Sabouraud pastille, originally introduced for the treatment of ringworm. Placed midway between the area under treatment and the anode of the focus tube, the pastille, which is coated with platinoeyanide of barium, changes from a yellow to a particular orange colour (Tint B) when a dose of x rays has been given sufficient to remove the hair from the scalp without producing an erythema. The pastille must be examined without exposure to light, or it will return to its original colour. With a 15-inch coil, worked with a current of 60 volts and 7 to 8 ampères in the primary, and 1.0 milliampère in the secondary circuit, a spark gap of about 15 cms., a tube with a penetration corresponding to No. 7 on the Benoist scale, and the area under treatment 15 cms. from the anode, I can get this result with great regularity in 12 minutes, with a dipper interrupter making 600 interruptions per minute. I find that this is a full dose for a rodent ulcer, and under ordinary circumstances an exposure of ten minutes is sufficient. Where the parts are thin and delicate, a still smaller dose is given. At the end of a fortnight there is usually a slight reaction, and when this has subsided a second dose may be required, and at the end of another fortnight a third. With smaller coils proportionately longer exposures are necessary, but with a little experience it is easy to regulate the conditions to get the required result. I find it more satisfactory to give the larger doses at longer intervals, than the frequent small doses which were formerly the rule. During the application, the parts free from disease are protected with sheet lead, or the whole focus tube is enclosed in a special shield of lead glass. The shield has an aperture opposite the anode, and to the margin of this aperture are attached short lead glass tubes of various calibres adapted to ulcers of different sizes. The advantage of this apparatus is

that the part under treatment is kept at a constant distance from the anode, and also that the rest of the patient's body, and the operator, are completely protected from the rays. After each treatment, the part is covered with lint or butter muslin spread with a simple ointment, hazeline ointment being very convenient. When the healing is complete, a beautiful, soft, supple scar is left. From time to time resistant cases are met with, and the applications of the rays may have to be repeated again and again, but with the conditions above mentioned, it is rarely necessary to give sittings at shorter intervals than a fortnight.

If the edge be not removed by the curette, larger doses of x rays will be necessary; and when there is a massive edge with much infiltration, or if the rodent is adherent to deep structures, large doses of x rays, equivalent to four to six pastille doses, through screens of aluminium from 1 to 4 mm. thick, give the best results. I usually give three of these large doses in ten days, and wait for three or four weeks before repeating them. If radium is available, applications of eight, twelve, or twenty-four hours' duration are given, the reaction from the α and superficial β rays being eliminated by interposing filters of lead.

Fig. 67. Rodent ulcer of 12 years' duration. Cured by x rays, 1906, and well to date.

Fig. 68. Rodent ulcer of 4 years' duration. Cured by radium, 1911, and well to date.

Superficial rodent ulcers of small area also do well when treated by zinc ions. A zinc plate attached to a suitable handle is connected with the *positive* pole of a galvanic battery. It is covered with lint soaked in a 2 per cent solution of sulphate or chloride of zinc, and the lint is pressed on the part under treatment. The circuit is completed by the patient holding the negative pole in the hand. A current gradually increased to 10 milliamperes is passed for five minutes at each sitting. Two applications are made a week. The process is painful, and some relief is obtained by the preliminary application of cocaine.

The application of solid carbon dioxide for forty seconds to one minute is sometimes remarkably successful in the treatment of early rodent ulcer. For details of the technique see article on CARBONIC ACID SNOW.

3. Lastly, we meet with rodent ulcers of long duration, in which bone and cartilage have been involved and cavities opened. Here a complete cure is usually impossible, but the x rays are particularly valuable. Pain is relieved, ulcerated areas clean remarkably, and large cavities often fill up. Some of the most unpromising cases do remarkably well, and a combination of surgery and radiotherapy offers the best hope of cure.

Some of the worst cases are those in which the orbit is involved. In these, an early clearing out of the cavity is advisable. It should be followed by prolonged applications of x rays or radium to the indurated edges. When the cavity is foul, antiseptic lotions must be used, and I have found lysol (1 drachm to a pint of water) and a 10-volume solution of peroxide of hydrogen valuable.

Recurrence after apparent cure by x -ray and radium treatment is not uncommon, but in many cases it is due to insufficient dosage, and to leaving small portions of the infiltrated margin untreated. The edge is always the most resistant part, and, unless dealt with in the manner described, usually gives trouble. Up to the present I have found recurrence in 35 per cent of my cases, but many of these were of very long standing. Small recurrences are usually dealt with easily by fresh x -ray treatment. Some patients treated by x rays have been quite well for twelve years, and I have some early cases treated by radium free from recurrence for ten years (see also *Figs. 67 and 68.*)

James H. Sequeira.

ROSACEA.—A very large number of the cases of this disease are consequent on seborrhœa of the scalp, and the treatment for that disease is followed, in such cases, by rapid improvement. (See **SEBORRHŒA.**)

Local applications hasten the disappearance of the eruption; of these, sulphur and calamine lotions (see under **ACNE**) are often useful. The glycerin so commonly added to such applications is often irritating, and may with advantage be omitted.

Although one is convinced that the relationship of indigestion to this condition is greatly exaggerated, there is no doubt that digestive disturbances do aggravate it; therefore, if these are present they should be appropriately treated.

The advantages, in this disease, of a vegetarian diet were first pointed out by Lerredde, and the writer has more than once seen great benefit result from its adoption.

In cases where there is much thickening, more active measures must be resorted to. The resorcin peeling method, which consists in the application of a 50 per cent resorcin paste, may be tried, while in those cases where hypertrophic changes lead to the disfiguring condition known as rhinophyma, or "potato nose," surgical measures are necessary. These are, however, exceedingly simple, all that is required being the paring down of the nose to any required shape. The raw surface left skins over in a remarkably short time. Less marked cases may be treated by the application of carbonic snow. (See also **NOSE, REDNESS OF.**)

Norman Walker.

ROUND WORMS.—(See **WORMS, INTESTINAL.**)

SALIVARY GLANDS, AFFECTIONS OF.

Salivation, or Ptyalism.

This most frequently results from excessive mercurialism, mercury in even minute doses, owing to idiosyncrasy, sometimes producing this effect in certain cases. It is known to be produced also by drugs such as iodine, potassium iodide, antimony, jaborandi and its alkaloid pilocarpine, tobacco, physostigmine, ipecacuanha, etc.; and in other toxic conditions, such as uræmia.

The free salivation associated with certain gastro-intestinal disorders—e.g., in pyrosis or water-brash, which is associated with hyperchlorhydria, the gush of saliva being, as Langdon Brown writes, occasioned in the vain attempt to neutralize the excess of acid; and in atonic dyspepsia (hypochlorhydria), occurring in those of nervous temperament, the so-called "idiopathic" type—should also be remembered. Salivation has been observed in pregnancy, during menstrual disturbances, and in certain abnormal conditions of the nose.

TREATMENT.—Removal of the exciting condition, drug, etc., when possible, and in the case of mercury, a chlorate of potash mouth-wash for the spongy

gums, with good nourishment, will generally effect a cure. The following prescription will be found useful:—

R Potassii Chloratis	gr x	Tincturæ Myrrhæ	℥ xij
Glycerini	3 ss	Aquæ	q.s. ad 3 j

In the idiopathic type above referred to, the appropriate treatment for hyper- or hypochlorhydria, combined with small doses of belladonna, should be tried: tr. bellad. ℥ viij to x, ter die, or extr. bellad. gr. $\frac{1}{2}$ to $\frac{1}{4}$, in pill, t.d. Belladonna has also been administered with benefit intramuscularly, or by inunction. Prophylaxis should always be attempted, prior to ordering a course of mercury, by careful attention to the state of the gums and teeth, utilizing this interval to give a general tonic, preferably iron, or iron and arsenic.

Where, as may be the case after removal of one or both halves of the tongue for cancer, there is a difficulty in disposing of the saliva, routine removal of the associated submaxillary gland or glands, salivary as well as lymphatic of course, is recommended by Legg and others.

Xerostomia, or Dry-mouth.

This affection, a sudden and acute form of which is exemplified in fright, is of nervous origin in many cases, and occurs as a primary trouble chiefly in elderly women, in whom there may be also similar dryness of the conjunctiva (xerosis) and of the nasal mucous membrane, due to the xerosis bacillus, which may possibly prove to be the origin of primary xerostomia. It has also been known as the result of a rapidly progressing atrophy of the chief salivary glands, death in one case, 30 months from the onset, which occurred one month after influenza, being attributed to the consequent loss of internal secretion. Secondly, it is a marked symptom, accompanying, and usually preceding, "symptomatic parotitis," a fact which serves to distinguish secondary parotitis from ordinary mumps.

Thirst and dryness of the mouth are always more marked after operations on the abdomen (especially on the stomach) than elsewhere. This is most noticeable where peritonitis is also present.

This condition has also been observed as a "precocious x-ray reaction" a few hours after exposure to the rays, and lasting a day (*Med. Ann.*, 1912).

In non-operative gastro-intestinal disturbances, e.g., cholelithiasis, suppression of salivary secretion may precede for a considerable time the symptomatic parotitis which not infrequently supervenes.

In chronic and recurrent parotitis due to gout, in saturnine parotitis due to plumbism, at the menopause, and during menstrual disturbance, xerostomia has been observed, and a toxic origin is suggested by Tebbs.

TREATMENT.—The mouth should be carefully examined for carious teeth; and other sources of irritation, such as have been indicated above, should be dealt with, and tonics administered. Mouth-washes, and sialagogues, such as injections of pilocarpine, have been suggested as prophylactic measures when operation is followed by xerostomia, but according to Walsham and Spencer they are not to be recommended. On the other hand, Fraser (*Edin. Hosp. Reps.*, vol. i.) recommends that the patient should hold in the mouth from time to time, for a few minutes, 5 minims of a 2 per cent solution of pilocarpine; or a $\frac{1}{4}$ gr. tabloid of the same drug may be allowed to dissolve on the tongue occasionally. Local galvanism for three months gave relief in one case recorded by Osler. (See also below, SECONDARY PAROTITIS.)

Primary Parotitis. (For Epidemic Parotitis see MUMPS).

Simple Parotitis is due to exposure to cold, resulting in catarrh ascending Stenson's duct; to the presence of a calculus obstructing the duct, more frequently seen in the case of the sublingual; or to injury, in which case suppuration may occur. Bilateral parotitis has also supervened as a precocious x-ray reaction, five hours after a sitting, during which both cheeks had been treated (*Med. Ann.*, 1912). A very obstinate form of parotitis has recently been found to be due to infection of the duct by the *Pneumococcus*, a vaccine of which organism has, in Wright's hands, yielded excellent results. To this

category belongs, it is highly probable, the series of 5 cases reported by Raymond Johnson (*Lancet*, 1896), of persistent unilateral enlargement of the parotid, not of the nature of symptomatic parotitis nor of parotid bubo, and not due to enlarged lymphatic glands; the swelling being attributed by the author to swelling of the parotid from interference with escape of its secretion by inflammation of Stenson's duct; the socia parotidis in one case was affected first, and in several slighter attacks was alone affected. A similar condition in the submaxillary is also on record. Periodical swelling of one or both parotids, sometimes associated with submaxillary and sublingual gland enlargement, and lasting from several hours to two or three days, is also described (*Med. Review*, 1912). It may recur for years. As it is not due to syphilis, and does not yield to iodides, mercury, or arsenic, but supervenes on chills, it is probably due to the *Pneumococcus*, and, if so, vaccine should be tried. Massage over the affected gland several times a day, producing free salivation, causes rapid diminution of the swelling, though recurrences are not uncommon. To prevent these, vaccine offers the best hope of cure.

Suppuration follows more commonly in secondary than in primary inflammation, and its occurrence is indicated by the increasing size of the gland, with redness and œdema of the skin. Owing to the density of the capsule, and the direction of the deep processes of the gland, pus tends to track towards the base of the skull, towards the mouth, and over the upper border of the superior constriction of the pharynx.

TREATMENT.—The painful swelling is relieved by belladonna fomentations. If suppuration supervenes, the pus should be evacuated through a small skin incision, horizontally placed, so as to avoid fibres of the facial nerve. While some prefer Hilton's method, others advocate a freer opening of the abscess. Recently, however, puncture with a tenotomy knife and the application of Bier's suction apparatus have given excellent results, and should be resorted to the moment pus-formation is suspected, if not earlier, as a preventive method. (See **BIER'S HYPERÆMIC TREATMENT.**)

Secondary Parotitis.

Secondary, or acute symptomatic, or metastatic parotitis occurs in the course of the exanthemata, typhoid fever, etc., pneumonia, and general pyæmia, during the puerperium, lesions of the alimentary canal, non-operative and post-operative; rarely, it may occur in acute articular rheumatism, when the attack is on the decline, and is unconnected with angina or stomatitis. After a temperature which may exceed 104° , resolution is complete in two to five days, under treatment with sodium salicylate in full doses (*Med. Review*, 1910); it may result from extension of inflammation to the parotid from adjacent tissues, lymphatic glands, face, and jaw, e.g., in a case of severe facial carbuncle with Ludwig's angina (*Lancet*, July 17th, 1909). Very rarely in the newly-born infant, the parotid or other glands may become infected, probably through the navel or nose (Still). To this group Tebbs applies the term *septic*, considering as *toxic* such cases as occur in connection with metabolism, gout, and plumbism, and genital auto-intoxication due to menstrual disturbances. Another group, mostly recurrent, is believed to be of vasomotor origin.

ETIOLOGY.—According to one view, symptomatic parotitis results from a dry, dirty mouth, i.e., from infection ascending up the duct from a mouth which has become septic, from becoming dry and coated with fur, e.g., during rectal feeding, etc. According to another view, the infection is generally by the blood, and is almost always the result of intra-abdominal sepsis. Ascending parotitis may also result from the toxic effects of mercury, lead, copper, iodine, or potassium iodide, etc.

TREATMENT.—On the first hypothesis, Bucknall emphasizes the necessity of preventing duct-infection by a thorough and constant use of mouth-washes, glycerin of borax (B.P.) 3j ad 3j, etc., and it can certainly do no harm. The value of this toilet of the mouth as a prophylactic measure has been absolutely denied by Tebbs, who believes that in the vast majority of cases infection is by the blood, so that only by the strictest asepsis during the operation, and by

damaging the peritoneum as little as possible, is there any hope of preventing this complication. In the above case, secondary to facial carbuncle, staphylococcic vaccine and repeated doses of citric acid effected a cure. Soltau Fenwick's routine use in abdominal cases of a rubber teat or "comforter," to promote salivation, may be tried as a prophylactic measure. A most useful mouth-wash for septic conditions of the mouth is, phenol gr. v., glyc. ℥xl., tr. myrrh. ℥xii., aq. ad 3j.

Attention should be directed to special causes at work—gout, plumbism, etc.

Syphilis, Tuberculosis.—The fact that tubercle and syphilis may occur in the salivary glands must be borne in mind, though more often it is the corresponding lymphatic glands lying over them which are primarily affected. In the rare cases of definite luetic infection, it is stated that the parotids may become involved in both the early and the later stages of syphilis, the submaxillary and sublingual in the early stages only. The present writer, however, has seen chronic syphilitic glossitis associated with a chronic indurated swelling of the submaxillary salivary gland. Symmetrical, chronic, non-inflammatory,

lymphomatous enlargement of the salivary and lacrymal glands (Mikulicz's Disease) has recently been recorded, associated with syphilis (Fig. 69).

TREATMENT consists in the administration of iodides and arsenic; x-ray treatment has proved useful (Sejournet, quoted by Hutchison).

Actinomycosis.—Söderlund (quoted in *Med. Review*, Dec. 1913) has described isolated primary actinomycosis in two instances in a sublingual gland, in four instances in the submaxillary gland, the glands being excised, in the absence of supuration, in the belief that the conditions were malignant or tuberculous. He is convinced that primary actinomycosis of the salivary glands is easily overlooked, laborious examination of serial sections being sometimes necessary for its detection in what otherwise appears to be simple chronic inflammation. As such may be the primary

Fig. 69.—Symmetrical enlargement of the lacrymal, parotid, and submaxillary glands. (Original case of Mikulicz.) (a, a) Sublingual glands.

focus from which actinomycosis enters the body, these observations have a very important practical bearing. (See also ACTINOMYCOSIS.)

Salivary Calculi.

TREATMENT.—Lockwood emphasizes the importance, both for diagnosis and treatment, of preventing the calculus slipping back along the duct, by placing one finger, or an assistant's thumb, outside the mouth, and another inside. In the case of the submaxillary, the outside finger below the angle of the jaw pushes up the gland and its duct, fixing the floor of the mouth; the inside finger feels for the stone, steadying it against the body of the lower jaw; the duct can then be incised, and, after extraction of the stone, is lightly plugged. In the case of a girl ten years old, Lockwood removed a calculus from the parotid duct by fixing it against the coronoid process of the lower jaw, and then with a curved knife cutting down upon it. A stenosed duct should be slit up after applying cocaine, 10 per cent, on mops; unless the stenosis is close to the orifice, a general anæsthetic is desirable. Removal of the submaxillary through a

curved incision below the jaw, through the skin and platysma and fascia over the gland, is sometimes necessary, especially where exploration has involved damage to the gland substance, with risk of subsequent salivary fistula, or where pain persists either after failure to extract a calculus, or when the gland has become fibrotic and permanently enlarged.

Operation.—After dissecting up the flap of skin, platysma, and fascia superficial to the gland, the facial vessels at its lower and posterior pole are ligatured and divided. The submaxillary is then freed, and the facial vessels, where they pass over the jaw, just in front of the masseter muscle, are again ligatured and divided. The anterior pole of the gland, where it extends forward along Wharton's duct, is drawn out from beneath the mylohyoid muscle, and the duct ligatured before its division and the removal of the gland, to prevent infection of the wound from the mouth (Treves).

Salivary Fistula.

This is seen almost exclusively in the case of the parotid gland, resulting from a wound of Stenson's duct, or of the gland, by a stab through the cheek, or from operation, or from the ulcerating through of a salivary calculus. There is a most troublesome flow of saliva over the cheek, worse during meal-times. A considerable portion of the duct may be destroyed, and, owing also to the presence of much cicatricial tissue, treatment of such cases may be very troublesome. Stenson's duct opens into the mouth through a papilla situated in the mucous membrane opposite the crown of the second upper molar tooth. A bristle can just be passed through the orifice, the duct itself being an eighth of an inch wide, acting as a reservoir of saliva in health, and so predisposing to infection of the duct in disease (metastatic parotitis).

TREATMENT consists in re-establishing a channel from fistula to mouth so that it becomes easier for the saliva to escape by the mouth than by the fistula. The following methods are recommended:—

A fine drainage tube threaded with silk at both ends is attached to the eye of a probe, the fine point of which is insinuated into the mouth of the duct and brought out on the cheek, leaving the tube in the duct. The silk threads are tied over the cheek at the angle of the mouth. After four days, the outer third, or less, of the tube is removed, and a silk thread allowed to remain in the outer part of the fistula, which then gradually contracts and closes; the inner two-thirds of the tube is gradually shortened, and finally removed.

Failing this, where most of the duct remains intact, the portion proximal to the fistula is freed, and brought into the mouth through an opening at the level of the anterior border of the masseter.

For the severer type of case, where there is much cicatricial tissue and most of the gland is destroyed, Dejardin and Gulikers' plan is to free the portion of the parotid lying over the masseter, through an incision made in the direction of the remnant of the duct. The gland and its duct are tucked in between the masseter and the ascending ramus of the jaw, and the duct is brought through the buccal mucous membrane and there sutured. (*Med. Ann.*, 1902.)

Parotid (Tumours of).—These are either *innocent* or *malignant*, and this prime distinction is often the only one possible, as it is certainly the only one of importance prior to operation. Of the innocent variety, many formerly described as "mixed tumours," are now considered to be endotheliomata, and occur in connection with both the parotid and the submaxillary glands, forming an additional reason for their early removal.

TREATMENT.—A benign growth, freely movable beneath the skin and over the deep structures, should be excised, lest malignancy supervene, apart from which, delay only increases the difficulty of operation, especially in the case of the parotid—which, besides the detached portion lying upon the masseter above Stenson's duct, called the *socia parotidis*, has several deep-lying processes passing inwards towards the pharynx and tonsil, or downwards towards the neck.

In operations on this gland, the important point is the preservation of the facial nerve, which enters at the posterior limit of the parotid and breaks up into its two main branches. These radiate forwards, upwards, and downwards, in a more or less horizontal direction, both within and superficial to the dense capsule of the gland derived from the deep cervical fascia. Branches of the facial nerve, though generally lying deep to a benign tumour, may pass superficially, and to avoid them, by bringing them clearly into view, an extensive horizontal skin incision over the swelling has been recommended. This is carefully deepened, retracting such nerve fibres as are seen, until the capsule, by blunt dissection, has been reached and incised, when the tumour can usually be shelled out without difficulty. In operating, it is essential to keep close to the capsule, to keep the wound mopped dry, and to work very cautiously and gently to avoid damaging nerve fibres. Carwardine (*Lancet*, 1907) excised the parotid successfully, first dissecting out the facial nerve ramifications and holding them aside in loops of catgut. The temporary facial paralysis disappeared in two months.

A vertical skin incision is less unsightly than the horizontal, and minimizes injury to the temporal vessels and nerves ascending in front of the tragus of the ear. The edges of the wound are then held aside, and the tumour is exposed by a horizontal incision through the fat, etc. Legg recommends, for a large benign parotid tumour, an incision along the posterior edge, curving forward along its lower margin, turning forward a flap of skin and subcutaneous tissue, avoiding such branches of the facial nerve as may be met with, and then exposing the capsule of the tumour.

Cheyne and Burghard recommend a curved incision along the anterior border of the sternomastoid, from the mastoid process downwards, and then forwards, and finally curving up across the ascending ramus of the jaw.

In the case of the submaxillary gland, the growth is exposed through a curved incision below the body of the lower jaw.

Lengthy treatment with radium, at intervals of four to six weeks, with an exposure of thirty hours' duration extended over forty-five days, is credited with improving and apparently curing parotid tumours (*Report of the Radium Institute*, 1912); but in view of the endotheliomatous origin of many benign tumours, and their tendency to become definitely malignant, early removal is the safer course to advise.

In the case of malignant tumours—if operable—the entire gland must be excised, sacrificing the facial nerve. Temporary or permanent ligature of the external carotid artery is generally necessary. For details, surgical text-books must be consulted.

Wounds of the Parotid Gland are serious, often resulting in a salivary fistula if the duct is divided, or involving damage to the facial nerve branches, or venous or arterial hæmorrhage, in checking which nerve branches may be injured. It is essential to keep the wound dry, to clearly see the bleeding point, so as not to include a nerve in the ligature. If the vessel cannot be defined, it is recommended to plug the wound in venous hæmorrhage; and in arterial bleeding, after preliminary plugging, to expose the external carotid artery near its origin. If, on now removing the plug the bleeding point is detected, it should also be ligatured, in view of the collateral circulation. The wound may then be closed, plugged, or allowed to granulate up, according to circumstances.

Henry Curtis.

SALPINGO-OOPHORITIS.—In the majority of cases of salpingo-oöphoritis, or inflamed appendages, no operation is necessary. During the acute stage the treatment consists in absolute rest in bed, administration of laxatives, fomentations, or turpentine stupes to the abdomen, and hot douching if it gives

relief to pain. When the condition has reached a chronic stage, counter-irritation to one or both sides of the lower abdomen is useful, e.g., painting with equal parts of tinct. iodi mitis (B.P.) and tinct. iodi fortis (10 per cent), or application of a blister.

If there is strong evidence that one of the Fallopian tubes contains pus, an operation should be performed, if possible after the acute stage is over, as the pus becomes less virulent after a lapse of time. Apart from evidence of the presence of a pyosalpinx, removal of an inflamed tube or ovary and tube may have to be advised on account of pain, impairment of general health, and recurrence of attacks of pelvic peritonitis. No minor uterine operation should be carried out during an attack of salpingo-oöphoritis: curetting in such circumstances may be followed by a severe pelvic peritonitis.

It must be noted that the ovaries are blameless in many cases of so-called "chronic ovarian pain." Neurasthenia, anæmia, constipation, and dyspepsia are common causes of this complaint. Attention to the general health, especially to the state of the bowels, with entire avoidance of local treatment, will often effect a cure. Nothing can be worse treatment in such a case than to tell the patient that her ovaries are responsible for her pain, and to direct her attention to the condition of her genital organs. If there is any local condition that really requires treatment, it should be treated, and the patient should be told that its bad effects begin and end in leucorrhœa, backache, etc., and that it is not responsible for her general condition; but unnecessary "tinkering," such as repeated cauterization of the cervix, insertion of tampons, etc., in a neurotic patient, and giving her detailed information as to the size, shape, and position of her uterus and ovaries, may do her an incalculable amount of harm.

H. Russell Andrews.

SCABIES.—By far the best treatment for this disease is the old-fashioned one of sulphur ointment. But it is not enough to apply it in a perfunctory manner, twice daily. In the severe cases, such as one meets in hospital practice, it is generally necessary to keep the patient freely anointed with the ointment, day and night for three days, while special attention should be paid to the hands, by which the disease is spread. The more rapid if somewhat cruel method in use in some foreign hospitals, of soaking the patient in a hot sulphur bath, then scrubbing him vigorously with soft soap and a nail brush, and allowing him to soak for a further hour in the bath, and then rubbing sulphur ointment freely in, is perhaps worthy the attention of municipal authorities; for scabies takes a heavy toll annually from the efficiency of the navy class.

In the more cleanly classes, while the same treatment may be resorted to, milder methods are often sufficient. The writer cannot speak so highly as some do of Peru balsam, and prefers to recommend in such cases the use of sulphur soaps, the lather of which may be diligently rubbed in night and morning to the axillæ and other parts where the disease is found in the cleanly.

It may be worth while also to adopt Sherwell's plan of dusting the bed with flowers of sulphur; he says it is the most efficient of all methods.

In children, the pustular lesions are often so tender looking as to dissuade the young practitioner from so irritating a remedy as sulphur, and in such cases β -naphthol, from 5 to 10 per cent in ointment, may be used instead.

Norman Walker.

SCALDS.—(See BURNS AND SCALDS.)

SCALP, CONTUSIONS OF.—These injuries differ in some respects from similar injuries in other parts of the body, and so need special mention. The receipt of a blow on the head is frequently followed by considerable extravasation of blood. This extravasation may be in one of three positions:—

1. *Subcutaneous*, in which case the tough subcutaneous tissue of the part prevents the effusion from becoming of great extent.

2. *Subaponeurotic* : the extravasation is in this case only limited in extent by the attachment of the epicranial aponeurosis, in front to the supraciliary ridges, laterally to the zygoma and mastoid process, and behind to the superior curved line of the occipital bone.

3. *Subpericranial* : the effusion of blood being limited by the attachment of the pericranium to the suture lines, the resulting hæmatoma assumes the form of one of the cranial bones.

A swelling occurring in any one of these three situations has characteristics which must be carefully noted. The central part of the swelling is soft and compressible, whilst the edge is hard and raised. The greatest care is called for to avoid mistaking this hard ridge for bone, and the central soft part for a depression of the vault. If firm pressure be made upon the hard ridge for a short time it is felt to disappear, and the smooth bone beneath is felt at its normal level ; moreover, similar pressure upon the soft centre will reveal the surface of the vault smooth and regular, not irregular and guttered as it would be in the case of a depressed fracture.

TREATMENT.—It is well to quote at the outset the saying of Hippocrates “ Nullum capitis vulnus contemnendum.” If there have been signs of concussion, or if there be any suspicion of intracranial lesion, it is the duty of the surgeon to insist upon the precautionary measures in the way of rest, etc., which are detailed under the head of BRAIN, CONCUSSION OF. The careful cleansing of any abrasion, and the application of evaporating lotions, are all that is necessary in direct treatment for the hæmatoma. Should suppuration ensue, the swelling should be incised immediately, the breaking-down clot turned out, and a drainage tube inserted in such a position as will ensure efficient drainage with the patient lying down.

S. Maynard Smith.

SCALP WOUNDS.—The subcutaneous tissue of the scalp is closely bound to the subjacent aponeurosis ; the aponeurosis, on the other hand, is but slightly connected with the pericranium over the bone beneath. It therefore follows that a superficial scalp wound will gape but little, whilst one which involves the aponeurosis will lie widely open. Again, the blood-vessels enter at the margins of the aponeurotic attachment. No vessels of appreciable size cross the sub-aponeurotic space to enter the flap. Consequently, all the bleeding from a torn-up flap of scalp comes from the torn edge ; there is none from the under aspect of the flap. For the same reason there is no danger of a flap sloughing so long as it has its marginal attachment, since the source of its blood-supply is uninjured.

TREATMENT.—The arrest of hæmorrhage sometimes gives rise to trouble. The vessels at the margin of the flap may be caught with artery or Spencer Wells' forceps, and tied with fine silk or catgut. If the deep temporal arteries be divided, it may be necessary to enlarge the wound to secure them. The chief essential in the treatment is to carry out thorough and careful purification of the wound and its neighbourhood : in the case of a large wound an anæsthetic should be given to facilitate this. The wound is protected by a piece of gauze wrung out of antiseptic lotion (carbolic 1-40 or perchloride 1-2000). The surrounding skin is then shaved ; this may, in the case of extensive wounds, involve the shaving of the whole or nearly the whole scalp. The skin is next scrubbed with soap and water, and finally cleansed with an antiseptic lotion. The gauze is now removed from the wound, and the cavity and edges of this are carefully treated with the same lotion, great care being taken to remove all hair and foreign substances. The iodine method is not suitable owing to the difficulty of dry

shaving the scalp, whilst if soap and water be employed for shaving, the efficacy of the iodine is greatly impaired. The wound is closed with silkworm gut sutures, but if it be at all extensive, a small rubber drainage tube, which has been boiled, should be inserted in the lower angle of the wound. A dressing is applied, and if all goes well the drainage tube is removed after forty-eight hours, and the stitches at the end of a week. If suppuration ensue, several of the sutures are removed, and drainage tubes inserted at two or three points along the wound; and if difficulty be experienced in securing free exit for discharge, a counter-opening is made through the most dependent part of the attached margin of the flap, and a drainage tube inserted there. Boracic fomentations are then applied, and changed every four hours.

S. Maynard Smith.

SCARLET FEVER.

The Malignant or Toxic Form.—The patient must be kept strictly in the recumbent position; hypodermic injections of strychnine should be given every two to four hours, and brandy or champagne by the mouth; if the temperature be high, the patient should be wet-packed, or sponged with cold or tepid water. There is usually too much prostration to permit baths. If there be vomiting, the milk should be peptonized, or nourishment given by enemata.

The Anginous or Septic Form.—The pyrexia, sleeplessness, and delirium are best treated with sponging, packs, or baths.

The local faucial lesion (inflammation followed by sloughing and ulceration) requires antiseptic treatment. In mild cases, gargling or spraying will be sufficient, but in severe cases the fauces and nasal passages should be flushed out with a Higginson's or a ball syringe, or with a douching apparatus. A sheet or large towel should be fastened round the child so as to restrain the arms. The patient's head should be held under the nurse's left arm over a basin; with the right hand the nurse uses the syringe. Two persons may be required for strong children, if they resist, as they are very likely to do when delirious. The following solutions may be used: chlorine water (to make this, 4 dr. chlorate of potash are put into a large dry bottle and 1½ dr. of pure hydrochloric acid are added; chlorine gas is given off; when the gas ceases to evolve, add 30 oz. of water, a few ounces at a time, shaking the bottle each time water is added: the gas is dissolved in the water: 1 oz. of syrup should be added to every 5 oz. of the solution, just before use); permanganate of potash, 15 gr. to the ounce; a saturated solution of boracic acid; chinosol, 1-600 to 1-1000; the alkaline lotion mentioned in the article on DIPHTHERIA. In very foul cases the following solution may be used as a spray:—

R Tint. Iodi Fort. (10 per cent)	℥xl	Glycerini	℥iv
Acidi Carbolicæ Liquefacti Puri	℥ij	Aquæ Destillatæ	q.s. ad ℥viij
Alcoholis	℥ss		

Later, when the swelling has subsided and the exudation or secretion is less abundant, the ulcerated surface should be swabbed with carbolic lotion 1-40, or 1-1000 perchloride of mercury. Gargling, flushing, spraying, and swabbing should be done as often as the case requires, from three times a day to every three or four hours. The pain in the throat may be allayed by the application of hot fomentations, and letting the patient suck ice. A 5 per cent solution of cocaine also may be occasionally applied.

For **Cervical Cellulitis** the writer does not recommend early incision. The treatment he adopts is fomentation with warm boracic lotion till the skin is beginning to give way; then the skin is slit up, the underlying slough removed, and the wound treated aseptically.

If the ulcerative process spreads from the fauces to the *larynx*, the patient

should be put in a steam tent; and, if severe dyspnœa supervene, submitted to tracheotomy. Intubation is harmful in this condition.

Otitis Media.—Occasionally earache is the first sign; this may be relieved by the instillation of a drop or two of warm laudanum or cocaine solution, and the application of hot fomentations over the whole ear. If these measures do not relieve, a leech over the upper part of the mastoid process will often succeed. If the tympanic membrane is found to be bulging, it should be punctured. There is nothing special about the treatment of the ear discharge that usually follows upon the earache (see *EAR, AFFECTIONS OF*).

Rhinorrhœa should be treated by syringing the nasal passages with one of the solutions already mentioned. It is also important to prevent the child from picking his nostrils, and so setting up a very intractable and infectious ulceration. Cardboard splints on the arms are the best means.

Nephritis.—It is quite unnecessary to keep the convalescent scarlet fever patient in bed in the hope of averting nephritis. Whether the patient be getting up or not, the urine should be examined at least every other day, and also upon the occurrence of any other complication, such as adenitis, otitis, or secondary tonsillitis; if albumin is found, the patient should be ordered back to bed at once, and put upon a milk diet. Three or four days will usually show whether the albuminuria is a symptom of nephritis or not. Usually, nephritis begins suddenly with hæmaturia. The patient should be kept on milk, not only till blood has ceased to appear in the urine, but also until the albumin has much diminished. He may then be allowed, in due course, fish, chicken, and, finally, meat diet. It is a mistake to keep nephritis cases, in which the acute symptoms have subsided, too long on a milk diet and in bed. When the diet is increased, they may be allowed to sit up in blankets or a dressing-gown, and later, even before the albumin has quite disappeared, to get up in clothes, and, in warm weather, walk out of doors.

During the acute stage of the kidney inflammation the patient should be encouraged to drink freely of water, or, better still, "imperial drink": two drachms of acid tartrate of potash are put in a large jug with the juice of one lemon and some syrup; two pints of boiling water are added, and the whole well stirred.

Linseed-meal poultices should be applied to the loins every three or four hours. Perspiration may be encouraged by hot-air baths, hot packs or baths once or twice a day. The bath should be brought to the bed-side. The bowels should be kept freely open by castor oil or salts.

Convulsions may usually be cut short by the inhalation of chloroform.

Coma (fortunately not common apart from convulsions, when it passes off soon after the convulsions cease) should be treated by dry-cupping the loins and giving hot packs. If these remedies fail, a few ounces of blood may be abstracted by venesection or the application of leeches to the loins.

Nephritis cases usually become anæmic, and during convalescence will require iron. Perhaps the best form is the alginoid, in 5- to 15-gr. doses.

Rheumatism.—Salicylate of soda or acetyl-salicylic acid will, as a rule, relieve the articular pain and swelling very quickly. The affected joints should be wrapped in wool, and the patient be put on a milk diet.

No special treatment is required for the remaining complications of this disease.

A word or two must be said concerning the use of serums and vaccines. In severe cases of scarlatina anginosa it is worth while trying a polyvalent anti-streptococcic serum in doses of 20 to 50 c.c. I have seen several cases in which much benefit has followed. On the other hand, in many cases the treatment has been of no avail.

Opinion as to the worth of vaccines varies widely. Personally, I have not seen any benefit result in the few cases in which a vaccine has been given during the acute stage of the attack, and little, if any, in such complications as persistent rhinorrhœa and otorrhœa. But other observers have reported favourable results, both in the disease itself and the complications mentioned. For the former, the dose is five to twenty million cocci, followed by double the amount in three or four days; an autogenous vaccine should be used unless the case is very urgent, when a stock vaccine made from a large number of different strains of cocci should be employed. In chronic otorrhœa and rhinorrhœa, an autogenous vaccine should be prepared. In no cases should local treatment be omitted.

With regard to the *general treatment*, the reader is referred to **FEVERS, ACUTE INFECTIOUS**. The patient may be allowed to sit up in a dressing-gown as soon as the temperature has been normal for six or seven days, provided there is no severe complication. In another five or six days he may be allowed to walk about in clothes. A very large number of the patients in the Metropolitan Asylums Board's Hospitals are transferred to the convalescent hospital in the country at the end of two to three weeks' stay in the town hospital, and they derive much benefit from the early change.

With respect to the period when the patient is to be considered free from infection, for some time past the writer has been discharging patients from the hospital at the end of four weeks' stay therein, quite irrespective of the desquamation; some of the patients have finished peeling by that time, others are still peeling vigorously. These patients, however, do not appear to be infectious. But if there is any discharge from the nose or ear, the patient should not be dismissed so early. It is also desirable that patients who have recovered from scarlet fever should be kept away from other susceptible children for at least a fortnight after their return home.

Quarantine period: one week.

E. W. Goodall.

SCHOTT-NAUHEIM TREATMENT.—The physical treatment of chronic affections of the circulatory organs, generally referred to as the Schott method, consists in the application of mineral baths and of therapeutic exercises as first systematized and carried out at Bad-Nauheim, of which the saline springs are by their nature pre-eminently suited to the balneological treatment of the circulatory organs.

THE BATHS.—The springs used at Nauheim for bathing purposes are those known as Nos. 12, 14, 7, 11. They are given in the order of their richness in sodium chloride, with the varying proportions of calcium chloride and carbonic acid gas.

No. 12 Friedrich Wilhelm's Spring*		No. 14 Neuer Sprudel (1900)*	No. 7 Grösser Sprudel*	No. 11 Gas Quelle*
NaCl	.. 29.2940	24.0692	21.8245	17.1388
CaCl ₂	.. 3.3249	1.6327	1.7000	1.2598
CO ₂	.. 1.0074	1.1905	3.1756	1.4136

It will be observed that No. 7 spring is by far the richest in carbonic acid gas. A course of baths, however, commences with waters which have thrown off, in tanks or reservoirs, practically the whole of their gas, and in so doing have acquired a yellow opacity due to the presence of undissolved iron peroxide and calcium carbonate (Thermal-Bad), generally those of No. 7. To these, as the case may require, are added in increasing

* The ingredients are given in grams as contained in 1000 grams of water.

portions from one to three or more litres of the uncrystallizable mother-liquor (Mutter-lauge) of the neighbouring salt works, which is rich in calcium chloride and bromine. Next in order come the waters of No. 7, 12, or 14, which have been stored in underground tanks under conditions which retain sufficient gas to hold in solution their iron and calcium salts (Thermal-Sprudelbad). Later comes the "Sprudel," drawn from No. 7 or No. 12, according to the temperature desired, containing a still larger residue of natural gas, and sufficient to induce in most subjects a well-marked rubefacience as well as a glow of warmth. Finally, but not for all patients, comes the flowing sprudel bath (Sprudel-Strombad), in which the waters of either No. 7, No. 12, or No. 14 forcibly enter, and, through exit pipes, leave the receptacle, during the entire period of immersion, and are capable of effecting rubefacience in a still higher degree. It will thus be seen that the waters employed increase, in regulated order, in mineral and gaseous ingredients, and represent stages of increasing balneological strength.

THE EXERCISES.—These should be so administered and regulated as to involve *little exertion and no fatigue*, and should be resisted on the part of the operator with an amount of force sufficient to oppose without arresting the movement. They may be conveniently tabulated as follows :—

No. 1.—The arms raised in the horizontal plane, with the palms of the hands in contact, are carried back in the same plane until in line with each other, and with an imaginary line drawn through the thorax from shoulder to shoulder. Reverse the movement.

No. 2.—The forearm of one side at a time, extended in the depending position, with the palm directed forwards, is flexed from the elbow until the hand rests on the corresponding shoulder-joint. Reverse.

No. 3.—Both arms placed in the same initial position are raised outwards from the shoulder until the thumbs meet over the head. Reverse.

No. 4.—The hands, with fingers flexed so that the second phalanges or corresponding fingers of the two hands are in contact, are pressed together in front of the hypogastrium, and raised until they are on a level with the vertex of the head. Reverse.

No. 5.—The arms extended in the depending position, with the palms touching the corresponding thigh, are raised in parallel planes until they are extended directly upwards. Reverse. The above movements are resisted at the wrist.

No. 6.—The trunk is flexed forwards, without the knees being bent, until it is at right angles with the lower extremities. Reverse. Resistance (a) the hand over the manubrium sterni; (b) over the scapulae.

No. 7.—The trunk is rotated without movement of the feet to the extreme right and the extreme left. Resistance by both hands, one in front of one shoulder, the other behind its fellow, the positions being reversed for the reverse movement.

No. 8.—The trunk is flexed laterally, first to one side, then completely over to the other, and finally brought back to the erect position. Resistance by hands placed one on the thigh, the other on the axilla, and the reverse for the recovering movement.

No. 9.—Is identical with No. 2, except that the fists are kept firmly clenched.

No. 10.—Is similar, except that the hand is turned outwards, the fist being clenched.

No. 11.—The arm is extended in the depending position, the palm in contact with the thigh, and made to execute a complete revolution from the shoulder-joint, forwards, upwards (when vertical the palm must be turned outwards), then backwards to the initial position. One arm at a time. The resistance is offered by first one hand, then the other, being placed against the side of the wrist.

No. 12.—Both arms are placed in the same initial position as in No. 11, and are then moved backwards and upwards in parallel planes to the extreme limit. Reverse. Resist by the hand placed on the wrist.

No. 13.—The thigh is flexed to the extreme limit, and then extended until the feet are side by side. The body is steadied by the hand of the opposite side (alternately) resting on a table or the back of a chair. Resist the upward movement by the hand placed on the patella, the reverse movement by placing it under the sole of the foot.

No. 14.—The body being supported as in the last movement, the lower extremities in succession are flexed from the hip-joint, first forwards, then backwards, to the extreme limit. Resist on the anterior and posterior aspects of the ankle-joint, alternately.

No. 15.—The patient, with his hands resting on a table or a chair in front of him, stands on either foot in succession, while the leg of the other side is flexed on the thigh. Resist as in the last movement.

No. 16.—Supported as in No. 14, the patient raises the lower extremities in succession outwards from the hip-joint, and reverses the movements. Resist as in the last movement.

No. 17.—The arms extended horizontally outwards are, in succession, rotated from the shoulder-joint to the extreme limits forwards and backwards. Resist with the hand folded round the wrist.

No. 18.—Flexion and extension of the hands successively, on the wrist-joint. Resist with one or two fingers placed alternately below and above those of the patient.

No. 19.—Flexion and extension of the feet, successively on the ankle-joint. Resist in a similar manner.

It will be apparent that in general outline the movements particularized are similar to, or identical with, many of those which form part of current systems of hygienic and physical training. The cardiovascular therapy of the movements—the essence of the system—lies in the science and technique of their administration as adapted to the condition of each individual patient. The movements may be given in any order that may be convenient, or be modified according to the condition of the patient and to any posture he may be obliged to maintain, such as the sitting and the recumbent positions; or others may be devised, provided that the rules of application be strictly observed. Many patients are unfit to perform more than three or four movements at the commencement of treatment, consistently with the avoidance of increased frequency of the pulse, accelerated breathing, and fatigue.

ARTIFICIALLY PREPARED NAUHEIM BATHS.—It will have been noticed in the account given of the baths as administered at Nauheim that, in the earliest stages of the treatment, the waters have, as far as possible, been made to give off their carbon dioxide. The question of effervescence does not, therefore, enter into the first stages of the treatment. It will also have been observed that the usual initial strength is 2 per cent of sodium chloride, and rather less per mille of calcium chloride. For all practical purposes, therefore, 6 lb. of the sodium salt and 8 oz. of the calcium salt dissolved in 40 gall. of water, giving a sp. gr. of 1005, constitute a useful initial bath. From time to time additions of 1 lb. of the one, and 1 oz. of the other salt, may be made, until at about the middle of a course of twenty-eight baths a strength of 10 lb. and 12 oz. has been attained. It will then devolve on the medical attendant to decide whether to proceed to effervescing baths. Half the contents of one of Sandow's boxes of effervescing ingredients added to the ingredients of the preceding bath will be approximately equivalent to the "thermal-sprudel" bath. The next step would be to add the entire contents of one box in order to produce the equivalent to the full-strength sprudel bath. The production of a bath equivalent to the sprudel-strom bath is not a matter of essential importance.

Points of Resemblance and Difference.—As is the case with the natural waters, those artificially prepared are regulated so as to present increasing degrees of balneological force, first in sodium and calcium salts, next in carbonic effervescence. It is possible that, volume for volume, the gas given off from solution in the natural waters may exercise a higher degree of pungency on the skin; but as in the artificially produced "sprudel" the gas is incessantly renewed during immersion, the result is in effect not less, as may be observed, in the degree of resulting rubefacence. In the artificial effervescing bath of full strength the water is kept in a continuous boil by the unbroken relays of nascent gas, and therefore approximates to the "strom-bad"; while, if it be desired to keep the water moving in a stream throughout immersion, it is not difficult to effect that purpose by mechanical means.

Physiological Action of the Baths.—The temperature of the baths is below the normal of the body, and must be regulated so as not to check, but rather to ensure, a rapid, if not immediate, reaction. The saline and gaseous ingredients of the waters effect cutaneous excitation much as would friction with a rough towel or a horse-hair glove; but the process begins with immersion and is progressive throughout. In many subjects the resulting rubefacence is obvious, more especially after the higher-grade baths.

The vasodilatation and increase in energy of the cardiac systole which ensue on and during immersion, and are maintained for varying periods after, are generally attributed to the stimulus conveyed through afferent nerves to the vasomotor and heart-controlling nerve mechanisms. It may also be suggested that the secondary effect of immersion in a medium below the normal is to promote the flow of an increasing volume of blood to the surface for the purpose of maintaining its temperature; and that, as in experiments conducted by other means by Dr. George Oliver, the weight of mineralized water pressing on the abdomen of a subject sitting at an angle of 45° to the base of the bath, effects a gentle, gradual, and sustained emptying of the splanchnic veins into the right heart, supplying from one of the natural reservoirs, and sending on for arterialization, the blood required to fill an expanding arterial area. The result

might be expected to be that the heart would retain less residual blood, and that its contraction, being more complete, would occupy a longer interval, making the pulse at once slower and fuller. Such is the case. The results, in fact, may be summarized as follows:—

1. A glow of warmth.
2. Increased pulse volume, with diminution of frequency.
3. Stronger cardiac systole.
4. Diminished area of dullness.
5. Relief of præcordial discomfort.
6. Deeper breathing.
7. A general sense of relief.

It should be added that improved metabolism, increased renal circulation, and the elimination of retrograde products combine to promote appetite, diuresis, thirst, and healthy perspiration.

Influence of the Baths on Blood-pressure.—In respect of blood-pressure the following axioms may be laid down:—

1. If the degree of arterio-dilatation be in excess of the increase of cardiac energy, the blood-pressure will fall.
2. If the increase of cardiac energy be in excess of the arterio-dilatation, the blood-pressure will rise.
3. If the increase of arterial capacity and of cardiac energy be exactly co-ordinate, the blood-pressure will remain unchanged.

It will be obvious that the relative conditions thus defined will, from the clinical point of view, be influenced by, and dependent on, the integrity of:—

1. The several nerve mechanisms involved.
2. The vascular tunics.
3. The cardiac structures, more especially of the myocardial tissue, the valves, and the coronary vessels. As a matter of fact, and speaking generally, the blood-pressure falls unless the vascular tunics have undergone such changes as inhibit or have abolished resilience and conductivity, or capillary obsolescence has proceeded so far as to induce irreparable changes.

TECHNIQUE.—During immersion, the patient should incline at an angle of about 45°, with only the head and neck out of the water. He should breathe regularly, abstain from talking, and only move as comfort may dictate. The sense of oppression, or of tightness across the chest, which frequently supervenes during the earliest baths in the course of the second or third minute, may be often relieved by a few deep inspirations, which facilitate the passage through the pulmonary circuit of the blood which is being driven into the right heart from the splanchnic and other venous reservoirs. The patient should leave the bath immediately on the expiration of the prescribed time limit, be enveloped from neck to feet in a warm bath towel, and, if there be dyspnœa or marked feebleness, be dried in the sitting posture by friction administered through the towel by an assistant. Not less than an hour's rest in the recumbent position, preferably in bed, should be enforced after each bath. It is not desirable to administer more than five baths in a week, at the rate of two or three in succession. In many cases the medical adviser may find it advisable, on account of physical weakness or of neurasthenia, to allow only one bath at a time, with intervals of one or two days spent in more or less complete repose of mind and body.

Physiological Action of the Exercises.—The effect of the exercises is identical with that of the baths, though less profound and apparently less permanent. On the other hand, they develop the musculature of the body to a degree which cannot be emulated by the baths, and so, without undue fatigue, prepare an enfeebled frame for the resumption of a more active life. Further, modified to adapt them to the recumbent or sitting posture, and carefully regulated, they can be applied as a preparatory measure to subjects as yet unfit to be raised and placed in a bath. It has been shown by experiment that after carefully regulated and gently resisted movements, the output of a divided

artery is, on removal of the ligature, found to be three-fold in volume, and it is easy to demonstrate, by observation of the face and ears, that arterial and capillary flushing are not limited to the parts exercised.

TECHNIQUE.—The person who administers the exercises may be called the operator and should strictly observe and enforce the following rules:—

1. Each movement is to be performed slowly and evenly; that is, at a uniform rate.
2. No movement is to be repeated twice in succession in the same limb or group of muscles.
3. Each single or combined movement is to be followed by an interval of rest.
4. The movements are not to be allowed to accelerate the patient's breathing, and the operator must watch the face for the slightest indications of (a) Dilatation of the *alae nasi*; (b) Drawing of the corners of the mouth; (c) Duskiness or pallor of the cheeks and lips; (d) Yawning; (e) Sweating; and (f) Palpitation.
5. The appearance of any one of the above signs of distress should be the signal for immediate interruption of the movement in process of execution, and for either supporting the limb which is being moved, or allowing it to subside into a state of rest.
6. The patient must be directed to breathe regularly and uninterruptedly, and should he find any difficulty in so doing, or for any reason show a tendency to hold his breath, he must be instructed to continue counting in a whisper during the progress of each movement.
7. No limb or portion of the body of the patient is to be so constricted as to check the flow of the blood by compression of the vessels.

Therapeutic Effects:—

1. *Vascular.*—Of repeated, prolonged, or permanent arteriole constriction may, and in fact does, conduce, even at relatively early periods of life, to fibrotic and atheromatous changes, diminishing capacity and conductivity generally, with not infrequent special incidence on particular organs. In respect of the kidneys, an affection at one time general may become not only locally accentuated, but develop into an autonomous and irremediable disease. But apart from localized effects of arteriosclerosis, the practitioner is confronted with such results as increased venosity of capillary and trunk channels, inducing permanent changes in both classes of vessels, congestion of pelvic and abdominal organs, as well as of respiratory passages, dilatation of arterial trunks, more especially of the aorta, with the possibility of aneurysm, not to speak of cardiac hypertrophy and dilatation, and gradual but progressive increase of residual blood in the chambers of the heart. In all conditions dependent on such changes, relief, and cure where tissue change has not passed beyond the range of repair, may be effected by judicious resort to baths, or exercises, or both, according to individual conditions. That the cure of early stages, and the relief of even later conditions of arteriosclerosis, may be effected has been abundantly shown. Obsolescent and obsolete capillaries may be restored to function; and conditions tending towards permanent varicosity relieved. It needs no argument to emphasize the importance of such considerations in connection with the auto-toxis of gout and of rheumatism, as well as with the tissue changes induced by alcohol, nicotine, and syphilis. It is, therefore, certain that in all such progressive morbid conditions, in which pharmaceutic treatment lags or fails, recourse to the methods under consideration will open up new and great possibilities of relief and repair.

2. *Cardiac.*—Once it is admitted that arterial lumen may be restored, tissues repaired, and patency restored to obsolescent capillaries, no difficulty will be encountered in realizing that a potent means of restoring cardiac structure and function has become available; for it would be unreasonable to suppose that the coronary vessels and capillaries alone would be shut off from the general change. Moreover, while peripheral resistance diminishes and arterial area expands, and the heart is co-ordinately stimulated to increased contraction, residual blood is expelled, and the muscles are set free to move in wider range. The heart, like other muscles, grows in response to increasing

energy in the exercise of its physiological office and an increasing supply of nutritive material. Therein lies the reply to the question as to the range of the application of physical treatment to cardiac affections, namely, that such treatment is suited to all cases in which it will be for the advantage of the patient to restore healthy substance, and therefore additional power, to the muscular and other tissues of the heart. The limit of its beneficial action lies in the conductivity of the nutrient vessels in relation especially to official obstruction, and to degenerative changes in their tunics. If either or both of those conditions be irretrievably established, increased work can result only in increasing exhaustion and consequent deterioration, with hastening of the inevitable end. It is scarcely necessary to point out that the structures in which the reparative process is most readily established are : those of the nutrient vessels themselves, whenever official patency remains or can be in any degree restored, and the myocardium, including the highly vascular specialized tissues which are responsible for the origin and conduction of rhythmic impulses ; and that, in the nature of things, deforming lesions of the valves stand outside the scope of any known treatment. On the other hand, the restoration of compensation for valvular defects, and the relief of dilatation in conjunction with vascular repair, may be said to be the special office of this treatment. It is needless, therefore, to enquire whether it is applicable to cases of valvular disease, in view of the obvious consideration that the safety of the individual, in such conditions, depends on the effectiveness of compensatory action and the delay or repair of parenchymatous degeneration and of dilatation as opposed to conservative hypertrophy. As, however, a statement has been promulgated to the effect that these methods are not applicable to aortic regurgitation, it is necessary to emphasize the fact that, in that condition, the maintenance of the histological integrity of the myocardium and of effective compensation is perhaps more immediately vital than in any other valvular lesion. On that point Professor Schott and the writer desire to record their opinion unequivocally. In extreme cases, the recourse to treatment should be cautious, because, as already indicated, increased heart work can bring only increased exhaustion if permanent coronary occlusion has been established.

Briefly, these methods are of pre-eminent value to bring about the restoration of compensation in valvular affections, whether stenotic, regurgitant, or both, and for the repair of myocardial degeneration, and in the following conditions :—

Athlete's heart (right side strain).

Minor epilepsy of the cardiac variety (often mistaken for syncope), including that which occurs in the early stages of the Stokes-Adams syndrome.

Palpitation, associated with gastric or intestinal distention, especially the night palpitation of the enfeebled heart.

Palpitation associated with high blood-pressure.

Air hunger, which is always accompanied by some degree of dilatation, an extreme form of which is often denominated cardiac asthma.

Early stages of brain waste, as indicated by loss of power of mental concentration and of memory for recent events.

Abnormal cardiac conditions associated with autotoxis, whether of alimentary origin or due to pathogenic organisms in other parts, such as tachycardia, bradycardia, Graves's disease, asthma, and ichthyosis, in which arterial atrophy is concurrent with, or dependent on, autotoxis.

The various arrhythmias, including auricular fibrillation, of which numerous cases have been successfully treated without recourse to drugs other than those required for the correction of toxæmia.

Cheyne-Stokes breathing dependent on the concurrence of arteriosclerosis,

high blood-pressure, and generally albuminuria (especially in conjunction with hypodermic injections of small doses of morphine).

Edema.

AFTER-TREATMENT.—A course of treatment should be followed by a sojourn of from a fortnight to a month's duration in a healthy situation which offers the advantages of a dry soil and walks both level and gently inclined, which lend themselves to regulated and gradually extending walking exercise. Carriage exercise is of secondary importance, except in those cases in which the walking powers are exceptionally limited and seasonal conditions make it difficult to remain long out-of-doors in a quiescent condition. Generally speaking, an inland place with a moderate altitude is to be preferred. Such are Hindhead, Crowborough, West Malvern, Buxton, and the health resorts on the Yorkshire Wolds. But it has to be remembered that in advanced cases of arteriosclerosis, with irreducible high blood-pressure, even so moderate an altitude as from 600 to 800 feet may rapidly induce dyspnoea or initiate temporary accesses of Cheyne-Stokes breathing. For such cases, and especially for those complicated with chronic bronchitis, asthma, and emphysema, a south-coast place with a mild and even somewhat moist air, and a supply of invalid chairs, is to be preferred. Breathing exercises, and gentle calisthenics practised without weights or mechanical appliances, are often useful adjuncts to a course of after-treatment.

W. Bezly Thorne.

SCIATICA.—Sciatica may be, and frequently is, only a symptom of disease situated in the spinal cord, the bodies of the vertebra, the pelvis, or the hips. Disease of the rectum, and new growth, may give rise to pain in the course of the sciatic nerve. Constipation is also a frequent cause of sciatica, and is said to explain the greater frequency of the affection in the left leg. Exposure to wet or cold, or the pressure of a hard seat, may under certain conditions induce an attack. It is especially liable to occur in gouty individuals and in those who pass uric acid in the urine. It also occurs in connection with rheumatism, gonorrhœa, and oral sepsis.

It is obvious, then, that successful treatment depends to a large extent on accurate diagnosis: but although a certain number of cases come under observation which may be due to the causes above indicated, a far larger number occur in which no very obvious cause can be demonstrated.

Treatment may be dealt with under the following heads: (1) Rest; (2) Application of heat; (3) Electricity; (4) Local applications; (5) Massage; (6) Diet; (7) Drugs; (8) Injections; (9) Change of climate; (10) Surgical treatment.

1. **Rest.**—In most cases rest in bed is advisable, and in acute cases essential. Complete rest to the affected limb is best secured by the use of a long splint. The limb should previously be carefully bound up with a flannel bandage. When a splint is not employed, the limb should be supported by pillows, and movement limited by the use of sand-bags.

2. **Application of Heat.**—This is of special value in the relief of pain. During the early stages of a mild attack, a Turkish bath undoubtedly gives good results.

Hot-air baths, applied locally, are also most beneficial, and a temperature of 300–400° F. can be made use of when suitable precautions are taken.

Such local heat may be obtained in a closed chamber heated by gas or a spirit lamp, or still more easily by the electric current. Both methods are somewhat expensive in application, and much good may be done by hot sand-bags, which can be heated in an ordinary oven and applied along the course of the sciatic nerve. Another simple and effectual method of applying heat is by means of a hot iron, the patient being ironed along the course of the sciatic nerve. A

hot-water bottle may also be used. The local hot-air bath should be applied at first every other day, and, since it gives rise to a considerable amount of sweating, the patient should be carefully protected both during and after its application. The local application of heat is also available in cases in which for general reasons it is inadvisable to sanction a Turkish bath.

A simple hot bath, to which an alkaline salt or ammonia has been added, is often beneficial.

3. **Electricity.**—Galvanism often gives satisfactory results. Static electricity and diathermy have been used in some most obstinate cases with striking effect; faradism and high frequency have also been used.

The galvanic current may be applied by means of a bath—the direction of the current being immaterial—or direct application may be made to the skin, the positive pole being placed on the thigh and the negative pole on the back. A current of 2 milliampères is gradually increased to 5 milliampères. This is allowed to pass for 5 to 10 minutes, the current then being gradually reduced and the electrodes removed when the current has been shut off. Ionic medication (kataphoresis) with iodine, sodium salicylate, etc., is of value in many cases (for details as to the method of application reference should be made to the article on ELECTROTHERAPEUTICS, *Ionic medication*, p. 311).

4. **Local Application.**—Blisters along the back of the thigh are sometimes successful in the relief of pain, two or three days being allowed to elapse between the application of each blister. Counter-irritation may be made by the actual cautery. The local application of belladonna, mesotan, turpentine, and iodine is also useful. In order to avoid pressure on the nerve, it is advisable for the patient to have an air cushion when seated for any length of time.

5. **Massage.**—Massage and passive movements are of service in the late stages of the disease, but should not be allowed during the acute stage.

6. **Diet.**—A restricted diet, such as is suitable in a case of gout or rheumatism, should be ordered. Alcoholic drinks should be avoided, but whisky may be ordered if necessary.

7. **Drugs.**—Drugs in some cases have a very marked beneficial effect, but in other cases seem almost useless. Quinine, iodides, bromides, salicylates, salicin, belladonna, sodium and potassium bicarbonate, colchicum, gelsemium, acetyl-salicylic acid, acetanilide, phenazone, and many others, have been used with good effect.

Quinine and iodine may be given together in the following mixture, three or four times a day :—

R Quinina Sulphatis	gr j	Acidi Sulphurici Diluti	℥j
Potassii Iodidi	gr iij	Aquæ Chloroformi	℥ss

The small quantity of acid is sufficient to keep the quinine in solution, and not incompatible with the iodide.

The following mixture will also be found of some service :—

R Sodii Salicylatis	gr x	Tincturæ Cardamomi Co.	℥ss
Tincturæ Gelsemii	℥x	Aquæ Chloroformi	q.s. ad ℥ss

The quantity of gelsemium is gradually increased, until the pain is relieved or poisonous symptoms are produced. Hypodermic injections of morphia give relief to pain, but should not be given until other remedies have failed.

8. **Injections.**—The infiltration of the sciatic nerve with normal warm saline solution and eucaine is of service in *chronic* cases. The nerve is found, with a needle 9 cm. long, in the neighbourhood of the notch, and is anæsthetized by the injection of 2 c.c. of 1·5 per cent solution of eucaine, or 5 per cent solution of novocain. After waiting a few minutes, 100 c.c. of normal saline solution is injected into the nerve. Two or three such injections may be required at

intervals of a week. The local injection of $\frac{1}{8}$ to $\frac{1}{4}$ gr. of cocaine is often beneficial.

9. Change of Climate.—A warm dry climate is that which suits most patients, and appears to be generally beneficial. The routine treatment by baths, waters, and diet at various hydropathics is often more beneficial than the same treatment when carried out at home. This is in part due to climatic conditions, but also to the enforced absence from work, which makes it possible for treatment to be carried out regularly and efficiently. Harrogate and Buxton are favourite resorts. Bath suits older patients, but does not as a rule agree so well with the younger.

10. Surgical Treatment.—Acupuncture of the nerve, nerve stretching, and splitting the sheath of the nerve, have all been successful in cases which had resisted other forms of treatment.

Shortly, it may be said that the treatment of sciatica consists of rest in bed, regulation of diet, diathermy, ionic medication, local application of heat, counter-irritants, or some form of liniment, the administration of drugs, and, failing a successful result from these methods, the application of electricity, acupuncture, and nerve-stretching. (See also ELECTROTHERAPEUTICS; NERVES, PERIPHERAL; and RHEUMATISM, CHRONIC.)

F. E. Batten.

SCOLIOSIS.—During the past few years great advances have been made in the treatment of scoliosis, especially in those cases which are usually classified as structural. The treatment of the more severe and intractable cases of rotato-lateral curvature differs so entirely from that in common use ten or twelve years ago, both in the theory and method of attack, that it has caused orthopædic surgeons everywhere to take a renewed interest in cases which formerly they looked on almost with despair.

Among the many factors which have contributed to the modern advances, the persevering and painstaking research and clinical work of Lovett, of Boston, has been to the writer and his pupils a constant stimulus to fresh endeavour; and no one familiar with the recent literature on this subject can fail to note how Lovett's work has influenced not only his followers but also exponents of rival views and methods.

The evolution of the present position may be illustrated by the changes in practice which have occurred in the writer's clinic during the past dozen years. Twelve years or more ago, the main idea of scoliosis was that it was a lateral curvature, while the rotation was regarded as a necessary concomitant deformity.

Although at that time the writer had already abandoned suspension with the idea of straightening out the spine, more or less traction in a longitudinal direction was employed, with the patient face downwards in a horizontal position. The surgeon then endeavoured by lateral traction and pressure to reduce the lateral deviation to a minimum—and a plaster jacket was then applied. Thus stage by stage the trunk was gradually moulded up in a fairly straight position. After a prolonged series of such jackets the general appearance of the patient when dressed was fairly symmetrical, but the backs were very stiff at first. With the patient undressed, the rotation, deformity, and bulging of the ribs on one side, with the corresponding flattening on the other, was very obvious. With exercise and gymnastics the back again became more supple, but at the same time a tendency to relapse showed itself, so that some form of permanent supporting apparatus was needed.

The first great advance in technique was made by Hoke and Andrews, of Atlantic City, who pointed out that in a patient with pronounced rotato-lateral scoliosis the chief respiratory movement took place in the long diagonal of the chest. That is to say, the bulging ribs on the convexity of the dorsal curve, and

the bulging ribs diagonally opposite on the front of the chest, moved freely in respiration, and the flattened parts of the chest scarcely moved at all. Further, this movement produces a torsion on the vertebræ which tends to increase the rotation deformity. The idea, therefore, occurred to them to apply plaster jackets in the best-corrected position obtainable, and then cut great respiration windows over the flattened parts of the thorax so as to encourage respiration in the short diagonal.

From 1905 onwards this method of utilizing the patient's respiration as a corrective exercise, continuing perforce day and night, became part of the writer's routine treatment of cases of scoliosis with structural deformity. The patients were placed, as before, in the prone position in an Adam's frame with pressure rods and plates applied to the prominences of the chest. By 1909-10 all longitudinal extension was abandoned, the patient was left face downwards in two longitudinal strips of webbing, and the aim of the surgeon became more and more to undo the rotation while the patient was fixed in the frame, and afterwards to follow up the advantages so gained by means of properly-placed respiration windows.

It was at this stage that Abbot, of Portland, Maine (1911-12), introduced the next revolutionary idea, which was that these cases should be treated with the trunk fully flexed, as well as correcting the rotation. This he did by placing the patient lying on her back in a slack canvas hammock, and applying lateral and rotatory traction by methods fully described in his various papers. This new position was tried in 1912, and it was at once evident that a greatly increased command over the deformity was obtained. By this method of twisting the patient and then the placing of large felt pads so as to get great freedom of movement in the desired direction, results were soon obtained such as had never before been seen; but as a rule it is not till he has applied several score jackets that a surgeon gets a real command of the possibilities of this latest method of treatment. It has attracted world-wide attention, and numerous modifications and variations have been put forward; but all contain three ideas, the respiratory window of Hoke and Andrews, rotation, and the flexion suggested by Abbot. To test the method, the writer set his assistants to treat every available case by it in the hospitals to which he is attached—excluding, of course, those cases in which the scoliosis was due to some active infective process, whether tuberculous or other, in which osseous union between the vertebræ excluded all hope of correction, or active disease contra-indicated vigorous manipulation.

Until this last method was adopted, only those cases were treated by plaster jackets where, under manipulation, it was found possible to produce some material improvement in position. The experience of the last two years has shown that the unilateral breathing which is brought about by a properly-applied Abbot's jacket is a tremendous corrective force which has greatly increased the range of cases which can be pronounced to be amenable to radical treatment.

The after-treatment is just as important, for it consists in wearing for a time a removable jacket, which is daily taken off while the patient gets exercise to strengthen the muscles of the back and general exercises to strengthen the limbs, and, in particular, practises voluntary unilateral breathing exercises of the same type as the unilateral breathing which was performed in the jacket.

The lessons learned from the new methods of treating the more severe cases of scoliosis have necessarily reacted on our methods of gymnastic treatment of the milder cases which occur among growing children. A mild case of scoliosis may be purely postural; that is, it is a bad habitual position which the child can correct completely by a voluntary muscular effort. Such cases are usually

merely lateral deviations ; when the child bends forward, no rotation can be seen in either lumbar or dorsal region when the surgeon takes a sight along the back as he would along a gun-barrel. These cases are almost invariably associated with round shoulder and hollow back, both indications that the muscles are weak. The child is usually growing fast : in the popular phrase, it is outgrowing its strength. The only treatment required is a good course of setting-up drill by symmetrical exercises.

The next stage is really the early stage of a structural scoliosis, for already ligaments and muscles are undergoing adaptive shortening on one side and lengthening on the other, so that the child can no longer completely correct the curve by voluntary muscular effort. On looking along the back, rotation can be seen in the dorsal or lumbar region or both, showing that structural changes are commencing. From this stage on to the severe ones, every gradation of deformity may be found. The initiation of such cases may be found in anything which makes for an habitual asymmetrical position—e.g., bad sitting position, unequal vision or hearing ; a slightly sprained ankle may cause a child to acquire a habit of carrying most of the weight on one foot ; or a transitory bronchopneumonia or pleurisy may cause her to acquire a habit of breathing more with one side of the chest than the other. Many of these cases may commence as a long single curve before the child is ten years old, and not be noticed till they become a double dorsal and lumbar curve two or three years later.

Of the latter type, we may distinguish clinical varieties for the purposes of treatment, regardless of their precise origin.

1. A case with lumbar curve and rotation of lumbar vertebrae—but practically no visible dorsal curve, and no visible rotation in the thoracic region.

It will be noticed that the child stands with one hip prominent, and this position (but not the pronounced rotation) can be obtained in a normal child by making her stand on one leg and drop the pelvis on the opposite side. The treatment, therefore, is to teach the child to stand chiefly on the other leg, and to depress the hip on the high side. An exercise which may be practised is to stand with one foot on a stool and depress the other foot towards the floor, keeping the shoulders perfectly square, and inspiring freely just when the stretch is taken. The heel of the boot should be raised on the side towards which the convexity of the lumbar curve is directed. In this way the balance of the pelvis is altered. The high heel takes the place of the stool in the exercise just described, and the girl should be taught to incorporate that exercise in her ordinary walking, at first as an exercise, later as a habit. If she does this she is correcting her deformity wherever she goes. This is the real key to gymnastic treatment.

The gymnastic exercises may be of two sorts :—

a. Those done with the gymnastic instructress—flexions, side-bendings, hanging, etc., which are directed towards stretching short structures, and making the spine more flexible.

b. Those movements which the patient must learn in order to acquire them as a corrective habit.

The first group of exercises are familiar to all properly trained gymnasts. The latter group must be modifications of ordinary movements to meet the peculiarity of the individual case, and should be as few and simple as possible. Their only value lies in the application of them to the movements of ordinary life.

2. So soon as we find that a case shows definite rotation in the thoracic region, we must regard the asymmetrical breathing which is part of this deformity as a very potent factor in increasing the latter ; therefore, taking our cue from Abbot's jacket, we have been teaching these cases to breathe asymmetrically so as to expand the flattened side of the chest.

The following exercise may be taken as a key to the movement. The patient sits astride the end of a bench, bends forwards and to the right, and lets the head and shoulders hang limply over the right knee. In this position the thorax in the neighbourhood of the left scapula is expanded in inspiration more than the right; in the case of a right dorsal scoliosis this means expansion of the flattened side of the chest.

It only requires an acquaintance with the ordinary movements, for example those used in Swedish gymnastics, to incorporate unilateral breathing with sitting and walking positions. The great thing is to teach the patient to cure herself by acquiring a good habit. If she will not take the trouble, very little can be done for her.

In such cases, our practice is to concentrate attention on the unilateral breathing first, as at this early stage thoracic inequality is comparatively easy to correct. At the same time the exercises for the lumbar curve are being learned. When the patient has mastered unilateral breathing, she can go on to concentrate her attention on her way of walking so as to correct the lumbar curve at each step. Remember each curve is dependent on the other, and whatever helps to correct one will indirectly or compensatively help to correct the other. It is a mistake to try to make the child do too many exercises; she can only concentrate her attention properly on two or three—the others should be given for relaxation and relief from the mental strain required to do the essential movements.

It is not possible to give a definite system of exercises in the short space of this article. Treatment by exercises is in a transition stage, and at present consists of varying combinations of the familiar movements formerly in common use, with modifications suggested by the modern treatment of severe cases.

Finally, every case should be finished by a good course of symmetrical gymnastic exercises.

It is not possible to draw a hard and fast line for the borderland cases between those which must begin with a plaster jacket and then go on to exercises, and those which will do quite well with exercises alone. Much depends on the skill and experience of the surgeon, and of the gymnastic instructress; but still more on the psychology of the patient.

Robert Jones.

SCURVY.—Try in the first place to get the patient away from the surroundings amidst which the disease has developed, and to place him in more hygienic conditions, chief amongst which are warmth, dryness, and fresh air. A radical alteration must be made in the diet, fresh vegetables and fruits, milk and fresh meat being abundantly supplied. Lemonade made from fresh lemons should be given as a beverage. Fresh infusion of malt is another powerful antiscorbutic, and several pints of it may be taken in the day. Cider and the French and Italian wines are also curative drinks. If the gums are spongy, they should be brushed with solid nitrate of silver every day, and antiseptic and astringent mouth-washes used freely, e.g. :—

R. Aluminis	gr. v	Tincturæ Myrrhæ	℥x
Acidi Sulphurici Diluti	℥xij	Aquæ Destillatæ	q.s. ad 3j

If diarrhœa be present, it should be treated with bismuth and opium. An extract of fresh Bael fruit has also been highly recommended in this complication. For subperiosteal hæmorrhages and hard swellings in the popliteal spaces and elsewhere, iodide of potash should be exhibited, and gentle massage used locally.

The Prophylaxis of scurvy demands attention to general hygiene, particularly the avoidance of overcrowding, and, most of all, the provision of a sufficiency of fresh elements in the dietary. If fresh vegetables or fruits are not available, oz. of lime-juice should be given every day, although it is apt to produce

"heartburn" in some subjects. Of preserved vegetables, "sauerkraut" is the best antiscorbutic. Fresh meat, even if eaten alone, is sufficient to prevent attacks of the disease.

Robert Hutchison.

SCURVY, INFANTILE.—The use of any tinned or proprietary food should at once be stopped, and the child put upon pure unboiled cow's milk. This may be supplemented by raw meat-juice, made by adding to finely-minced steak one-fourth of its volume of cold water, allowing to soak for an hour, and then squeezing through muslin. One ounce of the juice may be given in twenty-four hours. Broths in which a muslin bag containing chopped potato, carrot, or other fresh vegetables, has been suspended during cooking, are also useful, or the floury part of a baked potato may be rubbed up with some of the milk into a thin cream. A few teaspoonfuls of orange- or grape-juice should also be given every day. The use of drugs is unnecessary, but if rickets be present, as it usually is, cod-liver oil and iron should be administered.

If the legs are affected, they should be wrapped in cotton-wool secured by a light bandage, or swathed in wet towels which are allowed to dry *in situ* after they have adapted themselves to the contour of the limbs. A sand-bag should be placed on each side of the legs, and the weight of the bedclothes kept off them by a cage. If the arms are tender, they should be fixed by bandaging them gently to the chest.

Robert Hutchison.

SEA-SICKNESS.—Prior to undertaking a voyage, a simple diet should be observed for a few days, and the bowels freely opened on one or two occasions by a dose of blue pill, followed by a saline draught. If the sea passage be of short duration (less than twelve hours), a draught of chloral and bromide of ammonium (30 gr. of each) should be taken before starting, and the patient should assume a recumbent position on going on board, preferably lying on his right side with the knees well drawn up. A tight abdominal binder is found to be a useful adjuvant in many cases. As a preparation for a longer voyage, 20 gr. of bromide of ammonium should be administered three times a day for two days before the journey is begun, and similar, or larger, doses should be continued for a few days after sailing. As soon as any discomfort is experienced, the patient should seek his cabin and lie down as described above. He should abstain from all solid food, thirst being relieved by sucking fragments of ice, and if there be much depression, iced champagne may be given freely. If the sedative action of bromides is found insufficient, other narcotics may be tried, such as chloretone (5 gr. in capsule every three or four hours) or validol (10 to 15 drops on sugar, repeated as required). For the Channel passage, chloretone may be given in 5-gr. doses (in capsule) every three hours for three doses, the last being taken when going on board. Other useful sedatives are chlorobrom (which contains 30 gr. of chloral formamide and bromide of potassium in each oz.) in doses of from 2 to 4 dr., repeated if necessary; hydrobromide of hyosine ($\frac{1}{200}$ gr. by mouth or hypodermically); and cocaine, gr. $\frac{1}{4}$ in 1 oz. of chloroform water. The proprietary preparations "Zotos" and "Mothersill" contain chloretone; "Yanatas" chiefly depends for its activity upon bromide of potassium. In very severe cases, with prolonged vomiting, leading to exhaustion and collapse, it may be necessary to have recourse to the injection of morphia.

The hypodermic injection of strychnine sulphate ($\frac{1}{60}$ to $\frac{1}{30}$ gr.) along with atropine sulphate ($\frac{1}{30}$ gr.), or of atropine ($\frac{1}{60}$ gr.) alone, has also been recommended. The injection should be given at the very onset of nausea or discomfort, or as a prophylactic in sensitive persons, and may be repeated in a few hours if necessary.

Robert Hutchison.

SEBORRHŒA—The essential treatment of this condition is frequent washing of the scalp. This should be done with soap spirit, and it is important that the soap should be thoroughly washed out, not only with the water in which the washing has taken place, but with two or three fresh waters as well.

The most generally useful application is an ointment of sulphur and salicylic acid, and it must be borne in mind that the scalp will tolerate more concentrated remedies than most parts of the surface. The active ingredients should be in a strength of not less than 5 per cent, and may be used much stronger in suitable cases. Resorcin in the same strength is quite efficient, but it has the effect, not always appreciated by the patient, of giving the hair a distinctly auburn tinge.

On the body, the parts should be thoroughly washed, and one is guided with regard to the application by the degree of reaction in the skin. Thus, if the eruption is moist, a paste should be used, while if dry, an ointment is preferable. If the eruption is very extensive, mere economical considerations will suggest the use of a lotion.

The same drugs, sulphur and salicylic acid, are indicated, and although the application may be a little painful, the results are more rapid if they are used much stronger than usual. Much benefit, for instance, often results from a paste containing 15 or 20 per cent each of sulphur and salicylic acid, though obviously such cannot be applied to an extensive eruption. Indeed, one may say that the recognition of the seborrhœic element in a dermatitis is an indication to make the active ingredients in one's prescriptions sulphur and salicylic acid.

Norman Walker.

SEPTICÆMIA and PYÆMIA.—These two diseases are closely allied; indeed, the term pyosepticæmia has been coined to show the close relation between the two conditions. Strictly speaking, in *septicæmia* pathogenic micro-organisms are present in the blood-stream, producing severe constitutional effects by their toxic action on the tissues; in *pyæmia* a similar state of things is present, but there is a tendency to the development of multiple abscesses from localization of the process.

When once established, the treatment of *septicæmia* and *pyæmia* is almost entirely symptomatic. Wounds which have been responsible for the admission of the bacteria should certainly be treated by thorough evacuation and irrigation with antiseptics; but although this plan may prevent the further invasion of the tissues, it is clearly powerless to deal with those organisms which have already entered the circulation; besides, these diseases often arise from infections without any external wounds.

In cases of *pyæmia* where veins are full of infected clot, good results are said to follow the ligature of the main veins so as to prevent any further detachment of embolic particles into the circulation. Such treatment, eminently satisfactory in lateral sinus thrombosis, has been applied to the veins of the extremity in osteomyelitis, and to the pelvic veins in pyosepticæmia of uterine origin. It is too early yet to say whether this treatment should be recommended.

Apart from the details above mentioned, the treatment must be directed to maintaining the nutrition of the patient, so as to enable him to fight his invading enemy.

Diet must consist of foods rich in nourishment and easily assimilated—strong soups, beef extracts, eggs, plasmon, etc. Alcohol is of undoubted value, and may be used freely.

Drugs.—Iron, arsenic, quinine, opium, are found to be of service. Large doses of perchloride of iron have appeared very beneficial in septic states;

it is, however, not always tolerated by the stomach. Opium in one of its various forms may be given to relieve the restlessness, delirium, and pain.

Saline injections, either into the veins, the subcutaneous tissues, or the rectum, are very valuable. The saline solution dilutes the toxins and nourishes the tissues. Some authorities recommend that bleeding should be performed to remove some of the blood charged with poisonous substances. This treatment cannot be recommended, since the removal of a small quantity of blood, 8 to 10 oz., cannot really affect the amount of poison present in the body, while the abstraction of larger quantities will seriously weaken the patient. With regard to the injection of antiseptics into the blood-stream, we have little to say. *Credé* claims good results with collargol, injected into the veins of the arm. Various strengths have been used; *Wassermuth* has used it as strong as 2 per cent, of which 6 c.c. were injected into the median basilic vein with, it is stated, an excellent result. Experiments made in the laboratory do not give any proof of the efficacy of antiseptic injections in conditions of septicæmia and pyæmia, but the condition is so desperate, and this remedy apparently so harmless, that it may be tried.

Vaccine treatment has been used in some very severe cases of pyæmia and has been followed by success.

Any secondary abscesses which form in pyæmic states must be opened and drained.

W. H. Clayton-Greene.

SEPTUM NASI, ABNORMALITIES OF.

1. Thickenings, Deflections, and Dislocations.—Some irregularity of the nasal septum is extremely common; in fact, a perfectly symmetrical septum is hardly ever met with. It follows then that the great majority of deviations of the septum, and such irregularities as are generally termed ridges, spurs, or crests, produce no symptoms and require no treatment. It is only when the deformity of the septum is sufficient to produce nasal obstruction or other definite symptoms, that treatment becomes necessary. Even when obstruction is present, especially if not of long standing, it may be found to depend upon catarrhal swelling of the nasal mucous membrane, in which case the treatment for RHINITIS, CHRONIC (q.v.) should be adopted. Such treatment will often relieve the patient's symptoms, and no surgical interference may be required. When, on the other hand, there is marked deformity of the septum, causing complete unilateral or bilateral obstruction; when the patient suffers from repeated attacks of acute rhinitis, or from chronic rhinitis which does not yield to simple treatment, or from other symptoms which can be reasonably attributed to the nasal condition, surgical measures must be advised to restore a free air-way through the nose. The particular measure to be adopted depends upon the nature of the thickening or deviation of the septum, and upon the associated conditions. The important point to bear in mind is that a free air-way through the nose should be restored with as little damage to the nasal mucous membrane and as little general inconvenience and danger to the patient as possible. Also it is expedient to take special care in advising and in performing an operation on children, as apparently the natural growth of the parts has occasionally been arrested, and marked depression of the bridge of the nose has resulted.

The treatment of these conditions has been revolutionized by the introduction and perfecting of the operation of submucous resection.

The deformity of the septum may be a simple thickened ridge or spur, or a deflection of the cartilaginous or bony septum accompanied by more or less thickening of the deflected part. Sometimes only the anterior part of the cartilage is much affected, but this is usually associated with some deviation of the bony septum. Where there is a well-marked deflection of the cartilaginous

or bony septum, with or without thickening, it is best treated by a submucous resection. The chief points of the operation are as follows : Both sides of the septum should be packed with wool or gauze soaked in a solution of cocaine and suprarenal extract and lightly squeezed before being applied. This application should be made at least half an hour before commencing the operation. Many surgeons prefer to operate under local anæsthesia alone, but I think it is usually best to give also a general anæsthetic. The application of cocaine and suprarenal extract not only prevents hæmorrhage during the operation, but by producing local anæsthesia allows of very light general anæsthesia. Just sufficient chloroform should be given to abolish consciousness, but not enough to affect the pharyngeal and laryngeal reflexes.

The operation is carried out in a darkened room by the aid of strong reflected light ; and, whether a general anæsthetic is given or not, the patient should recline on a couch with the head slightly raised and turned to face the operator. The speculum is introduced into the narrowed nostril and an incision made on the convex side of the septum just in front of the deflected portion. This incision should be deepened carefully so as to divide the mucous membrane, perichondrium, and cartilage, but it must not penetrate the perichondrium and mucous membrane on the opposite side. It should be straight or slightly curved, and if there be a marked ridge on the floor of the nose, should be carried back for a slight distance under this ridge. With a small blunt dissector, the mucous membrane and the perichondrium are now separated backward from the incision on both sides of the septum. In separating them on the convexity, great care must be exercised to prevent tearing the mucous membrane. The cartilage, when it has been bared, is cut away with a Killian's or Ballenger's septum knife. Into the opening thus made nasal specula with long blades, such as Thomson's, are introduced, and the periosteum is separated from the septum on either side as far back as the deflection or thickening extends. The deflected or thickened bony portions are now broken away and removed by strong forceps, such as Luc's. There is often a particularly thick and hard ridge of bone near the floor of the nose, which is most easily removed with chisel and hammer. The operation must be continued until the whole of the affected part of the septum has been removed. The soft parts of the two sides of the septum are now allowed to fall in contact, and the edges of the incision are carefully adjusted. Next, both nostrils must be examined, and any hypertrophy of the inferior turbinates or other cause of nasal obstruction sought for and removed. The septum is retained in position by lightly packing both nostrils with strips of gauze. These strips should be enclosed in a broad strip of green protective, which greatly facilitates their removal. The packing not only serves to arrest hæmorrhage, which is apt to be profuse when the effect of the suprarenal extract has passed off, especially when the turbinates have been cut, but also prevents effusion between the two layers of the septum, which may cause bulging of the septum and maintain the nasal obstruction. The packing should be removed in twenty-four hours, and the nose irrigated with a simple antiseptic solution for a few days until healing has taken place and all secretion has ceased. The results of the operation are excellent. The incision heals in a few days, and a perfectly straight septum is left, without any perforation. There is no raw surface to heal over, and therefore no tendency to subsequent crusting.

When the deformity of the septum is limited to a bony ridge or spur far back in the nose, its removal where necessary is very simple. Some cocaine and suprarenal extract should be applied to allow of a good view of the affected part, then nitrous oxide may be administered. A good light being thrown into the nose, the blade of a spokeshave is passed over the posterior end of the ridge

and drawn sharply and strongly forward. In this way the ridge is generally brought cleanly away, and the removal of a small portion of the mucous membrane in the posterior part of the nose produces no ill-effect. After-treatment consists in gently irrigating the nose with boracic lotion for a few days; no packing is required.

In children, the operation of submucous resection is difficult owing to the small size of the parts. It is dangerous also to take away too much of the septum, as the operation may possibly interfere with its continued growth, and result subsequently in a falling-in of the bridge of the nose. This result has certainly followed the operation. When the amount of obstruction in children is such that it is necessary to do something, I think it is wiser to carry out a partial submucous resection. Cocaine and adrenalin should be applied in the usual way and a general anæsthetic (chloroform) should be given. The operation is then carried out as above described, but only the most deflected and thickened part of the septum is touched. The apex, as it were, of the deflected portion is removed, but care is taken to preserve a large piece of the septum above the deflection, so as not to approach too near the bridge of the nose. In this way sufficient can usually be removed to give a fair air-way through the nose without risk of deformity, and as the nose continues to grow larger, the septum will probably grow straighter. It must also be borne in mind that the removal of adenoids or portions of turbinates, especially of the inferior turbinates, either anteriorly or posteriorly, may give a sufficient air-way without touching the septum.

2. Adhesions between Septum and Turbinates.—Adhesions between the turbinates and the septum only require operation when they produce nasal obstruction, or prevent the removal of nasal secretion, or interfere with intra-nasal treatment. If they consist of slender bands they may be removed under local anæsthesia with punch forceps, or destroyed by the electric cautery. An extensive adhesion is usually the result of an imperfect operation upon a septal spur or upon a hypertrophied inferior turbinate in a narrow nose, when the opposing surfaces of mucous membrane have been simultaneously denuded of epithelium without the removal of a sufficiently large portion to keep the wounded surfaces apart. The best treatment is to cut through the attachment of the inferior turbinate with stout scissors, as in anterior turbinectomy, and then with the spokeshave to remove the adherent portion of the turbinate, together with the whole of the septal ridge. In this way the wounded surfaces are so far apart that there is no tendency for the adhesion to re-form. The nose should be watched until healing has taken place, so that if any exuberant granulations form they may be at once removed.

3. Abscess of Septum Nasi.—This usually results from trauma: it is a suppurating hæmatoma. When it is certain that pus is present, free incisions should be made into the most prominent part of the swelling on each side of the septum. A general anæsthetic is usually necessary, as cocaine has little effect. The incisions should be as large as possible, and they should be kept open by inserting a probe every day for the first few days after the operation. When all discharge has ceased, the incisions should be allowed to close. As a rule, this method is followed by a complete cure, but in a few cases the incisions show a great tendency to heal rapidly, and the pus re-accumulates. If this occur, it is best to snip out a portion of the abscess wall and thus secure effective drainage. Occasionally also, if operation has been too long delayed, necrosis of the cartilage may occur and delay the healing. When there has been delay in opening the abscess, or when the original injury was severe, considerable deformity (a sinking in of the bridge) of the nose may ultimately result.

H. Lambert Lack.

SETON, TREATMENT BY.—For many centuries the seton has been used for curing or alleviating diseases that tended to assume a chronic nature. In reviewing the literature on the subject it becomes evident that whenever there seemed a possibility of its falling into disuse it was at once revived and very highly extolled by members of the profession who had derived undeniable benefit from its employment. The diseases that were treated by it in the past were as varied in character as they were numerous, and among them may be briefly mentioned: tuberculous disease in all its aspects, diseases of the eyes, diseases of the nose—especially *ozæna*—chronic discharge of the ears, chronic laryngitis, tumours, sciatica, and affections of the brain with or without paralysis.

HOW THE SETON ACTS.—The chief actions of a seton may be regarded as: (1) Counter-irritating, and (2) Suggestive. In olden times the seton was regarded almost exclusively as an *eliminant* (or “evacuant” as it was then called), whereby certain noxious elements were got rid of from the body by means of the continued discharge it occasioned. Now, however, we do not feel justified in attributing to this action of the seton the importance conferred upon it by our medical forefathers. The discharge occasioned by a seton is, as a rule, not profuse; so that it is improbable that the small amount of discarded constituents of the blood, whether of a physiological or a chemical nature, could produce any signal effect. In the *counter-irritating* action of a seton undoubtedly lies its chief power. The full physiological action of a long-continued counter-irritation has yet to be explained, but the localized determination of blood, with its concurrent leucocytosis, at the seton-site is surely responsible for a lessened hyperæmia in a disordered part, if the seton be placed in its near proximity. This is probably brought about by the intervention of the vasomotor system. As an example it may be mentioned that distressing attacks of vertigo (with or without Ménière’s complex of symptoms), due to hyperæmia of the labyrinthine vessels, which have persistently resisted every other recognized form of treatment, have been either entirely cured or much alleviated by a seton placed at a spot midway between the nape of the neck and the mastoid process on the affected side. The *suggestive* or hypnotic action of a seton is also, in some cases, a strong remedial agent. Whether this be brought about by afferent impulses reaching the central nervous system from the seton site, and reflected down efferent channels to the seat of the disorder, inducing tonic vasomotor changes in this abnormal hyperæmic or anæmic area, or whether the result be effected by more obscure psychological causes, it would be unwise to dogmatize.

INDICATIONS FOR THE USE OF THE SETON.—Within the last few years the seton has been used with marked effect in certain distressing chronic affections which are characterized by acute paroxysmal outbursts. This class of case has at first usually received at the hands of competent men the best remedial treatment that can be adopted, but with little or no improvement. A seton has been tried as a *dernier ressort*, with a result that has oftentimes astonished the practitioner. Among those diseases likely to be benefited by seton treatment are migraine, chronic congestive headache or hemicrania, chronic neuralgia, Ménière’s symptoms, Ménière’s disease, symptoms of obscure cerebral or cerebellar disease, and epilepsy. It has also been used with success in rheumatoid arthritis.

HOW TO MAKE AND USE A SETON.—The simplest way to make a seton is to use a specially constructed knife. This instrument consists of a steel shaft with a sharp-pointed, gradually-thickening, harpoon-shaped blade at one end, and a broadened-out handle bearing an eye large enough to carry a half or three-quarter-inch tape at the other. All that is necessary to be done is to pinch up a fold of skin between the thumb and forefinger of the left hand, and with a stabbing-like thrust, pass, with the right, the seton knife-needle, loaded with its tape, through the base of the fold, piercing the double layer of skin, and draw the

instrument through. When the knife has been disengaged and the two ends of the tape have been secured, the seton is made.

Several points should be observed in carrying out this little operation :—

1. It is best to make the stab in a slanting direction, so that the discharge may gravitate to the lower opening.

2. The fold of skin should be held and the knife passed in such a manner that the entrance and exit incisions should lie at least from $1\frac{1}{2}$ to 2 inches apart. There is a strong tendency for a seton to heal, and it will be found that if a fair space be not left between the little wounds, the bridge of skin will quickly become thinned and gradually disappear, so that the making of a fresh seton becomes imperative.

3. For the latter reason also it is advisable to make the incisions a little larger than the breadth of the tape, in order that the wounds may not contract by healing too rapidly upon the tape. This can be done by a little sawing movement as the knife-needle is passing through the fold of skin.

It is best to do this little operation under nitrous oxide gas.

For the making of a seton various substances have been employed. Cords made of silk were common in past times, and were found of practical value. Specially prepared seton-tape, with a glossy surface to avoid contamination with the discharge, can be procured from any surgical instrument maker, and is highly recommended by those who employ the side-to-side method. The writer, however, recommends ordinary domestic tape as being as serviceable a material as any, and he would recommend its being used in the following manner : Take a piece of tape $\frac{1}{2}$ to $\frac{3}{4}$ in. wide and about 20 in. long. Thread the tape

Fig. 70.—Seton Knife-needle, three-fourths natural size.

into the eye of the knife-needle (Fig. 70), having previously sterilized tape and knife. It used to be considered rather a favourable circumstance for the wounds to become septic, as it was thought to intensify the action of the seton. This is not at all necessary, and in the writer's opinion it is dangerous. The reason for choosing so long a piece of tape is that the ancient method of pulling the same piece of material from side to side each day is unsurgical as well as extremely offensive to the patient. When, therefore, the tape has been passed, the short end should be secured by means of a safety pin to that portion of the "long end" that lies immediately outside the upper wound. The rest of the "long end" is folded and placed in a borie-lint or oiled-silk pocket to ensure its being kept aseptic. Each day the "short end" is pulled so that that portion of the tape that has rested in the wound during the previous twenty-four hours is drawn out and cut off, and a fresh portion of the "long end" takes its place. When the 20 inches of tape is almost expended, a second length of sterilized tape is sewn on to the upper end of the old piece and the story continued as before.

When no special instrument is at hand for the making of a seton, it can be managed, though not so comfortably, by means of an ordinary long-bladed scalpel and a sterilized bodkin. Under nitrous oxide gas a fold of skin is pinched up as before, and the scalpel inserted and held in position till the bodkin bearing the sterilized tape has been introduced. As this is being passed, the blade of the knife is withdrawn and the tape pulled through.

Each day the wound should receive an antiseptic wipe with a piece of lint moistened in some antiseptic lotion, after which it should be well dried and covered with a pad of boric lint. There is little pain or discomfort in the wearing of a seton, and the relief it affords for severe paroxysms of pain or vertigo will more than compensate for any slight inconvenience it may cause. For any severe chronic condition it should be kept *in situ* for from three to six months.

T. Wilson Parry.

SHOCK, SURGICAL.—As in the case of sepsis, it is easier to prevent shock than to treat it when once it has developed, and the greatest attention must be paid to preventing its occurrence during surgical procedures.

PREVENTION.—As a general rule, it may be stated that the degree of shock produced by an operation is dependent upon the amount of traumatism to the nerve elements of the parts operated upon. The degree of shock is in direct proportion to the area of skin and muscle injured, and the relative number of nerve-endings in them. In operations upon the abdomen, the extent of the shock produced depends very much upon the area of peritoneum exposed and the duration of the exposure. Any form of manipulation of the peritoneum, such as traction upon it, sponging, flushing with hot water, and even simple exposure, causes a fall in blood-pressure. Evisceration and extensive intra-abdominal manipulation, especially in the upper regions of the abdomen, very soon produce shock. For these reasons it is advisable to avoid lengthy operations and to reduce the handling of the tissues to the irreducible minimum. Much can also be done to prevent shock by keeping the patient warm and covered up as much as possible during operations. In cases where shock is likely to be a serious danger, it is important to avoid free purging just before operation, and the bowels should be emptied some two days previously; also such patients must not be starved previous to operation, except for a few hours. Small doses of strychnine administered every day for a week prior to operation are useful, and a morphia injection of $\frac{1}{4}$ gr. hypodermically just before commencing the anæsthetic is a most valuable means of combating shock.

TREATMENT.—*Strychnine and other stimulants must not be given, as they tend to increase the shock*, and not, as was previously supposed, to get rid of it. The foot of the patient's bed should be raised on blocks sufficiently to make the head the lowest part of the body. Bandaging the limbs is also useful in bad cases.

Large rectal injections of warm saline solution should be given. The fluid should be run in slowly with the buttocks well raised; two or three pints should be injected in this way with a douche syringe, and repeated if benefit results. This is not of much use in severe cases, however, as the fluid is not absorbed. In such cases intravenous infusion with physiological saline solution should be performed at once, and kept up, or repeated at frequent intervals. To be successful, saline intravenous infusion must be done early, and several pints of solution allowed to flow into the veins. It does the greatest amount of good in collapse due to hæmorrhage, because in such cases the nerve centres are not exhausted.

There are two drugs which are of great value in the treatment of shock, if properly used: epinephrin and the extract of the infundibular portion of the pituitary gland. (This drug is now obtainable in sealed capsules from the leading pharmaceutical chemists.) Epinephrin is of the greatest value, and will raise the patient's blood-pressure to a safe level even in the most extreme degrees of shock. It *must* be administered intravenously, and the best way is to add some epinephrin to the physiological saline solution used for intravenous infusion. The strength of the epinephrin solution should be from 1-30,000 to 1-50,000 of

the saline solution. This fluid should be allowed to run into the veins rapidly until the pulse recovers, and then very slowly, just sufficiently fast to maintain the blood-pressure at a safe level. The injection of epinephrin subcutaneously is useless. The pituitary extract is not quite so powerful as epinephrin, but its effects are more lasting; it can also be used as a subcutaneous injection. No drug, however, is of any use administered subcutaneously in severe cases of shock, as there is not sufficient capillary circulation to get it into the main blood-stream.

The treatment may be summarized as follows: (1) Do not give stimulants; (2) Raise the blood-pressure in the vital parts of the circulation by raising the foot of the bed and by bandaging the abdomen and limbs; (3) Give hypodermic injections of morphia to cut off inflowing sensory stimuli; (4) Perform intravenous saline infusion as early as possible; (5) If the shock continues for some time, give nourishment either by mouth or rectum; (6) Infuse with epinephrin, 1-50,000, or give an injection of pituitary extract.

Deferred Shock.—This is frequently seen in children and in old people. The shock comes on some four or five hours after operation. It is best treated by small injections of morphia, and may often be prevented by treating all such patients after operation as if shock had already developed.

J. P. Lockhart Mummery.

SINUSITIS, ACCESSORY.—(See NOSE, ACCESSORY SINUSES OF.)

SKULL, FRACTURES OF.—From the point of view of treatment, fractures of the skull may be classified as follows: (1) *Fractures of the vault without depression*; (2) *Fractures of the vault with depression*; (3) *Fractures of the base*. Any one of these may be simple or compound.

1. Fractures of the Vault without Depression.—It is unlikely that this lesion will be diagnosed with certainty unless it be compound, in which case a fine red line of fracture will be seen crossing the exposed bone at the bottom of the scalp wound. The occurrence of a linear hæmatoma should, however, cause the existence of a fracture to be suspected. In all cases of fracture or suspected fracture, whether of vault or base, the importance of complete and sufficiently prolonged rest cannot be over-estimated. The patient should be put to bed in a darkened room, he should be kept free from worry, and the visits of friends and relations as far as possible controlled. A purge should be administered at the outset, and attention should subsequently be paid to the regular evacuation of the bowels. The diet should consist of "slops," and stimulants be altogether withheld. The appropriate treatment for scalp wound or hæmatoma, should such exist, is carried out, and a careful watch is kept for signs of compression or indications of intracranial hæmorrhage or suppuration. When a fracture has taken place, it is necessary that the patient should not return to work for at least six weeks. (See also BRAIN, CONCUSSION OF.)

2. Fractures of the Vault with Depression.—The general treatment is the same as for fractures without depression, but it is necessary in dealing with injuries of this class to realize clearly certain well-substantiated facts. In the first place, the amount of depression which is apparent to the observer by external examination is no safe index to the amount of pressure on the brain beneath; a slight depression of the outer table may be, and often is, associated with extensive splintering and depression of the inner table, the fragments of which may be pressing upon and lacerating the underlying brain. Again, the absence of immediate signs of compression does not in the least indicate that no ultimate trouble is to be apprehended; fragments may be pressing upon or even lacerating the cerebral tissue, and only give note of their existence by the subsequent development of persistent headache or Jacksonian epilepsy. Further, the

operation for the removal of depressed bone is, in present circumstances, devoid of risk. For these reasons it is advised that all cases of depressed fracture, whether simple or compound, whether accompanied or not by signs of compression, should be submitted to immediate operation. (A single exception may be made to this rule: in the case of extensive shallow depressions in infants and young children operation is not called for in the absence of signs of compression of the brain.) A flap of sufficient size is turned down, or the wound, if such exist, is enlarged, and the depressed area is thus freely exposed. If there be a small depressed area, a disc of bone may be removed with a trephine so as to include it. If more extensive depression exist, a trephine hole should be made at the edge of the depression and the fragments removed by means of elevator and sequester forceps. Often, when there is extensive comminution of the bone, the fragments may be removed readily without the use of a trephine. In simple fractures where there are large pieces of bone depressed, it may be advisable to raise them to their normal level by means of an elevator, and leave them. In compound fractures the danger of necrosis of loose fragments is too great to warrant the attempt to save them. The gap left becomes filled in by a dense and tough fibrous membrane which, unless the deficiency be very wide, affords good protection. Any lacerations of the dura must be closed carefully with fine sutures. The operation being completed, the flap is stitched into position, a drainage tube being left in for forty-eight hours.

3. Fractures of the Base.—The general treatment called for is that given under the heading of *Fractures of the Vault without Depression*. It must be remembered, however, that fractures of the base are, more often than not, compound. When the anterior fossa is affected, the cavity of the nose is opened; when it is the middle fossa which is fractured, the ear or the roof of the nasopharynx may be involved; whilst in the case of the posterior fossa, the latter cavity is again likely to suffer. It follows, therefore, that the chief object towards which treatment must be directed is the prevention or the minimization of the risk of the involvement of the brain and its meninges in septic processes originating in and spreading from the cavities above-mentioned. If the fracture involve the nasal cavity, that cavity is sprayed frequently with a lotion containing 10 gr. each of sodium bicarbonate and borax and 1 gr. of carbolic acid to each ounce, after which iodoform powder may be insufflated. When the ear is involved, it should be swabbed out gently with carbolic lotion (1-60), and protected by a dressing. When the cavity of the mouth is opened, the nasopharynx is to be kept as clean as possible by the use of the nasal spray and antiseptic mouth-washes. Basal fractures are often accompanied by intradural hæmorrhage, giving rise to symptoms of generalized compression. Should definite symptoms of this nature be present, a decompressive operation (see p. 469) should be performed. Some surgeons claim to have improved their results in treating basal fractures by the routine performance of a subtemporal decompression on one or both sides.

SKULL, GUNSHOT WOUNDS OF.—(See GUNSHOT WOUNDS.)

SLEEPING SICKNESS.—(See TRYPANOSOMIASIS.)

SLEEPLESSNESS.—(See INSOMNIA.)

SMALL-POX.—(See also FEVERS, ACUTE INFECTIOUS.) Mild, discrete, and modified cases require little special treatment; but in the severer forms, both general treatment of the febrile symptoms, and local treatment of the eruption, require attention.

The lumbar pain so frequently occurring during the *prodromal period* may be relieved by the application of linseed-meal poultices, or belladonna and glycerin, to the loins; for vomiting, morphia is the best remedy; for sleeplessness and delirium, opium.

When the *eruption* is at all copious, the hair and beard should be cut short. In the early stages of the eruption, the cutaneous swelling and irritation call for relief; this is best afforded by the application of cold—even iced—water compresses, frequently renewed; or of lint soaked in glycerin (1 dr.) and iced water (1 oz.), covered with oiled silk. If these applications are not agreeable to the patient, an astringent powder should be dusted over the skin, such as starch and oxide of zinc, boric acid, or fullers' earth.

Another useful method of treatment is to paint the skin with undiluted weak tincture of iodine (B.P.); this should be commenced as early as possible in the eruptive stage, and continued once or twice a day. After eight or nine days the skin begins to peel; the iodine should then be discontinued, and some antiseptic ointment be applied. In patients whose skin is very sensitive, the undiluted weak tincture of iodine (B.P.) is too strong, and a weaker solution must be used. Some patients cannot bear the iodine at all, and recourse must be had to some other method (Welch and Schamberg).

When *scabs and crusts* have formed, the object should be to hasten their separation; and this is best accomplished by the use of moist applications; dry applications must on no account be used. The best treatment is that employed by Dr. J. MacCombie: A mask is made of a single thickness of lint, holes being cut for the eyes, nostrils, and mouth; on the mask a thin layer of linseed-meal poultice is spread, and on this layer some vaseline and iodoform; the mask is applied to the face, being renewed at least every two hours. In very severe cases the same application may be used for the eruption on other parts, but usually wet boracic-acid dressings will suffice.

When the crusts have separated, the ulcerated surface that is left should be treated by antiseptic dressings—boracic acid, iodoform and vaseline, or carbolic oil (1–20). Tense and deeply-seated pustules, such as are found where the skin is thick, should be opened with a lancet or stout needle, and treated aseptically.

Baths may be given at any stage of the disease, but are particularly useful during the eruptive period, especially when pustulation is taking place. The temperature of the bath will depend upon the object for which it is given. In severe, confluent cases, the continuous warm bath is of great value.

R. Denman has found, in a recent epidemic in Mauritius, that intravenous injections of electrargol were apparently of great value in severe cases. The dose is 10 c.c., increased later to 30 c.c., every twenty-four hours.

During the eruptive stage the nurse should be very careful not to give the patient any pain or discomfort when she is moving him. For instance, when raising the head and shoulders, her arm should be placed under the pillow. The bed should be soft, and the linen fine and light. A water bed should be used when the eruption is profuse.

In the nursing of delirious patients incessant watchfulness is essential. They will endeavour to escape from door or window if the slightest opportunity is afforded, and if actively restrained will become angry and violent, and attack the nurse or attendant in order to free themselves. Opium is the best drug for this condition; but in some cases other hypnotics or sedatives are more suitable. At times, however, even large doses of these drugs fail, and then the nurse must exercise all her tact in humouring the patient as much as possible: for instance, if he insists on getting up, she may allow him to walk about the room in dressing-gown and slippers; he will, in most instances, quickly become fatigued and be glad to return to bed.

Complications must be treated as they arise. For laryngitis the patient should be placed in a steam tent. If there is serious laryngeal obstruction, tracheotomy will be necessary. The swelling of the tongue usually yields to ice; but if it be extreme, an incision should be made in each half of the organ. When there is much eruption on the mucosa and the palate, pharynx, mouth, and nose, these passages must be frequently washed out with one of the solutions mentioned in the articles DIPHTHERIA and SCARLET FEVER.

It is most important to pay attention to the eyes, which should be examined daily. They should be frequently bathed with boracic lotion to prevent the lids from sticking together with dried secretion. Vaseline should be smeared on the edges of the lids. Should ocular complications, such as severe conjunctivitis, keratitis, corneal ulcer, and the like, arise, they must be treated in the usual way.

Abscesses must be freely opened and drained.

In hæmorrhagic small-pox nothing can be done except to relieve symptoms and administer stimulants; but full doses of turpentine and ergot may be tried.

In discrete and confluent small-pox the patient may be allowed to get up daily as soon as his strength permits; but in very mild cases he needs to remain in bed only for a day or two.

No patient should be considered free from infection until all scabs have separated and ulcers have healed.

Quarantine period: fifteen days.

SPECIFIC THERAPY (Bacteriotherapeutics).

A.—GENERAL.

1. Non-specific and Specific Treatment of Infective Disease.—The treatment of patients suffering from diseases due to infection by micro-organisms may be considered under two heads: (1) *Non-specific treatment*; and (2) *Specific treatment*. Non-specific treatment includes all those measures which are not directly concerned with the causal microbe, but which tend to increase the general well-being of the patient, such as fresh air, rest, food, hydrotherapy, eliminative drugs, etc. Specific treatment includes all measures directly concerned with the destruction of the causal microbe, the inhibition of its growth, and the neutralization of its poisons, such as the use of immune sera, vaccines, etc. The distinction as thus drawn is not, of course, an absolute one. Certain drugs have a specific effect upon the causal microbes of disease (quinine in malaria, mercury and arsenic in syphilis), so that it is necessary to further limit the definition of specific therapy by stating that the measures spoken of act by assisting the natural mechanism of immunity. Or, seeing that no drugs are as yet known which directly influence the growth of bacteria, as opposed to more highly organized microbes such as the hæmatozoön of malaria and the spirochæte of syphilis, the definition may be taken to refer to bacteria proper.

Until recently, the treatment of infective diseases was almost wholly non-specific. With the discovery of pathogenic microbes, and with the rapid growth of bacteriology, there has sprung up a system of specific therapy which has already proved of great value in certain diseases, and which promises to be equally so in many others. The link between the study of bacteria as the causal agents of infective diseases, and specific therapy, is the science of immunity, or the study of the mechanism of resistance by the body to microbic infection.

In this science of immunity a large number of workers are constantly engaged correlating the results of laboratory experiments with clinical observations. Although many important gaps in this science remain to be filled, a great mass of facts has been collected whereby a rational attempt can be made to combat disease due to bacterial infection.

2. The Scope of Specific Therapy.—Strictly speaking, accurate knowledge both of the bacteriology and the immunity of each particular infective disease is necessary before its specific therapy can be completely successful. But in this respect there is a fundamental difference between the two necessities. The bacteriology of the disease is an absolute necessity, the exact knowledge of the mechanism of its immunity is only a relative necessity. The pathologist is absolutely dependent upon the isolation of the causal microbe to produce whatever therapeutic agent he wishes to employ. He is not absolutely dependent upon knowing the steps in the immune process; the very trial of the remedy may further his knowledge of the mechanism of immunity as operating in the particular disease he is studying. In relation to specific therapy, therefore, microbial diseases fall into three groups. In the first group no specific treatment can be adopted, because the causal agent is unknown: such diseases are measles, mumps, varicella. In the second group of diseases the causal agent is known, and this knowledge admits of the preparation of specific remedies and of their use: such diseases are diphtheria, tetanus, anthrax, plague, cholera, typhoid fever, Malta fever, pneumonia, streptococcus, staphylococcus, and gonococcus infections, etc. In the third group of diseases, although the causal agent is not known with certainty, specific therapy, though highly experimental, is at times undertaken because these diseases have affinities with others of which the causal agents are known. These affinities are perhaps concerned with certain common complications of the diseases proper: such diseases are scarlet fever, rheumatic fever, influenza, and pertussis.

3. Toxins and Antibodies.—In all diseases of bacterial origin, the disease-process is due to the operation of the specific poisons incidental to the life of the bacteria (*toxins*). Toxins are of two kinds: those produced in the medium in which the bacteria thrive (*exotoxins*), and those existing in the bodies of the bacteria and set free by their disintegration or solution (*endotoxins*). Microbic diseases may therefore be considered to be of two kinds, according as the poisons leading to the symptoms of the disease are chiefly exotoxins or endotoxins. Diseases of the first kind are tetanus and diphtheria; of the second, cholera, typhoid fever, and affections due to the pyogenic micro-organisms (streptococcus, pneumococcus, etc.).

It will not be necessary in this article to go even superficially into the theories as to how immunity to bacterial diseases is acquired naturally. It seems certain that the invasion of the body by living bacteria leads to the production of a series of protective substances (*antibodies*) of highly complex nature, which act beneficially as regards the tissues. This beneficial action is either exerted by neutralization of the exotoxins (*antitoxins*), by direct destruction of the bacteria (*bacteriolysins*), or by stimulation of the leucocytes to phagocytosis (*opsonins*). Specific therapy has as its object the artificial increase of these antibodies.

4. Passive and Active Immunity: Sera and Vaccines.—The above object may be attained in two very different ways: the patient may be supplied with ready-made antibodies, or he may be induced to manufacture his own antibodies on a larger and more efficient scale than he is already doing. To supply ready-made antibodies is to confer *passive immunity*; to stimulate the manufacture of antibodies is to confer *active immunity*. The method of conferring passive immunity most commonly in use is the employment of *immunized serum*

derived from other animals (e.g., the horse). The method of conferring active immunity most commonly in use is the employment of *bacterial vaccines*. These two methods may be combined in the treatment of certain diseases. Together, they almost cover the present range of practical specific therapy; they are therefore the two methods with which this article chiefly deals.

Immunization by the use of specially prepared sera is of two kinds—immunization against bacterial exotoxins and immunization against the bacteria themselves. It follows from what has already been said about exo- and endotoxins that in those diseases in which the symptoms are chiefly due to exotoxins (e.g., diphtheria), the desideratum is a serum rich in antitoxin; such a serum is termed an *antitoxin serum*. Again, in those diseases in which the symptoms are chiefly due to endotoxins (e.g., streptococcal infections), the desideratum is a serum rich in bactericidal substances; such a serum is spoken of as *bactericidal serum*. Antitoxin sera are produced by the injection into suitable animals of exotoxins in increasing quantities until the blood-serum possesses a high antitoxin content. Bactericidal sera are produced by the inoculation of suitable animals with killed or with living bacteria in increasing numbers, or with bacteria of increasing virulence, until the blood-serum possesses a high bactericidal content.

In some infective processes it may be advisable to employ both immune serum and vaccine. This conjoint use of both remedies may be undertaken in two ways: (a) Serum and vaccine may be injected independently into the patient; or (b) The vaccine may be submitted to the action of the immune serum before its introduction into the body; the result of this action is that the vaccine abstracts the specific antibody from the immune serum, with the production of what is termed *sensitized vaccine*. The use of sensitized vaccines is of recent introduction, but their employment has already led to some very promising results.

To sum up, the available means of employing specific therapy to-day are:—

a. The use of *immune sera*: (i) *Antitoxin sera*, which chiefly act by neutralization of exotoxins formed by bacteria in the body; (ii) *Bactericidal sera*, which chiefly act by destruction of the bacteria, and thereby preventing the increase of endotoxins.

b. The use of *bacterial vaccines*, which serve to stimulate the natural mechanism of immunity.

c. The use of immune sera and vaccines conjointly, either as separate remedies or in the form of *sensitized vaccine*.

5. **The Choice of Specific Remedies in different Cases.**—The choice of the particular remedy to be employed in any case of infective disease depends upon (a) The nature of the infection; (b) Whether it is local or general; (c) Its acuteness or chronicity, and (d) The stage at which the infection has arrived. These considerations will be discussed briefly as the various infective diseases are dealt with. Whilst still dealing with general points, however, let it be noted that there are two very important differences to be observed between sera and vaccines, fundamental differences arising out of their mode of action as already outlined: (i) Immune sera act rapidly, but their action is transient; vaccines act slowly, but their action is more prolonged; (ii) Immune sera supply important substances that are lacking in the body, and they probably do not require much active response on the part of the tissues in order to produce their effects; vaccines depend for their action upon a latent power in the tissues of producing antibodies when specifically stimulated to do so. There follow from these generalizations certain rough indications for the choice of specific remedies in any case in which a choice is possible. It may be said that *the more acute and generalized the condition, and the more ill the patient, the more likely is immune*

serum to prove efficacious; the more chronic and localized the condition, and the better the patient, the more likely is a suitable vaccine to do good. It is often advisable to begin the treatment of a severe case of infection by the immediate and liberal use of an appropriate serum, and to follow up any advantage thus gained by inoculation with a vaccine which has been prepared in the meantime.

Before proceeding to deal with the various infective diseases in which specific therapy has proved of service, there remain to be discussed certain general points, such as the preparation of sera and vaccines, their standardization, the methods of their administration, and the local and general effects of their use other than effects directly connected with the disease-process. Only those points which bear directly upon treatment will be dealt with.

6. The Preparation and Standardization of Immune Sera.

a. Antitoxin Sera.—These are prepared by injecting the exotoxins of bacteria into healthy horses in gradually increasing amounts. The horses are carefully chosen and are proved by the mallein test to be free from glanders. In the case of diphtheria the strength of the exotoxin used for the inoculation is ascertained by estimating its lethal effect upon guinea-pigs of standard weight. The progress of the horse's immunization to the exotoxin is tested from time to time, and when this has reached a satisfactory point, the horse is bled to the extent of several litres. The blood, collected with sterile precautions, is allowed to clot, and the serum which separates out constitutes the "antitoxin" required. This antitoxin serum is tested for sterility and for absence of exotoxin, and is then standardized. The present methods of standardization of diphtheria antitoxin are the outcome of an original method which turned upon the choice of an arbitrary "unit" of antitoxin introduced by Behring. This unit was the amount of antitoxin necessary to neutralize 100 times the minimal lethal dose of exotoxin for a guinea-pig weighing 250 grams. In the case of tetanus antitoxin, standardization is achieved on somewhat similar lines, the "unit" having reference to an amount of exotoxin lethal to a given weight of mice. The strength of the antitoxin sera being ascertained, they are put up in hermetically sealed phials, usually protected from bacterial contamination by the addition of a minute amount of some antiseptic, such as tricresol.

b. Bactericidal Sera.—These are prepared in a very similar manner, but the horses are inoculated with the bacteria themselves (endotoxin) instead of with their chemical products. In the case of the bactericidal serum most often used—antistreptococcus serum—various methods have been employed from time to time to secure a potent remedy. One is to inject cocci whose virulence has been raised by passage through susceptible animals. Another is to use cocci derived directly from the human host, without loss of virulence by sub-culture. The matter is complicated by the fact that the genus streptococcus has various types, just as the genus *B. coli* has, and a serum immunized against one type is not necessarily immunized against another. This difficulty was thought at one time to be solved by inoculating the same horse with a large number of different strains of streptococci. The resulting "polyvalent" serum has become very popular, but more so perhaps on account of the notion underlying its preparation than on account of practical results. This question will be considered more fully in dealing with streptococcus infections. No efficient means of standardization of bactericidal sera has yet been evolved, because as yet there is no definite knowledge of the nature of the active principles present in the serum. Even the idea that the essential ingredient is a bactericidal substance is based upon slight evidence; certainly no such substance can be estimated with any degree of accuracy. Of late years, with the growing popularity of vaccines, it has been suggested that when a serum does good it does so by virtue of opsonins present in it; but of this there is as little evidence as that its

efficacy is due to bacteriolysins or antitoxins. Bactericidal sera are usually put up in phials containing 10 and 25 c.c., the same precautions being used as in the case of antitoxin sera.

7. The Preparation and Standardization of Bacterial Vaccines.—By the term bacterial vaccine is meant a suspension of killed micro-organisms in some neutral liquid medium such as normal salt solution. In preparing such a vaccine the object aimed at is so to treat the micro-organism that it may be obtained free from exotoxins, killed, and suspended in the salt solution for the purpose of subcutaneous injection. This suspension, or emulsion as it is generally called, is, to all intents and purposes, a preparation of the endotoxins of the micro-organism. The first step is to isolate in pure culture the causal micro-organism of the disease to be treated. The method of doing this will depend upon whether the infection is local or general. (a) If a local lesion is to be dealt with, a portion of the exudate, secretion, or tissue concerned is obtained, as free as possible from contaminations, and is forwarded promptly in a sealed sterile vessel to the pathologist. If the practitioner has culture tubes by him he may make his own cultivations and forward the inoculated tubes to the pathologist. In some instances this is almost imperative; thus, in a case of pyorrhœa alveolaris it is necessary to clean the surface of the gum thoroughly, and to inoculate an agar slope with a little of the pus which is squeezed out from the pocket lying between the gum and the tooth. (b) In the case of a patient suffering from a general blood infection without a local lesion, a blood-culture must first be made, care being taken that a sufficient quantity of blood is removed with the proper technique.

In most cases the infection is by a single micro-organism; sometimes, however, the infection is mixed, in which case a vaccine may be prepared from the various micro-organisms separately. The bacteriologist will only prepare his vaccines from pure cultures. The colonies of growth are collected together, scraped off the surface of the medium, and transferred to a measured bulk of salt solution so as to form a uniform emulsion, which is then sterilized by being heated to 65° C. for an hour. Standardization is effected by actually counting the micro-organisms by the aid of a Thoma-Zeiss pipette, as used for blood-counts. The vaccine is then so diluted as to yield appropriate doses per c.c. (e.g., 5, 10, 100, 1000 million per c.c.), and is transferred to small glass ampoules, which are sealed in the blowpipe flame. The greatest care is exercised, in preparing the vaccine, to observe the principles of strict asepsis combined with accuracy.

8. The Preparation and Standardization of Sensitized Vaccine.—Sensitized vaccines are made in the following manner. An emulsion of the micro-organism is prepared as in the case of an ordinary vaccine, by obtaining a uniform suspension of the elements in saline solution. The strength of the emulsion is determined by the method of counting already described. This emulsion is now brought in contact with the appropriate immune serum, and the mixture is allowed to stand at the room temperature for twelve hours. At the end of this time the micro-organisms will be found to be deposited as a sediment at the bottom of the tube. The serum is now pipetted off and more saline is added. The tube is then centrifuged until the micro-organisms have again sedimented. The process of pipetting and adding saline is repeated, so that all traces of the serum are removed. The result is an emulsion of the bodies of the micro-organism in saline, with the specific antibody of the immune serum attached to them (Besredka).

The process of manufacture of sensitized sera is not difficult; but certain practical points are important. (a) The serum must contain a definite antibody to the micro-organism used. (b) As little antibody should be used as is

compatible with sensitization. (c) The whole process should be completed in one day (M. H. Gordon).

The micro-organisms may be killed after this process of sensitization, or the emulsion may be used without this safeguard.

9. The Mode of Administration of Immune Sera.

a. *By Subcutaneous Injection.*—This is the method most often chosen. The procedure is extremely simple. The skin of the flank is prepared by being well washed with soap and water and subsequently rubbed with cotton-wool soaked in acetone or absolute alcohol. An all-glass serum syringe, which has meanwhile been boiling in water, is fitted with a clean and sharp needle, also boiled, and the serum is taken up into the syringe directly from the phial. Air is expelled from the syringe, and the contents are injected into the subcutaneous tissues. It is important to make certain that the point of the needle is quite free in the loose cellular tissues, and that it has not re-entered the deep layers of the skin at a point remote from the puncture. This fallacy is not at all uncommon, and is due to the pinching up of too narrow a fold of skin. As a matter of fact it is scarcely necessary to pinch up a fold of skin at all; the injection is less painful if the needle is inserted into almost flat skin, kept slightly stretched by the finger and thumb held about two inches apart. The serum is injected *slowly*: the injection of 10 c.c. should occupy quite a minute. If this direction is followed, and if the needle is clean and sharp, the discomfort to the patient is quite trivial. It is sometimes advisable to give a large quantity of serum—as much as 50 c.c.; it is then a good plan to put half the quantity into each flank.

b. *By Intravenous Injection.*—This method is indicated in cases of very severe infection, or when for any reason the application of the remedy has been delayed. It is perhaps adopted less often than it should be. It requires care and strict cleanliness, but with these precautions it is quite free from risk to the patient. It is advisable to dilute the serum by at least four times its bulk of normal saline. The skin over the veins at the bend of the elbow is well washed and treated as above mentioned. The piston of the syringe must not be quite at the top of the barrel, because it is necessary to allow a little blood to run into the neck of the syringe to prove that the needle is in the vein. When the syringe is ready, the arm is bandaged well above the elbow, and is allowed to hang out of the bed fully extended. The most prominent vein is chosen and is punctured. If blood oozes into the syringe when the piston is gently withdrawn, the serum is slowly injected. If no blood oozes into the syringe, the needle is withdrawn a very short distance to ensure its point not being in the wall of the vein on the side opposite the puncture. On no account must the serum be injected until proof is forthcoming that the vein has actually been entered. When the serum has been injected, the needle is withdrawn and the operator's finger is placed against the puncture whilst the arm is raised and the bandage removed.

c. *Per Rectum.*—Sera are often given per rectum, but this route is usually chosen because it is assumed that the subcutaneous route entails pain and distress. Immune sera are often prescribed for non-specific purposes (e.g., anti-streptococcus serum in gonorrhœal rheumatism, etc.), and it may be that their administration per rectum is in these circumstances fraught with some virtue not as yet understood. But if the indication for the use of an immune specific serum is definite, it should be given in one of the two ways already described.

10. *The Mode of Administration of Vaccines.*—The common mode of administering vaccines is *by subcutaneous injection*. For patients in bed the region of the flank is most convenient; for those who are not in bed the lateral aspect of the upper arm is best. There is some reason for thinking that the introduction of the vaccine near the seat of a local lesion is of advantage. As to the exact depth to which the needle should be inserted to get a better result,

whether into the subcutaneous tissues merely, or into the muscle, there is no knowledge to serve as a guide. Less discomfort appears to follow subcutaneous than intramuscular inoculation, and this fact may well determine the matter for the present. The skin is prepared as in the case of serum injections, and the same precautions are observed in regard to the syringe and needle. The ampoule is well rolled between the hands to ensure uniform suspension of the bacteria, which may have formed a sediment on standing. If the ampoule has a wide neck it is necessary to tap the shoulder of the ampoule sharply several times in order to get the fluid in the neck well below the file mark or the constriction. The neck is then broken off, and the contents are taken up into the syringe. The mode of injection is the same as in the use of sera. No dressing of any kind is necessary to cover the puncture.

Some authorities administer tuberculin vaccine *by mouth*, and recommend this route. It is perhaps of service in little children. If given in this way, the vaccine is mixed with a convenient bulk of normal saline solution, and is swallowed at a time when the stomach is thought to be empty. Considering the small bulk of the vaccines as usually prepared (1 c.c.), and the fact that their subcutaneous injection is free from more than trivial discomfort, it seems desirable at present to continue this method of administration, as tending more easily to accuracy of observations in regard to results. Moreover, there is experimental evidence that the specific activity of some vaccines at least (e.g., tuberculin) is destroyed by pepsin and trypsin.

11. Non-specific Effects of Serum Injections: "Serum Sickness."—The introduction of a foreign serum into the tissues leads at times to a local and general disturbance which is a matter quite apart from the neutralization of toxins or the destruction of infecting bacteria. These effects are certainly not due to the presence of small amounts of antiseptics in the serum. The symptoms of "serum sickness" usually appear about the period of the eighth to tenth day after the first dose. The commonest symptom is an urticarial rash, often most troublesome near the situation of the puncture, and sometimes confined to this situation. It may be accompanied by slight general œdema. Joint-pains are fairly common, often with slight swelling of the synovial membranes and stiffness of the joints. Albuminuria and adenitis are less common. A certain degree of fever is usually present if the other symptoms are at all marked. The treatment of this condition is entirely palliative. It is rarely serious. But if the joint affections precede the rash, some difficulty in diagnosis may arise.

12. The Immediate Effects of Vaccine Inoculation.

a. Local effects.—There is no uniformity of opinion as to how little or how much local "reaction" should be aimed at when a vaccine is used therapeutically. When given for prophylaxis (e.g., *B. typhosus* vaccine against typhoid fever), a local reaction is anticipated. In treatment, however, it is not certain that any definite reaction at the site of inoculation is necessary in order to get good effects. The degree of this reaction is probably directly proportional to the amount of the dose, and also to the virulence of the bacterial endotoxin. Unfortunately there is at present no standard of virulence of bacterial endotoxins. Different strains of the same micro-organism differ much in virulence, and a virulent strain is apt to lose its potency, it may be very quickly, on sub-culture. For these reasons it is a matter of great difficulty to anticipate the degree of reaction which a vaccine of known strength as regards the number of bacteria it contains will produce. The principle of practice with most workers appears to be that in cases of chronic and of local infection a mild but definite reaction is aimed at, but in cases of acute and of general infection no reaction is sought. By a "mild but definite" reaction is meant as follows: From four to eight hours after the introduction of the vaccine a tender spot appears, surrounded by a

small area over which the skin presents a faint blush. Slight swelling is also present, and this extends somewhat beyond the redness. The affected area is tender, and there is slight stiffness of the limb on movement. After eighteen to twenty-four hours, the inflammation begins to subside, leaving only a tender spot, with slight thickening of the subcutaneous tissues. After forty-eight hours all these effects pass away. A dose which is unnecessarily large for its purpose, or which is very highly toxic, produces a more marked reaction, and may lead to redness and swelling of a large part of the arm, and much attendant discomfort. It cannot be said that if no reaction at all occurs the dose used has been too small for its purpose. Care in the choice of the dose will almost always suffice to prevent an undue reaction; and this care should be exercised in every case, seeing that such extreme reactions rarely, if ever, appear to have any therapeutic benefit which may not be obtained without them. It happens quite often that such a moderate reaction as that just described follows the first of a series of doses of vaccines, but is not seen after subsequent doses, even when these are increased in size. After the injection of tuberculin (T.R.) in the therapeutic doses usually given nowadays, no reaction at all is to be expected.

b. General effects.—After the inoculation of a prophylactic dose of vaccine, when, as is the rule, a large dose is chosen, there is usually set up a fairly marked general disturbance: headache, lassitude, pain in the limbs, and a rise of temperature to 100° to 102° F. These symptoms come on a few hours after the injection, and subside during the second twelve hours. After the initial therapeutic dose in chronic infective processes, nothing so severe as this occurs; but there is often a feeling of slight malaise during the day following the inoculation. In some cases the patient complains of nervous irritability, in others of drowsiness. After the initial dose, even if the number of micro-organisms be increased, it is unusual to see any such general effects. With the small doses chosen in the treatment of acute and generalized infective processes, no constitutional disturbance supervenes. In chronic and local infective processes, even if there be slight initial disturbance, this is often followed by a state of general invigoration, in some cases quite marked.

13. The Prophylactic use of Immune Sera and Bacterial Vaccines.

a. Immune Sera.—Diphtheria and tetanus are the two diseases in which immune sera are sometimes administered for preventive purposes. In the former disease, at all events, there is evidence that a prophylactic dose of antitoxin is of definite service in protecting against infection for a period of some days. Questions of dosage will be discussed later.

b. Bacterial Vaccines.—In preventive medicine, the principle of inoculation has been applied on a large scale to plague, typhoid fever, and cholera. In each of these diseases a certain amount of active immunity appears to be conferred by specific inoculation, and various methods of carrying out the principle are still on trial. Of late years a good many animal experiments have been made relative to the prophylactic use of vaccines, but much still needs to be done in this direction. The susceptibility of rabbits to infection by staphylococci and streptococci may readily be lessened by inoculation with moderate doses of vaccines prepared from these micro-organisms. This raises the important question whether a similar result may not be brought about in patients who are to be submitted to operations involving risk of pyogenic infections afterwards, as in removal of the tongue, etc. Such protective vaccination has, indeed, been introduced into surgery, and is actually practised by a few careful surgeons. The inoculations should be made during the week but one preceding the operation. It is not uncommon for patients who have recently been inoculated on account of furunculosis or some other staphylococcal infection, to remark upon an unwonted freedom from suppuration when they incur some

accidental damage to the skin or deeper tissues. It has been shown experimentally that rabbits enjoy a very high degree of immunity to the endotoxin of the meningococcus after prophylactic inoculation by killed cocci, and it is possible that children might with benefit be inoculated in a similar manner in the presence of an epidemic of cerebrospinal meningitis.

i. The chief use in England of prophylactic inoculation by killed bacteria is in connection with *typhoid fever*. Persons going into districts abroad where typhoid fever is endemic, especially if they are adolescent, and therefore at a susceptible age, are well advised to be thus inoculated. There is a growing mass of evidence that such vaccination confers a relative immunity which may last for several years. The inoculation should be completed at least one week before the person sails, so that the resulting malaise shall not increase any tendency there may be to sea-sickness. In order to lessen both the malaise and the local reaction at the site of inoculation, it is advisable to give the vaccine in two doses with a week's interval. The writer's own practice is to inject a dose of 1000 million killed bacilli, and to follow this, after an interval of seven or ten days, by a second dose of 2000 million bacilli. The vaccine is freshly prepared, and two or three different strains of typhoid bacilli are used in its manufacture. The first dose is conveniently given at such a time that the person inoculated can arrange to stay indoors and have little or nothing to do during the next day. The extent of the reaction differs considerably in different individuals; it is not usually sufficient to make lying in bed a necessity. It has generally passed off forty-eight hours afterwards. The second dose, though of double the size, usually produces a much slighter reaction than the first; this second dose may therefore be given as late as the day before embarking, or if the patient be a good sailor and the voyage is to last longer than ten days, this dose may be given on board. It should be remembered, however, that it is desirable to allow a clear fortnight to elapse between the second inoculation and the time of arrival at the district where typhoid fever is rife.

ii. Reference has been made to the use of bacterial vaccines before *surgical operations*. In operations involving technique of a prolonged kind, as in perineal abdominal excision of the rectum for cancer, it is advisable to prepare the patient for the fortnight prior to the operation by prophylactic treatment with colon bacillus vaccine, or with this in conjunction with *Streptococcus faecalis* vaccine. It may soon become a pertinent question whether it is not advisable to administer a prophylactic dose of *Streptococcus pyogenes* vaccine prior to every operation involving the opening of the peritoneum, when the necessary time can be allowed. It is true that sepsis is becoming less and less common with the modern surgeon's careful technique, but the occasional occurrence of general peritonitis after laparotomy is so disastrous an event, and is so constantly due to infection by *S. pyogenes*, that the question merits some consideration. It is, perhaps, well to use a sensitized vaccine in such cases, as it has been shown that the immunity thus produced is greater, and lasts longer, than that produced by a "naked" vaccine. Moreover, the immediate toxic effect of the vaccine is in this way lessened.

iii. More recently attempts have been made to immunize persons against certain acute infective processes of a different class by means of inoculation. The infective processes referred to are *influenza*, *acute rhinitis* and *nasopharyngitis* (*common cold*), and various forms of *acute sore throat*. A few comments of a general kind may not be out of place in regard to it. When faced with the question as to the practicability of protective inoculation against *influenza*, the first consideration which arises is whether or not the causal microbe of uncomplicated influenza has as yet been isolated. Despite the claims made in this respect for Pfeiffer's bacillus, there remain several points lacking in the complete

proof that this micro-organism is the *materies morbi* of the disease. It is quite possible that Pfeiffer's bacillus is only the most frequent of the various secondary infective agents common in the disease, and that the essential causal factor in the primary infection is unknown. If this be so, a close analogy exists, in respect of certain etiological points, between influenza and scarlet fever. For just as in scarlet fever the uncomplicated disease is usually a somewhat trivial affair, its common association with pathogenic streptococci rendering it oft-times very serious, so in influenza a sharp but short febrile attack, of itself not often very troublesome, may become of grave import when complicated by other infections. In addition to Pfeiffer's bacillus, the pneumococcus and *M. catarrhalis* are perhaps the most common micro-organisms found in association with influenza. It follows from this argument that when a person is "immunized against influenza" by inoculation with *B. influenzae*, there is a large presumption underlying the treatment. But such experiment, if carried out on a large scale upon susceptible persons, would be very valuable. It appears to be the custom of some "immunizers" to inoculate "against influenza" by a mixture of vaccines derived from Pfeiffer's bacillus, pneumococcus, and *M. catarrhalis*, a frank confession of doubt as to the specificity of the first-named microbe. The procedure, however, seems rational, seeing that, as already stated, the ill-effects of the disease are in great measure due to the secondary infections that are commonly grafted upon it. An alternative to this triple-barrelled measure is to await an attack in the susceptible person, and to investigate the flora of the upper respiratory tract during the first twenty-four hours of the disease. Actual information is thus yielded concerning the nature of the infective process, and a vaccine which has the great advantage of being homologous may be prepared for present and for future use. In a number of cases in which, after a fair statement as to the experimental nature of the whole process, patients have desired the writer to attempt a process of protective immunization in this way, the results have been very promising. But it is worthy of note that as often as not the micro-organism against which these patients have been vaccinated has been another than Pfeiffer's bacillus, e.g., pneumococcus, *M. catarrhalis*, and various strains of streptococcus.

The present position of prophylactic inoculation in regard to *colds* is much the same as it is in regard to influenza. The writer's own practice is to await an attack, to obtain an expert quantitative estimation of the flora of the nasal mucus early in the course of the illness, and to proceed accordingly. Several times it has happened, in doing this, that the dominant micro-organism has been quite other than might have been anticipated. Here again, a prevalent practice, but in the writer's opinion a bad one, is to inoculate with a vaccine prepared from a mixture of several micro-organisms commonly found in acute nasal catarrh. The writer has had experience of prophylactic inoculation in several cases of *recurring acute sore throat*, in most instances streptococcal in nature, and can report some very satisfactory results. In these cases the preparation of an autogenous vaccine is desirable, for the streptococci concerned vary much in different cases.

14. General Remarks upon Treatment by Specific Inoculation.—Since the introduction of specific inoculation in the treatment of bacterial infections, antisera have very largely fallen into disrepute, probably undeservedly so. The pendulum has very likely swung too far in the direction of the newer remedy. The combination of both methods of treatment is eminently rational, and not seldom proves beneficial when one method alone fails. The recent trials of "sensitized vaccines" (see sect. 8) promise good results in the near future. However this may be, the present vogue favours bacterial vaccines. Some authorities go so far as to suggest that when antisera are helpful in treatment

their value is due to their acting in the same manner as the injection of killed micro-organisms, viz., stimulating phagocytosis. But it must be remembered that this mode of action of vaccines is purely hypothetical. A few general considerations concerning the use of vaccines will precede the detailed description of the methods employed in the various infective diseases.

a. Cases suitable for treatment.—At the present stage of our knowledge of specific inoculation as a therapeutic measure, still very largely an experimental stage, it is impossible to lay down any definite rules that will guide the practitioner in the choice of cases likely to give good results. It will be assumed that he does not share the obsession that enthralled a few, that vaccine therapy is a panacea for all diseases that are of microbic origin. A distinction must constantly be made between certain hypotheses connected with the mode of action of bacterial vaccines, and the ascertained facts of actual observation; and seeing that as yet very little experimental work has been done along the lines of curative vaccine therapy, the only way by which the hypotheses can be properly tested at present is by the individual experience of careful workers. When the disappointments of vaccine therapy have been properly noted and the successes temperately recorded, some proportionate view of the usefulness of this system of treatment will doubtless be revealed. In the meantime no curb need be put upon any reasonable trial of the method; rather should every opportunity be taken of testing its efficacy. The only desiderata are careful technique and an unbiassed review of results. As in the employment of other modes of treatment, so here: much room exists for accurate observation, but none for enthusiasm.

b. The choice of dose and frequency of administration.—In the suggestions made with regard to dosage in the subsequent consideration of various infective diseases, experience will be taken as the chief guide in the matter. Fallacious as this guide is notoriously known to be, it is believed by the writer to be more useful than that which is said to control the inoculations of many who make a study of this mode of treatment of infective processes; that is, the opsonic index. There are numerous reasons for considering that the opsonic index, though it may be of some value in diagnosis, does not always measure the degree of total immunity of a patient to the infecting micro-organism. These reasons cannot well be gone into here. Whether it is that this opinion has come to be shared by a growing number of clinical pathologists, whether the hypothesis upon which the opsonic index rests is now regarded as more improbable than was the case formerly, or whether, as is more likely, a determination of the opsonic index has been found to be unnecessary for the purposes of actual practice, need not be dwelt upon. It is quite certain that a very large amount of highly successful specific inoculation goes on to-day which is quite uncontrolled by opsonic determinations. It is equally certain that these empirical inoculations are very frequently undertaken by workers who formerly taught that such proceedings were highly dangerous and were to be strongly deprecated.

For the choice of dose and for the frequency of its administration, reliance should be placed upon a careful study of the clinical condition of the patient, and upon experience of similar cases already treated. There is good evidence from animal experiments, as the writer has shown, that the effective range of dosage of bacterial vaccines is fairly wide, and that within this range no ill effects are likely to ensue to the patient. An equal degree of immunity to staphylococcal infection may be conferred upon rabbits by the use of vaccines differing in amount in similar animals by as much as 100 per cent. It may also be shown that animals will tolerate very large doses of bacterial vaccines when injected subcutaneously without loss of weight and without other evidence of ill health. Of greater importance than these observations on animals is the fact that in man, careful employment of vaccines, uncontrolled by opsonic indices, has not

led to any of the dire calamities which were predicted for it. On the other hand, it has led to a large number of good results in the treatment of bacterial infections, and promises still better results when experience of the treatment shall have ripened.

Although this form of therapeutics may be now said to have passed the experimental stage, considerable differences of opinion and of practice still exist in regard to dosage. It does not, however, follow that even when experience of the treatment is much greater than at present, the question of dosage will settle down into one fixed rule which all will observe. Despite the many observations that have been made with regard to the use of anti-diphtheritic serum, opinions still vary as to the optimum size and frequency of dose; but the results of this therapeutic measure are, in the main, universally good. And in this instance, be it observed, there is no existing hypothesis which claims to control the question of dosage. The doses of vaccine suggested below are those which are most generally employed. They are set out tentatively, for they are by no means arbitrary, being modified in individual cases as seems necessary. One of the great difficulties attending the question of dosage of bacterial vaccines is the variation in virulence of different strains of the same micro-organism, and of the same strain after sub-culture. Particularly does this difficulty apply to various strains of the streptococcus group, to the pneumococcus, and to the gonococcus. It is very doubtful if this difficulty is sufficiently recognized by those authorities who claim that the opsonic index gives a correct guide to the amount of vaccine (bacterial endotoxin) which should be employed. Tables of suggested doses, say of killed gonococci, which are recommended by an observer for use in particular cases, lose much of their value on account of this important fallacy. Experience shows that, whereas in the case of one strain a dose of five million killed gonococci produces a marked local reaction at the site of inoculation and is followed by an exacerbation of a urethral discharge, in the case of another strain neither of these effects follows the use of a dose of a hundred million killed cocci. Another difficulty in the adjustment of dosage, though apparently a less disturbing factor than that just named, arises from the individual differences seen in the response made by various patients to the same dose of the same strain of a micro-organism. This difference is often seen in the simple case of prophylactic inoculation against typhoid fever. A similar position exists, in a more complicated fashion, in regard to many cases of curative inoculation. Although no definite rules can be laid down for the size of the dose of vaccine which it is desirable to use in the treatment of various infective processes, the following principle may be safely stated: *the more virulent the micro-organism, and the more acute and the more generalized the disease-process, the smaller should be the dose of vaccine employed.*

c. *The use of stock vaccines.*—Several of the stringent rules originally laid down for the employment of vaccine therapy have lately been relaxed, as well by those authorities who enunciated such rules as by those who from the first doubted the wisdom of proceeding by rule at all in a path as yet so little trodden. One of the first of these rules to yield was that which made it imperative to employ a vaccine made from the micro-organism actually isolated from the patient under treatment. It has become a moot question whether this particular rule has not been relaxed too much, and whether the indiscriminate use of vaccines that are kept in stock by the wholesale chemists will not shortly bring the whole subject of vaccine therapy into disrepute; for the "stocking" of vaccines leads to a temptation to waive the important matter of bacteriological diagnosis, without which successful treatment cannot possibly be expected. Moreover, it is certain that vaccines deteriorate by keeping; *whenever it is possible, therefore, the particular vaccine used should be specially prepared for each*

patient. There are instances, however, in which the use of a stock vaccine is not only allowable but compulsory. Thus, it may be advisable to treat gonorrhoeal arthritis in a patient from whose blood, joints, and urethra no gonococci can be isolated; in this case appropriate doses of a vaccine recently prepared from another strain, or better, from a number of different strains, are therefore given. Again, in a case of erysipelas it may not be possible to cultivate the streptococcus which is most probably the cause of the skin infection; a small dose of *Streptococcus pyogenes* vaccine obtained from another case of erysipelas, or, failing this, from any case of acute *Streptococcus pyogenes* infection, is administered. But such procedures should always be regarded as "second best," and are to be strictly reserved for cases of bacterial infection in which it is customary to employ "stock vaccines"—those in which the cultivation of the micro-organism concerned is very difficult and its growth very slow. Examples are—all cases of tuberculosis, some cases of actinomycosis and other streptothrix infections, cases of simple acne, etc. One or other of the various forms of commercial tuberculin is almost invariably used in the vaccine treatment of tuberculosis. But even here it should be remembered that vaccine specially prepared from the patient's own strain of tubercle bacillus may conceivably lead to better a result, and recent methods of facilitating the growth of the bacillus on artificial media render this procedure less difficult than formerly. Lastly, it is sound practice to use a stock vaccine of a more virulent strain of micro-organism than the one isolated, or of a mixture of several different strains, if it is found that little or no good follows the use of the micro-organism actually present in the lesion under treatment.

Stock vaccines for the diseases detailed later may be obtained from Burroughs, Wellcome and Co., Lederle Antitoxin Laboratories, H. K. Mulford Co., G. H. Sherman, M.D., E. R. Squibb's Sons.

B.—SPECIAL.

Consideration will now be given to particular microbial infections that are, in actual practice, treated by some form of specific therapy. Stress will be laid upon those infections commonly met with in Great Britain. These, so far as specific treatment is concerned, may be grouped as follows:—

1. TREATED BY IMMUNE SERA:—

a. *By antitoxic sera*: diphtheria, tetanus.

b. *By (?) bactericidal sera*: streptococcal and pneumococcal infections, anthrax, cerebrospinal fever.

2. TREATED BY BACTERIAL VACCINES:—

Staphylococcal, streptococcal, pneumococcal, gonococcal, and *B. coli* infections, typhoid fever, tuberculosis, streptothrix infections.

The various infections will be dealt with in the order above enumerated.

DIPHTHERIA.

This, the first of the infective diseases to be treated by specific measures, remains the most successful instance of serum therapy. Diphtheria antitoxin (antidiphtheritic serum) has reduced the mortality of the disease from 30 to 10 per cent, and is nowadays regarded, quite justly, as constituting the essential treatment at all stages of the infection. The chief desideratum is to give the serum *at the earliest possible day of the disease*; any delay, even for a few hours, after the diagnosis has been made by bacteriological investigation, or strongly suspected by careful clinical examination, constitutes a serious error in practice; for it is shown by statistical records that, even with antitoxin treatment, the mortality of the disease rises steadily from the second to the fifth day with each day's delay in the administration of the remedy. The second desideratum is to give a *sufficiently large dose of the antitoxin*. The later the date at which the treatment is commenced, the larger should be the dose of antitoxin given. Thus, if the

treatment begins on the second day, and the case is one of only moderate severity, 3,000 units will probably suffice. But if it begins on the fifth day, as is often the case in hospital practice, a dose of 6,000 units should be given. These doses should be increased, quite apart from the duration of the disease, if the infection is an extensive one and if the constitutional disturbance is marked. Thus, in a case in which there are both faucial and laryngeal involvement, and treatment is begun on the fourth or fifth day, a dose of 8,000 units is none too much.*

Age does not affect the dose of antitoxin—a child should receive as much as an adult. This rule of practice is followed because the disease is a more serious affair in children than in the adult, and carries a more grave prognosis.

It is important not to wait for bacteriological confirmation of the clinical diagnosis, where this is made, before giving the antitoxin. On the other hand, if a bacteriological investigation demonstrates the presence of diphtheria bacilli in a case previously thought on clinical grounds not to be diphtheritic, the patient should then be given the benefit of the antitoxin treatment.

The initial dose having been given, its size being determined by the above considerations, the practitioner now waits some eight to twelve hours, watching the progress of the case. If unfavourable, the antitoxin is repeated, and it is now advisable to give a still larger dose. Many authorities say that a dose double the initial one should be given, and this recommendation may well be followed. At the end of a second twelve hours, if the condition has not improved, a third dose, again double the initial dose in size, is recommended. After this, it is very unlikely that any further benefit will be derived from the serum.

The mode of administration is injection by the subcutaneous route, as described in Section A. 9. But in very severe cases, and when the treatment is begun late, it is a good plan to give the initial dose intravenously (See A. 9). Oral and rectal administration of the serum, even if proved to be efficacious in certain cases, are not to be recommended as being equal in efficacy to the subcutaneous use of the serum. The *type of the disease* is quite immaterial to the success of the remedy: all varieties of diphtheritic infection—even skin infections—indicate the use of the serum.

The *prophylactic value* of diphtheria antitoxin is firmly established. The immunity conferred appears to last about three weeks. In epidemics occurring in schools or other institutions, the use of the serum in the case of contacts is of great value. The dose usually chosen is 1,000 units.

Diphtheria antitoxin of reliable kinds may be obtained from Burroughs and Wellcome, New York City Department of Health, Lederle Antitoxin Laboratories, H. K. Mulford Co., E. R. Squibb's Sons, Eli Lilly and Co., G. H. Sherman, M.D. The serum keeps very well, for a year certainly. It should be kept in the dark and in as cold a place as possible.

TETANUS.

This is the infective disease for which there is the greatest evidence, next to diphtheria, that a degree of immunity may be conferred by the use of antiserum. As in diphtheria, the serum is a true antitoxin. The experimental evidence of its efficacy is undoubted, but the results of its use in practice are much more ambiguous; this is explained, quite rationally, by the supposition that the tetanus toxin has already fixed itself upon the nerve tissues at the time when the antitoxin is administered. Unlike diphtheria, tetanus cannot be diagnosed by means of the initial local lesion, and therefore the constitutional effects of the poison cannot be anticipated, unless it be by systematic bacteriological examination of all suspicious wounds, a procedure that has much to

* On account of the slow rate of absorption, many authorities recommend that an initial dose of 8,000 to 10,000 units be given in severe cases as soon as the diagnosis is made.—AMERICAN EDITOR.

recommend it. By the time the disease is made manifest, therefore, much of the poison is locked up in the central nervous system, and the results of treatment by antitoxin are of necessity often unsatisfactory. The prophylactic treatment of wounds likely to lead to tetanus should, on the other hand, prove very beneficial.

However this may be, it is certainly a very desirable thing to administer tetanus antitoxin at the earliest possible moment after disease has been recognized.

The *dose* of the antitoxin varies according to the particular preparation used. The practitioner must be guided by the instructions issued with the several preparations. (See A. 6.) The *mode of administration* is a much debated question. Some authorities advise intraneural, lumbar, and intracerebral injections of the serum, so as to endeavour to neutralize the poison in the nerve structures. Of late there has been a tendency to revert to the older method of giving the serum subcutaneously. Perhaps the best method at present, and until more accurate knowledge is forthcoming, is to give an initial injection of 10 c.c. of the serum (equivalent to about 1,000 units) into the spinal theca by an ordinary lumbar puncture, and to follow this by 50 c.c. into the subcutaneous tissues daily (see p. 861). If the case is acute, and treatment is late, it may be advisable, in addition to the above, to inject 10 c.c. of the serum directly into the cerebral ventricles by means of a small trephine hole.

The *prophylactic* use of the antitoxin is recommended for wounds contaminated by dirt or soil. Ten c.c. of the serum are given, and this is repeated once or twice during the two or three weeks immediately following the infliction of the wound.

Tetanus antitoxin is prepared and supplied by the firms mentioned under DIPHTHERIA.

STREPTOCOCCUS INFECTIONS.

The success of antidiphtheritic serum was such that great hopes were entertained for similar good results from antistreptococcus serum when it was first introduced. These hopes have been by no means fulfilled. Streptococcus infections are, however, of various kinds, and in a considerable proportion of them there is evidence that the micro-organism exists in the blood-stream, a state of things not obtaining in diphtheria. Moreover the genus streptococcus comprises several species, and these differ amongst themselves by wide variations. This latter difficulty has been thought by serum manufacturers to be overcome by the introduction of "polyvalent" serum, to which reference has already been made (A. 6). But it should be noted that a "polyvalent" serum is one prepared by inoculating the horse with streptococci derived from a variety of sources, not one prepared by using streptococci showing differences in biochemical reactions.

This may account for some, at least, of the failures in the use of the serum. However this may be, it seems clear, from clinical experience, that antistreptococcus serum sometimes "works miracles" and sometimes produces no good results whatever. Unfortunately it is not yet fully apparent why this discrepancy exists.

At the present stage of specific therapy, streptococcus infections are treated both by immune sera and by vaccines. Broadly speaking, it may be said that *the more acute the infection, the more likely is immune serum to do good; the more chronic the infection, the more likely is vaccine to do good*. It is sound practice to begin treatment in an acute case by a liberal administration, either intravenously or subcutaneously, of antistreptococcus serum, and to follow this by the employment of homologous vaccine. Even better than this, probably, is the method of using a sensitized vaccine (See A. 8), for it is in the treatment

of acute streptococcal infections that this method has given the best results up to date. In a chronic case the serum may be omitted and vaccines used from the first. If the infection is by *S. pyogenes*, the writer is strongly of opinion that a *univalent pyogenes serum* is best. If the infection is by a streptococcus of the salivary or faecal type, a "polyvalent" serum is probably best. If a sensitized vaccine be used, the appropriate serum should be used for its manufacture. The subject is a very difficult one, and little more than general hints can be given in the following consideration of the chief types of streptococcus infection. The local infections will be considered first, the general infections afterwards.

1. **Erysipelas.**—The infection is probably always by *S. pyogenes*. The treatment recommended is to begin by giving 50 c.c. of serum, choosing the univalent pyogenes serum, and following this by small doses of vaccine, such as from 2 to 5 million cocci, on alternate days, for four doses. If a sensitized vaccine be used, doses of 100, 250, and 500 million may be given on successive days. If it is possible to cultivate the streptococcus from a vesicle of the actual case under treatment, so much the better. Promptness in the use of any available material is an important consideration. If the isolation of the streptococcus from the actual case is not possible, a stock vaccine derived from a case of erysipelas, or, failing that, from an infection due to *S. pyogenes*, should be used.

2. **Cellulitis and Acute Abscess Formation.**—A similar line of treatment may be adopted.

3. **Pyorrhœa Alveolaris.**—This is, in the opinion of the writer, generally if not always due to *S. salivarius*, a short-chained streptococcus of feeble virulence, yielding reactions distinct from *S. pyogenes*. Local treatment failing to cure the disease, or only attaining partial success, it is advisable to try the effect of a course of vaccine therapy. (The writer does not, however, share the opinion of those who consider that local treatment is of secondary value compared with treatment by vaccines.) It is advisable to begin with doses of 10 million cocci, given at intervals of eight to ten days, increasing gradually, if necessary, to 500 million cocci. The material from which the vaccine is prepared is to be taken from the depths of the pockets (or, better still, from the fang of an extracted tooth, if such there be), and not from the cheesy pus lying about the surface of the gums.

4. **Septicæmia and Pyæmia** (puerperal fever, infective endocarditis, etc.).—It is quite certain that in general streptococcal infections the results of treatment by vaccines have been less promising than in cases of localized infection. It would appear that the more generalized the infection the less marked the benefits of specific inoculation.

The method of treatment of these very grave conditions which gave most promise until very recently was by an initial use of a large dose of immune serum, given intravenously, and repeated subcutaneously on alternate days or every third day. The initial dose should not be less than 50 c.c. As soon as the vaccine could be prepared, a very small dose was given, such as 0.5 million cocci, and this was very gradually increased to 2 to 5 million by inoculation on alternate days or on each third day. Sometimes a distinctly good result followed the use of a large dose, even of 50 million cocci, but such a dose as this must only be given after careful consideration of all the features of the case, and of the type of streptococcus at work. (Thus, in cases of *puerperal fever*, especially in those in which auto-infection takes place—? from the bowel—the streptococcus isolated from the uterus or from the blood-stream is often *S. faecalis*, and as this type of streptococcus is not nearly so virulent as *S. pyogenes*, larger doses of the endotoxin may be given for the purpose of stimulating the formation of antibodies.) But quite recently still better results have followed the use of sensitized vaccine. The dosage varies in the hands of different workers. A common mode of administration is by the "steppage" method: giving, say, three successive daily doses

of 100, 250, and 500 million cocci, then, after an interval of three or four days or longer, according to the course of the disease, a similar series of 250, 500, and 1000 million cocci—and so on. In cases of *ulcerative endocarditis* specific therapy of any kind is notoriously disappointing. This is especially true in the cases of chronic infection, which are not at all uncommon. However, the best hope still lies along the line of treatment just indicated. The cases that have recovered after specific treatment have demonstrated the necessity for very thorough trial of the measure. It seems certain that, despite the recent additions to knowledge concerning this grave malady, there remains still unknown some important clue to successful treatment of this type of infection. Antistreptococcus serum may be obtained from Lederle Antitoxin Laboratories, H. K. Mulford Co., E. R. Squibb's Sons, Burroughs, Wellcome and Co. The last-named firm make a *univalent pyogenes serum*, acting upon suggestions made by Andrewes and the writer.

PNEUMOCOCCUS INFECTIONS.

Next to antistreptococcus serum, the "bactericidal" serum to which most extensive trial has been given is the antipneumococcus serum; but the results have been even more disappointing than with the antistreptococcus serum, so far as the brands of immune serum at present on the market are concerned. One or two local pneumococcal infections, however, appear to have been markedly benefited by the serum, particularly that form of *corneal ulcer* which is due to the pneumococcus. The brand of serum credited with this good result is Römer's, obtainable from Merck. The other brand of serum on the market is Pane's, supplied in England by Burroughs, Wellcome & Co.

At the time when the inefficacy of immune serum led to a pause in the specific treatment of pneumococcal infections, the introduction of vaccines in the treatment of pyogenic diseases gave a definite fillip to the efforts of the therapist. A variety of pneumococcal infections have been treated in this way, often with very good results.

1. **Pneumonia.**—By some observers the time of crisis is said to be hastened by the use of small doses of vaccine. Others do not confirm this. There is certainly no very noticeable difference in the course of the disease when untreated or when treated by vaccines. It is, of course, highly probable that in the great majority of cases of pneumonia adequate "auto-inoculation" is proceeding, and it is probable, too, that the crisis is the sign that this "auto-inoculation" has been successful. If, however, a case of pneumonia is not running a satisfactory course—if, for instance, the crisis has not arrived by the tenth day of the disease—it is advisable to give a small dose of vaccine, such as 5 million cocci, and to repeat this in two or three days if necessary. The vaccine should be prepared from the actual strain of pneumococcus causing the infection, derived either from the sputum or from a lung puncture.

2. **Empyema.**—After drainage has been established, the healing process may be hastened by the use of a vaccine, and this should certainly be tried if the case "hangs fire." Weekly doses of 10 to 50 million cocci may be given.

3. **Bronchopneumonia.**—Good results follow vaccine treatment more often in lobular than in lobar pneumonia, perhaps because the former disease much less often runs a "natural course." Small doses of vaccine should be given, such as 2 to 5 million cocci, with three to four days' interval between the doses.

4. **Bronchitis; Asthma; Infections of the Upper Air-passages.**—These and some other catarrhal conditions are often treated by vaccines with success. As with other diseases, it is, of course, advisable to use the vaccines as adjuncts in the treatment, and not to rely solely upon them. The infections in these cases are often "mixed," especially with *M. catarrhalis* and Pfeiffer's bacillus (*B.*

influenzæ). When this is the case a mixed vaccine may be employed. The doses, and intervals between the inoculations, will depend much upon the nature of the case under treatment, and can only be decided by experience and a careful study of the patient's condition. Chronic cases indicate larger doses than acute ones. Careful quantitative bacteriological examination of the sputum is essential to success.

5. Pneumococcal Septicæmia and Pyæmia.—The principles of combined treatment by serum and vaccine, or better, by sensitized vaccine, as indicated for streptococcal infections, should be carried out here also.

ANTHRAX.

The drastic surgical treatment of malignant pustule formerly adopted has in recent years become less universal. Some authorities now prefer local treatment by fomentations, and attention to the general condition. Whichever of these methods be adopted, it is advisable to add the use of an immune serum, seeing that very favourable results have been recorded as following its administration. The serum most used, prepared originally from goats and later from asses, is Selavo's. It is thought to be "bactericidal" in its action. A large dose is used, preferably 50 c.c., injected into each flank. If the case is very acute and severe, it is advisable to give the injection intravenously. (See A. 9.)

Selavo's anti-anthrax serum may be obtained from Messrs. Allen & Hanburys.

CEREBROSPINAL FEVER (MENINGOCOCCAL MENINGITIS).

Several workers have succeeded in manufacturing an *antimeningococcus serum*, the use of which certainly appears to be of benefit in cases of cerebrospinal meningitis, whether sporadic or epidemic. Flexner's serum is to be specially recommended. The dose of this serum varies from .15 to 45 c.c., according to the severity of the case. It should be given intraspinally, after removing by lumbar puncture a quantity of cerebrospinal fluid equal to the dose of the serum. Subcutaneous administration of the serum is useless. The serum should be repeated after forty-eight hours, and again if necessary. Doubtless some of the good effects seen are due to the lumbar puncture and consequent drainage. An *antimeningococcus serum* is made by Burroughs, Wellcome & Co. Kolle's serum, much used in Germany, is obtainable through Messrs. Rebman, Limited. New York City Department of Health, Lederle Antitoxin Laboratories, H. K. Mulford Co., E. R. Squibb's Sons.

STAPHYLOCOCCUS INFECTIONS.

The treatment of staphylococcal infections by vaccines has been proved of such value that immune sera, never shown to be of much benefit, have quite fallen into disuse.

1. Chronic Local Infections.—The diseases coming under this head are *boils*, *carbuncle*, *sycosis*, *pustular acne*, some forms of *eczema*, *ciliary blepharitis*, *otitis media*, and *suppurating Meibomian cyst*. Of these diseases, boils react best to vaccine treatment; so well do they react that a cure, more or less long-standing, may confidently be promised to almost every patient. Historically the first of the staphylococcal infections to be treated by Wright's method, furunculosis still remains the most responsive to the new therapeutic measure. Taken as a whole, the furunculosis group of cases stands almost alone in respect of the uniformity of results obtained with the treatment; so much so, that a guarded prognosis must always be given in the other forms of staphylococcus infection. But even here individual cases often do remarkably well, though now and again others are disappointing. In *acne* some degree of success may always be promised, but the ultimate result differs according to the various

etiological factors present. As an adjunct to other modes of treatment, vaccine therapy is invaluable. If attention to the general health, digestion, etc., be omitted, and no pains be taken with the toilet of the skin, failures will certainly be met with in those cases where the infective element is not dominant. Patients are often too sanguine on account of the glowing testimonial of some friend whose lesions were quite different from their own; they must be led to modify their expectations, and must be prepared to add to the inoculation treatment the less novel aids to recovery already referred to.

Under the same heading may be mentioned the treatment of *sinuses* left after the bursting or opening of abscesses, or after operations. Here it is of great importance to commence treatment early. It goes without saying that efficient surgical measures must always be undertaken in conjunction with the inoculation treatment; to overlook an abscess or to neglect proper drainage of a sinus is but to court disappointment. Vaccine therapy is often an adjunct, but never a substitute, in sound surgery.

As regards *dosage*, custom has changed at least twice since the introduction of vaccine treatment for furunculosis, and this despite the fact that the principles underlying the opsonic hypothesis have not altered. It is probable that the changes have been the natural result of clinical observations, oscillations such as often occur in medical opinion pending the trial of a new remedy. At first comparatively large doses of cocci were used—at least 1,000 million—and this dose was often increased still further. Some of the results proving unsatisfactory, the pendulum swung in the other direction, and 100 to 250 million were considered appropriate initial doses. Some workers still use such doses, but most observers agree that 1,000 million is the best with which to begin the treatment of an ordinary case. This is followed by doses of 250 to 500 million, with intervals of seven to ten days, if improvement follows the first dose. Should relapses occur, it is probable either because the dose is not high enough, or because inoculations are too frequently repeated, and this can usually be discovered by a little care. Much individual difference exists in this matter. In most cases the doses of vaccine can be “spaced” further after the fourth dose, allowing fortnightly, three-weekly, monthly, and two-monthly intervals. It must be confessed that by proceeding in the opposite manner, and graduating the doses upwards, equally good results are often obtained, and some workers adopt this plan as a routine. Thus, 250 million may be given as the initial dose, 500 million a week later, and 1,000 million at the third or fourth inoculation. This latter method is perhaps better for patients who are constitutionally affected (e.g., diabetics, etc.).

Chronic carbuncle is treated in the same way, whether surgical interference be also adopted or not. In the treatment of *acne* much the same line is adopted. In nearly all cases the concurrent use of local applications will be found of advantage. The exact relation of Sabouraud's bacillus to the lesions of acne is still a matter of debate. Dr. Alexander Fleming has recorded good results from the use of a mixed vaccine of staphylococcus and the “acne bacillus,” and many observers have confirmed these results. In *sycosis* the response to the smaller doses used in furunculosis is usually good if the treatment is carried out early. If, however, the case is of some standing, and deep-seated inflammation with induration is present, the effect of the inoculations is not so good. In such long-standing cases good effects will sometimes follow dosage of 2000 to 5000 million cocci when previous inoculation by smaller doses produces very little result. The same remark applies to some cases of long-standing acne with much induration. In these, injection of the vaccine close to the seat of the lesions is often of benefit. In connection with *sycosis*, as with *acne*, it is courting disappointment to neglect other forms of treatment, such as epilation

and the free use of mercurial applications. In *chronic sinus infections*, again, the result of small doses of vaccine is usually disappointing; these sinuses are apt to be lined by fibrous tissue, and they need radical surgical treatment, with vaccines as an adjuvant. In *ciliary blepharitis*, success usually follows the use of doses recommended for furunculosis.

2. Acute Local Infections.—*Acute boils and carbuncles* tend to abort when treated with an early dose of vaccine, and no ill effects appear to follow such treatment. In favour of treating these conditions by vaccine is the fact that either of them may prove more serious than at first sight promises. Thus, subsequent unfavourable developments may be due to the position of the lesion, e.g., near to the inner canthus of the eye, leading to orbital abscess or even to meningitis, or they may be due to the general condition of the patient, e.g., the enfeebled resistance of old age. For these reasons any opportunity of influencing beneficially the patient's degree of immunity by vaccine treatment at an early stage should certainly be undertaken. If it appears probable that a boil or a carbuncle, when first seen in the stage of redness and induration, will eventually "come to a head," this sequence may be encouraged by the use of a large dose of vaccine, i.e., 1,000 million cocci. In this way time may be saved and eventual scarring minimized. In the case of boils of the external auditory meatus, of the nose, and of other situations which are very painful, such saving of time is much appreciated by the patient.

If the carbuncle is already developed, it is best treated by small doses of killed cocci on alternate days, say 20 to 50 million. Other acute staphylococcal infections may be similarly dealt with (e.g., *poisoned fingers*, and *acute abscesses* after surgical treatment).

3. Chronic General Infections.—In *chronic staphylococcal pyæmia*, 50 to 100 million killed cocci may be administered every four to seven days, omitting the inoculation just prior to, and just after, any surgical treatment of abscesses or sinuses that may develop.

4. Acute General Infections.—A *résumé* of an actual case will serve to illustrate the method of treatment that may be tentatively adopted. *Osteomyelitis of ilium*; *S. aureus*; *pyæmia*.—The patient was a man aged 35 years. *S. aureus* was isolated in pure culture from a local lesion and from the blood-stream. The abscess in the bone was opened without any abatement of the symptoms; a few days later an abscess was also opened in the shoulder-joint. The patient was extremely ill, and his life despaired of. A dose of 50 million killed cocci, prepared from the positive blood-culture, was administered, and this was quickly followed by marked improvement. A similar dose was given five days later. Four days after this second dose, the dose was increased to 100 million cocci; the condition still further improved, and the temperature now became normal. Ten days after the third inoculation, pus was withdrawn from the knee-joint; this pus was sterile on culture, and the knee-joint did not require further drainage. A fourth dose, consisting of 100 million cocci, was now given. The patient recovered completely, his sinuses healing rapidly. He was discharged from the hospital quite well, three months after admission.

GONOCOCCUS INFECTIONS.

The use of immune sera has not led to any promising results; in this respect gonococcus infections resemble infections due to staphylococci, to which group the gonococcus probably belongs in a strict bacteriological sense. In 1905, the writer employed an antigonococcus serum in the treatment of some cases of gonococcal arthritis, and with success; but some control cases treated by normal horse serum also gave good results, and made it doubtful if the good effects of the immune serum were really due to any specific antibody present

in the serum. At present, the only kind of specific therapy extensively used in this form of infection is inoculation by bacterial vaccines.

1. **Acute Urethritis, Vaginitis, and Cervicitis.**—The course of these cases is probably shortened by the employment of small doses of vaccine (from 1 to 5 million cocci) every three or four days. If local treatment is also used, the chemicals should be very weak, and adapted to simple cleansing rather than to irritation of the mucosa.

2. **Chronic Urethritis and "Gleet."**—The dose of vaccine may be larger (from 10 to 500 million cocci), every seven to ten days. Care must be exercised to exclude mixed infections, especially by staphylococci and by diphtheroids, and if these are present to any degree, appropriate vaccines must be prepared and administered. In cases of long-standing gleet, the results of vaccine treatment are sometimes disappointing, but this is occasionally due to neglect of the secondary infection.

3. **Gonococcal Arthritis (Gonorrhœal Rheumatism).**—Good results are more uniformly seen in this class of case than in either of the two preceding groups. The system of dosage must be adapted to the type of case under treatment. (a) In *acute* cases doses of 1 to 5 million may be given at intervals of three to five days, the effect upon the temperature and symptoms being watched. (b) In *subacute* cases these doses may be somewhat larger and less frequent. (c) In *chronic* cases treatment should be begun tentatively with doses of 10 to 20 million cocci, to test the virulence of the strain of vaccine used. This is done because in this class of case it is not possible, except in rare instances, to get the patient's own micro-organism; recourse has therefore to be made to a stock vaccine. The dose will probably need a considerable increase before good effects follow—to 50, 100, and 200 million cocci. The doses are "spaced" more widely than in less chronic cases—with two, three, and four weeks' interval as the treatment progresses. The writer has seen excellent results from doses as large as 400 and 500 million cocci in cases of very old-standing pains in the feet, ankles, knees, and spine. Some American workers have given doses as large as 1,000 million cocci for a single inoculation, and have reported good results (cf. dosage in chronic staphylococcal infections).

4. **Iritis.**—In acute iritis, if accompanying the original urethral infection, care must be taken to employ very small doses of vaccine (0.5 to 1 million cocci). In the recurring iritis which is so significant a feature in some cases of gonococcus infection, and which sometimes shows the persistence of the disease for a number of years, the writer's method is as follows: During the evolution of the attack the non-specific measures in the treatment are supplemented by very small doses of vaccine, as above. When the attack has subsided, the dose is gradually increased, and the interval of administration is at the same time lengthened. By this means the tendency to recurrence is in a fair number of the cases diminished or altogether destroyed.

Homologous and Heterologous Vaccines.—Reference has already been made to the varying virulence of difference strains of gonococci. Wherever possible, therefore, it is important to employ the actual strain of gonococcus causing the infection from which to prepare the vaccine. This is only possible where the local lesion is still present, or where a general infection leads to the presence of the micro-organisms in the blood-stream or in a joint. In a large number of the cases presenting themselves for treatment, neither of these conditions prevails. The practitioner must then fall back upon a "stock" vaccine. *A stock gonococcus vaccine should be made from recent cultures of several strains of gonococci.* Such a vaccine can usually be obtained from pathological institutes on the staff of which is a bacteriologist interested in vaccine therapy.

BACILLUS COLI INFECTIONS.

An *anti-colon bacillus serum* (prepared and sold by Burroughs, Wellcome & Co.) is on trial, but as yet there is little definite evidence of its value as a therapeutic agent.

B. coli vaccine is, however, very definitely of service in a large number of infections by this micro-organism. Its efficacy perhaps ranks next to that of staphylococcus vaccine in the experience of many.

i. **Infections of the Urinary Tract.**—Cases of *cystitis* and *pyelitis* due to *B. coli* infection, which resist treatment by local means and urinary antiseptics, should be treated by vaccines prepared from fresh cultures of the urine. The results are very variable. In the main it may be said that where constitutional symptoms are present they are almost always benefited; frequency of micturition and dysuria are relieved; pus is reduced in quantity, and often completely disappears; a mere state of bacilluria, however, is rarely (in the experience of the writer) affected beneficially. A very useful mode of procedure is to begin by inoculations at weekly intervals, giving 10 million bacilli for a series of four doses. The dose is then increased to 20 million for a series of four more doses, at intervals of a week to ten days. This dose may then, if necessary, be further increased to 50 million bacilli at intervals of a fortnight. It is rarely necessary to increase the dose beyond this amount; but in a few chronic cases doses up to 250 million bacilli appear to produce good results when smaller doses are ineffectual. *In all long-standing cases it is essential to deal with fresh cultures of the bacillus at stated intervals.*

ii. **Post-operative Suppuration** is not seldom due to *B. coli* infection, especially after appendix operations. The cases are sometimes due to mixed infections, such as *B. coli* and *staphylococcus* or *B. coli* and *Streptococcus faecalis*. Some of the most successful instances of treatment by specific inoculation are found in this group of infective conditions complicating surgical procedures. Delayed convalescence after abdominal operations, when local infective processes are going on in the neighbourhood of the wound, indicate treatment by vaccines. Small doses are sufficient (e.g., 5 to 10 million *B. coli*, or 10 to 50 million *Staphylococci*) to begin with; subsequent doses must be determined by the progress of the case.

iii. In **Colitis**, whether simple, "mucous," or ulcerative, the patient may be submitted to vaccine treatment in conjunction with whatever other methods of therapeutics are being undertaken. Most of the cases are associated with infection by a coliform micro-organism. Cases of "chronic dysentery" come into the same group so far as this indication is concerned. Great care must be exercised in the selection of the colonies of growth (usually obtained from the stools) from which the vaccine is prepared, and for this purpose expert bacteriological knowledge is necessary. "Stock" vaccines are to be avoided, or disappointment is courted. The results are by no means uniformly good. In cases associated with marked nervous symptoms, and in "ulcerative colitis," the treatment is rarely satisfactory. But in many cases lying between these two extremes much benefit is seen from inoculation. In not a few cases there is infection of both the urinary and the intestinal tracts: the cases should certainly be given a chance of improvement or cure by vaccine therapy. The dosage recommended is much the same as in dealing with urinary infections.

TYPHOID FEVER.

An *antityphoid serum*, introduced by Chantemesse, has had considerable vogue in France, especially in prolonged cases of the disease. It has not been used to any extent in England. Burroughs, Wellcome & Co. also stock an antityphoid serum.

Typhoid vaccine may be administered in bad or prolonged cases: a dose of 10 million bacilli, repeated on alternate days for six doses, seemed to the writer to determine a successful issue to an extremely severe case in which meningitis was present. Some observers have given much larger doses, and claim good results. The vaccine should be specially made for each patient, and by preference from the bacillus recovered from the circulation by blood culture. Sensitized typhoid vaccine is perhaps preferable.

TUBERCULOSIS.

Although *antituberculous sera* have been introduced by Marmorek and others, there appears to be very little evidence that their use is of any definite value in tuberculous infection. The only form of specific treatment at all widely adopted is by "*tuberculin*" in some form or other. Roughly speaking, there are three substances available for the purpose of specific inoculation: (a) *Tuberculin*—an extract of the bacillus with or without its toxins—of which there are several varieties (Koch's, Béraneck's, Denys', etc.); (b) *Bacillary emulsion*—a true "vaccine" of the tubercle bacillus, made exactly as in the case of other vaccines (q.v.); and (c) *Tuberculosis sero-vaccine*, a form of sensitized tubercle bacilli prepared after the manner of sensitized vaccine, referred to in Section A. 8. The last-named substance has only recently been available. The second-named material is growing in favour. The first-named product is the one in general use, and to it the following remarks apply. The variety of tuberculin in common use is Koch's tuberculin T.R. ("new tuberculin," *T. rückstand*).

At the present time there exist considerable differences of opinion both in the choice of cases to submit to tuberculin treatment, and in the manner of dosage.

i. *Choice of Cases*.—Most authorities agree that it is inadvisable to give tuberculin to patients who are markedly febrile, and particularly those febrile patients who show much oscillation in their temperatures and in their general condition. There is also a large consensus of opinion that no patient should be started upon a course of tuberculin treatment immediately he comes under observation. The best cases to select are undoubtedly those in whom there have been produced, as the result of non-specific measures, some definite retrogressive changes in the tuberculous lesions. Upon the return to ordinary life, for example, of a phthisical patient who has undergone sanatorium treatment with satisfactory results, but who cannot avail himself of this mode of treatment up to the point of complete healing, a course of tuberculin may well be added to those non-specific measures which, if he be wise, he has learnt to weave into his daily routine of life. In such cases small doses of tuberculin appear to act beneficially by stimulating resistance and hastening the processes of healing.

These considerations do not take into account those experimental efforts made to check the course of rapidly progressive and desperate forms of tuberculosis which show no response at all to other methods of treatment. Such efforts upon rare occasions *seem* to be fraught with success; and the most that can be said against them, provided great caution be exercised in the choice of dose, is that they are usually doomed to disappointment.

The most definitely satisfactory results of tuberculin treatment are probably seen in cases of *genito-urinary* infection, in cases of *early adenitis*, and in tuberculosis of the *peritoneum* and of the *joints and bones*. In *lupus*, most authorities agree that some results of tuberculin treatment are very good.

ii. *Choice of Dose*.—There is no rule guiding the size of dose of tuberculin, or the frequency of its administration; both have decreased a good deal of late

in the practice of most observers. The rule already formulated concerning vaccines in general should be observed here : the more acute and generalized the infection, the smaller should be the dose. Seeing that some workers employ what seem to the writer unnecessarily heroic doses, and others give doses that seem unnecessarily minute, and yet both claim good results, it appears reasonable to strike a middle course, and this is probably what most practitioners do. In cases of average severity, an initial dose of $\frac{1}{20000}$ mgm may be chosen, and repeated for a series of four doses. The time interval should be determined by the nature of the case. The more acute it is, the longer the interval should be. Three clear days is a common interval for a chronic case, seven to ten days for a subacute case. A second series of four doses of $\frac{1}{10000}$ mgm may now follow, somewhat longer intervals being observed ; and so on, advancing by $\frac{1}{10000}$ mgm at every fifth dose until the dose reaches $\frac{1}{1000}$ mgm. It is doubtful if anything is gained by an increase past this point.

It is probably of no service in the treatment to aim at a "reaction" to the dose of tuberculin employed ; indeed, should any dose be followed by a reaction, either at the site of the lesion or elsewhere, or by a rise of temperature, the dose should not be increased for a while. It is therefore advisable to take the patient's temperature four-hourly during the forty-eight hours following an injection.

Some authorities give tuberculin by mouth, and recommend this method of administration. The writer cannot endorse the recommendation, except perhaps in the case of little children, and even then tactful management usually serves to make the subcutaneous route possible. In addition to the disadvantages set forth in Section A. 10, it has been shown that enormous doses of alt-tuberculin may be given by mouth to susceptible persons without reactions and without producing immunity to diagnostic tuberculin.

Thomas J. Horder.

SPERMATORRHŒA.—Spermatorrhœa may be defined as the involuntary escape of semen unattended by erection, voluptuous sensation, or desire ; it is not a disease, but is rather a symptom of the condition known as sexual neurasthenia, and described under the heading of IMPOTENCE. Seminal emissions occur in the perfectly healthy, and are due to a simple physiological reflex action, the distention of the seminal vesicles giving rise to a contraction of the muscular fibres by which they are surrounded, and so causing an expulsion of their contents. But should such emissions occur at frequent intervals, they may be prejudicial to health, and are usually due to an abuse of the sexual organs. This condition is commonly associated with nervous IMPOTENCE, and the treatment of it is described under that heading.

J. Ernest Lane.

SPHENOIDAL SINUSITIS.—(See NOSE, ACCESSORY SINUSES OF.)

SPINA BIFIDA.—Posteriorly the spinal canal is completed by the fusion of the laminae or neural arches at the root of the spinous processes. There is a separate centre of ossification for each half of a neural arch. If fusion does not take place, there occurs posteriorly a median defect of spines and laminae seen in spina bifida. This defect most frequently appears in the sacral and lumbosacral regions, the neural arches in these regions being the last to ossify.

Spina bifida is a hernia of the membranes through a congenital defect in the posterior wall of the spinal column. This forms a tumour containing cerebro-spinal fluid, and in over 50 per cent of cases spinal cord also, wholly or in part.

The principal varieties of spina bifida are : (1) *Meningocele*, where the contents are simply spinal fluid and membrane ; (2) *Meningomyelocele*, where both cord and membranes are found ; (3) *Syringomyelocele*, where the sac is lined by a neural layer formed by distention of the central canal of the cord.

The diagnosis is usually simple. It may be arrived at by the history, position, and appearance of the tumour, and the connection of its contents with those of the spinal canal. If the communication between the cyst and spinal canal be very slight, it may be mistaken for a congenital tumour not connected with the spinal membranes.

The prognosis depends upon the character of the overlying skin, the size of the tumour, the contents of the sac, and the accompanying malformations.

TREATMENT.—A certain proportion of cases are best left alone, notably those where paralytic symptoms co-exist with other congenital deformities. Palliative, rather than operative, measures are indicated in very enfeebled children with extensive openings into the spinal canal, or in those cases where there is every prospect of the child growing up.

In quite a number of cases a shield may prove useful—namely, those in which the sac is ulcerated, or where it is so thin and extensive that a danger exists of puncture. The shield should be very large, to prevent the danger of the tumour being irritated by its edges, and should be well-ventilated by numerous holes.

The only operative measures which have been successful are those of (a) Injection; and (b) Excision of sac.

a. Injection.—Morton's fluid (iodine 10 gr., pot. iod. 30 gr., glycerin 1 oz.) has proved the best solution for introducing into the cavity. It is intended to produce irritation and thickening of the sac wall, followed later by its obliteration. The operation has to be performed very carefully, with strict antiseptic precautions. If the tumour is tense, some of the spinal fluid should be carefully withdrawn by means of a needle sufficiently large not to be easily occluded. It should be introduced through the side of the tumour, and not through its thinnest part, in order to avoid the danger of subsequent leakage. About one-third of the contents should be removed. The puckered skin or depressions in the sac should be avoided, as they generally indicate nerve attachments. About 15 to 60 minims of Morton's fluid should be introduced into the sac, the amount depending somewhat on the size of the tumour. The needle should be carefully withdrawn, the skin dried, and collodion applied. To prevent diffusion into the spinal canal the child should be kept semi-recumbent. Later, it is well to keep the child lying on his face or side, to prevent the escape of cerebrospinal fluid.

The cases most suitable for Morton's injection are those of simple meningocele in very young children when the tumour is rapidly increasing, and in those cases where an ulcerated surface contra-indicates excision. As death sometimes follows the injection, it is well to leave alone those cases which do not give rise to danger. It is usually necessary to repeat the injections at intervals of about fourteen days.

b. Excision of the Sac should be practised in those cases where it is covered by normal skin and does not contain nerve elements but where it continues to grow in size; in those cases where the sac is membranous, or partly so, and contains neural elements; and in those cases where the sac is in danger of rupture, with subsequent fatal infection. The operation is grave, and is fully described in text-books.

Robert Jones.

SPINAL SYPHILIS.—(See SYPHILIS OF THE NERVOUS SYSTEM.)

SPINAL TUMOURS.—Neoplasms of the vertebræ, the spinal membranes, and of the cord itself, produce their major effects, and ultimately if left alone prove fatal, from secondary complications due to interference with the conductivity of the cord. The majority of such tumours of the vertebral column are malignant in character, being primary or secondary sarcomata, or secondary carcinomata. For these little can be done, either surgically or by any other

means. The intramedullary tumours, too, are usually malignant; whilst those arising in the membranes, whether intrathecal or extrathecal, are more often benign. It is in this last-named class that surgery has achieved some of its most notable triumphs.

The diagnosis of malignant disease of the vertebral column rests upon the evidence of the local bone pain, root pains, rigidity and deformity of the spine, and often the presence of primary cancer elsewhere, together with symptoms of rapidly increasing pressure upon the cord. When no primary growth exists elsewhere, it may be difficult to differentiate from tuberculous caries; so that in some cases an exploratory operation is demanded. Relief, by laminectomy, of pressure upon the cord and upon nerve roots, especially in the case of tumours affecting the cauda equina, may prolong life for many months and abolish pain.

Meningeal tumours produce a clinical picture which is often unmistakable, though other lesions, particularly meningeal cysts, are capable of giving rise to a similar train of symptoms. The picture is that of a steadily progressive transverse lesion of the cord, the level remaining constant and precise. It is not always possible to distinguish with certainty between intramedullary and extramedullary tumours. It is not possible to distinguish clinically between intrathecal and extrathecal tumours. The extramedullary tumour is most frequently intrathecal; it may extend over several segments of the cord; it is generally attached but loosely to the meninges, and lies in a cuplike depression in the cord. Complete exposure, by removal of several laminae, is an essential step in the operation, for working with an inadequate opening is likely to be followed by damage to the cord. Once thoroughly exposed, the tumour can be lifted out of its bed with little difficulty, and as a rule with but trifling hæmorrhage.

When the tumour is intramedullary, a median longitudinal incision into the cord may be made, so as to evacuate a cyst, or, if the tumour is a solid one, to allow of its spontaneous extrusion; in either case, the pressure on the overlying cord tissue will be relieved.

The after-treatment is of the greatest importance. The patient must lie upon a water-bed, and receive the most assiduous attention directed to the prevention of bedsores. Hexamethylenamine or helmitol should be given; this, together with regular catheterization and bladder washing, should prevent, and will certainly minimize, the dangers of cystitis and pyelitis. Regular massage will improve both the muscles and the patient's general nutrition.

The prognosis depends primarily upon the simple or malignant character of the tumour, and the completeness with which it can be removed without further damage to the cord; whilst the rapidity and extent of recovery depend chiefly upon the degree to which the cord has already been damaged before operation, and the effectiveness with which the after-treatment is carried out.

Percy Sargent.

SPINE, CARIES OF.—The proper treatment for caries of the spine is *absolute and uninterrupted rest*, and this is best secured by putting the patient flat in a pillowless bed; he must not be allowed to sit up or to roll about. As Brodie said, "From the first moment in which the nature of the case is indicated, the patient should abandon his usual habits and be confined altogether to his bed or couch." There is no treatment better than, or so good as, this. But though a child is to be lying flat for six, twelve, twenty-four, or more months, he is not to be shut up in a close bedroom; the windows are to be kept open, and he is to be carried out of doors every day. He should also be given general massage.

When much of my work lay with out-patients, I had many of the children with spinal caries placed in the empty boxes in which oranges are imported. A box could be bought for a few pence; and an old blanket folded on the bottom of it served as a mattress. In the process of evolution the orange-box became, for

certain children, a Phelps's box-splint. By some such means a child with caries can be carried from one room to another or taken into the open air without risk, and by slightly tilting the box or tray the child can see what is going on around him, and thus feel that he is not entirely shut out from the bustling world.

The plaster-of-Paris jacket treatment (of which, I confess, I have been, and still am, a warm advocate) must be held responsible for much of the existing deformity of Pott's disease. Many a time have I seen the angular projection coming on and increasing when the child has been walking about in a plaster jacket or some other form of support. It is the *ambulatory* treatment with the plaster jacket to which I take exception: the child *must* be kept flat. But the plaster jacket may be used in lumbar and low dorsal caries as soon as the disease is practically at an end.

Cervical and High Dorsal Caries.—The patient lying flat in bed, a shallow, firm pillow may be laid beneath the nape of the neck, and on either side of the head a sand-pillow of the size of a quartern loaf should be placed, so as to prevent all movement. If the child is restless, a coronet of webbing may be fixed around the head, the ends of the webbing being sewn to the sand-pillows. Further security may be obtained by fixing a band around the child's head and attaching a cord to it which runs over a pulley at the bed-head, a weight of a few pounds being hung to the free end of the cord. This band takes its bearings from beneath the chin and the occiput. It is not suggested that the weight at the end of the cord effects a separation of one inflamed vertebra from another: the intervertebral and the common ligaments of the spine would absolutely prevent such separation. A long bed-cradle should be placed over the feet and legs, otherwise the weight of the bed-clothes will produce a permanent over-extension of the foot. Massage of the legs and feet should be done regularly every day.

Fig. 71.—Leather splint for cervical and high dorsal caries. (Messrs. Spratt & Brooke.)

I have had considerable experience of the use of the *jury-mast*, as introduced by the late Professor Sayre, and have long since discarded it. It was designed to allow rotatory movements of the neck, but no movement whatever should be permitted. The principle is wrong.

When active disease has passed away, as is shown by the disappearance of local pains and of the peripheral neuralgias, the patient may be fitted with a leather cuirass (Fig. 71), which, taking its bearings from the chest, shores up the occiput and the chin. Poroplastic material also answers well, but it cannot be moulded so closely as wet undressed leather, and therefore is not so comfortable or efficient.

For cervical or high dorsal caries, the ordinary poroplastic or gypsum jacket which takes its bearings from the hips is, obviously, of no service.

Low Dorsal and Lumbar Caries.—When the disease is below the level of the shoulder-blades and the patient has undergone a sufficient course of complete rest in the horizontal position, a stiff jacket may be applied which fits close to the trunk and takes its bearings from the pelvis, reaching down to the top of the great trochanters. It may be made of leather stiffened with steel, of poroplastic felt, or of crinoline muslin soaked in a creamy mixture of plaster-of-Paris. In my opinion, the worst form of spinal appliance is the antiquated steel "support" made by the surgical mechanician; it is as heavy and cumbersome as it is expensive. The best is of "undressed" leather, which is closely moulded

on when in a wet and soft condition. The cheapest and the most serviceable for general use is that of plaster-of-Paris. For these cases a double Thomas's hip-splint is also extremely useful.

How long should the Patient be kept lying down?—This is the question which is constantly being put to the surgeon, and the answer is, "Until the disease and the chance of its return have passed away." If the patient is allowed up too soon, there is recurrence, and the rest-treatment has to be begun over again. For cervical or high dorsal caries—if all goes on well—two years, or two and a half, may suffice. But if the case was a severe one, three years will not be too much. The wise surgeon makes no promise. For low dorsal or lumbar disease two years, or perhaps less, may suffice. The return to the vertical position must be gradual, beginning with one hour a day, and going on slowly increasing the time, the jacket still being worn. Then the support may be left off for half a day once a week; then for half a day, say, Sundays and Wednesdays; then for a whole day; and so on; but watching the child carefully the while, and keeping the ear open for complaints of peripheral pains. The important thing is not to be in a hurry.

Angular Deformity often results from spinal caries. It may make its appearance even though the patient has been kept flat on his back during the whole progress of the disease. It is due partly to the contraction of the fibrous tissue filling in the carious patch, but still more to the contraction of the recti and other abdominal muscles. A few years ago a good deal was talked about the immediate and forcible straightening of angular deformity due to caries; some of the children subjected to that treatment died from shock, or were left with paraplegia, and it was not long before the method was discredited, and allowed to sink into deserved oblivion. The surprise is that any practical English surgeons ever could have thought of resorting to it.

"Spinal Abscess" is the term usually applied to the collection of fluid into which the tuberculous granulomatous mass breaks down; but, unless septic micro-organisms have found access to it from the colon or elsewhere, its contents are not exactly *purulent*, and it must be the surgeon's care that, in his active treatment of the "abscess," it does not become septic. It may be dealt with by aspiration with a large hollow needle, and this treatment may be repeated several times if necessary. It is useless to employ a slender needle, for it is certain to become blocked. If after several aspirations the fluid re-collects, it will be advisable to incise and empty the "abscess," to remove the lining by scraping and swabbing, and to finish the cleansing process by abundant flushings with hot water, to which a little tincture of iodine has been added. When the lotion comes back clear the cavity may be squeezed empty and the wound sewn up tight. No drainage tube should be inserted; its presence is not needed, and it might entail the cavity becoming septic and the child falling a victim to hectic fever or to lardaceous disease.

Paraplegia.—Chronic inflammation of the vertebræ is necessarily accompanied by thickening of the membranes of the cord—*pachymeningitis*. The motor strands of the cord are nearer the diseased bone, and they, therefore, are the filaments implicated, the sensory strands escaping. Disease of the vertebræ is apt to set up an ascending and descending myelitis, and, if the myelitis becomes chronic, sclerosis of the cord results. With perfect rest paraplegia usually passes off.

Laminectomy, the removal of the posterior arches of the diseased vertebræ, is sometimes resorted to with the view of restoring the motor functions of the cord. But in proposing its adoption, two important facts must be borne in mind: first, that the paralysis may very probably clear up of its own accord if Nature be given a fair chance; and, secondly, that the operation not only

entails a serious amount of shock, but involves the sacrifice of the only part of the vertebral support of that region which is free from disease. The conservative surgeon sees better results from the simple rest-treatment of paraplegia than he whose inclination is for operation. The former finds that paraplegic patients gradually and completely recover their power of walking, even though their general and local condition at one time seemed absolutely hopeless.

Edmund Owen.

SPINE, FRACTURES AND DISLOCATIONS OF.—The bony spinal column may suffer injury in three ways: (1) From direct violence; (2) From indirect violence due to falls on the feet or head causing compression of the vertebral bodies; and (3) The result of overflexion or overextension. These may cause fracture, dislocation, or fracture-dislocation. The 4th, 5th, and 6th cervical, the 12th dorsal, and the 1st lumbar vertebræ are those most often involved.

Fractures of the Spine are important on account of their complications. So far as the bony lesion is concerned, the treatment adopted for fracture elsewhere is indicated. But in the large majority of instances the spinal cord is irremediably damaged. The treatment therefore, consists chiefly in the skilful management of a patient with a transverse lesion of the spinal cord.

Fractures may be divided into the complete and the incomplete; the former into those associated with dislocation and those without, and, what is far more important from the point of view of prognosis and treatment, into the complicated, in which a lesion of the nervous system exists, and the uncomplicated, in which this is absent. Although the complete and the incomplete correspond closely to the complicated and the uncomplicated, yet it must be remembered that a complete fracture by no means always leads to complications of a nervous nature. Several cases of fracture of the 5th or 6th cervical vertebra have come under my notice, in which no suspicion of the nature of the injury was aroused at the time of its infliction, but the patient came under observation later on account of persistent stiffness of the neck. The physical signs pointed to fractured cervical spine, which was confirmed by the radiograph. In the compression fractures, in which the bodies of one or more vertebræ are crushed as the result of falls upon the feet, buttocks, or head, there may be no nerve symptoms. This fracture is not usually recognized at the time of the accident, but the pain and deformity which may develop later bring the patient under observation. At this time it may be difficult to distinguish it from tuberculous disease of the spine without *x-ray* examination. Again, certain cases of incomplete fracture may cause injury to the spinal cord, e.g., fracture of the laminae.

Examination.—This must be conducted to discover the extent of the damage to nervous structures, the level at which this has occurred, and finally, the nature and degree of the bony injury.

If nerve injury be absent, the greatest care must be taken to avoid its production; if existing, to guard against aggravating it. The examination should proceed in an orderly manner, the condition of the muscles being first investigated, then sensibility, and finally, the condition of the bladder. The diagnosis of complete or incomplete interference with conduction is made from the condition found. The examination of all cases in which the continuity of the bony column is destroyed must be gentle; the patient must not be turned in bed to ascertain this. In most cases passing the hand beneath the patient's back at once reveals the nature of the injury, kyphosis with irregularity of the spinous processes being present.

INCOMPLETE FRACTURE.—A spinous process, or one or both laminae, may be fractured, usually as the result of direct violence. Few of these cases are complicated, but they require careful and in many cases prolonged treatment. Considerable laceration of the soft parts is inevitable in all cases, and also

extradural hæmorrhage in fracture of the lamina; this may cause pressure on the cord, or the pressure may be due to depressed bone when both laminae are fractured.

After deciding that no indication for operation is present, the patient should be kept at rest in bed. Pain is best relieved by hot applications, and all pressure on the seat of the injury is to be avoided. In about a week massage may be employed, but no active movements until pain has ceased. In many cases five or six weeks' rest is necessary.

For persistent pain in old cases, counter-irritation by the actual cautery or blisters often gives relief, and it may be necessary to employ passive movement to break down adhesions, after excluding other causes of rigidity, such as traumatic spondylitis and tubercle.

Operation is indicated in bilateral fracture of laminae, or for extradural hæmorrhage. In the former case, after exposing the seat of the injury by means of a vertical incision or raising a flap, great care must be taken to avoid any pressure on the cord. The laminae must be raised with care by seizing the spinous process with forceps. Search should be made for loose spicules of bone or a laceration of the dura mater. The lamina should not be replaced.

COMPLETE FRACTURE AND FRACTURE-DISLOCATION.—In the examination of a case of injury to the spinal column, with signs of pressure on the spinal cord or nerves, in addition to the points already mentioned we must ascertain at once if the case is one needing operative treatment. Care must be taken that fracture of the lamina with depression is not overlooked; in these cases operation should be carried out at once. Unfortunately, in the large majority of cases the injury to the cord is inflicted at the time of the accident, and from its nature is irremediable by operation; the symptoms are not due to bony pressure.

Considerable difference of opinion exists with regard to the cases in which operation should be done. All will agree that injuries involving nerve structures below the level of the termination of the cord at the lower border of the first lumbar vertebra should be submitted to operation. But there is a difference of opinion as to the time at which this should be carried out. In lesions of the cauda equina, exploration should be undertaken as soon after the accident as possible; we should not wait for six weeks to see if the lesion will be recovered from spontaneously; if this is done the difficulties of the operation are much increased and the prognosis is less favourable. In cases first coming under observation some weeks or months after the accident, the rules governing the treatment of injuries of the peripheral nerves apply: exploration with suture if possible; if this cannot be carried out, nerve anastomosis.

Where the symptoms point to partial interruption of conduction in the spinal cord, if there is any suspicion that this is due to bone or a foreign body, or if it has appeared or increased in extent since the accident (hæmorrhage), operation should be carried out.

It is in the cases of complete interruption of conduction in the spinal cord that divergent opinions have been expressed, some surgeons considering that the patient should be given a chance by operation. For example, Scudder, in his book on the treatment of fractures, takes up the advanced position that "all fractures showing complete transverse lesion of the cord should be treated by immediate operation. Profound shock requires reasonable delay only." The experience of most surgeons, however, coincides with that of Cushing, who writes, "It is an unjustifiable ordeal for both patient and operator."

If called to see the patient at the time of the accident, transport to the patient's home or to hospital must be so arranged as to avoid inflicting damage on the cord or increasing any existing injury. After the diagnosis has been arrived at,

no attempt should be made to disturb the patient until everything is ready for his removal. A firm stretcher should be used, a shutter or hurdle answering the purpose if one cannot be obtained. Lifting must be performed with the utmost gentleness, and extension should be made by assistants while the surgeon supports the injured part.

Before the patient is moved from the stretcher the bed must be prepared, and the patient lifted under the care of the surgeon. In hospital this duty must not be left to the discretion of the porters and nurses. The bed must be prepared with fracture boards and the fracture mattress, its central portion consisting of two halves which can be removed for the attention necessary from time to time. The patient should be placed on his back with his legs flexed over a pillow. A water-bed is not advisable for a few weeks.

Shock must be combated in the usual way, and care taken that the hot bottles do not come into contact with skin devoid of sensibility. The bladder must next be attended to: if it is distended, a rubber catheter should be passed. Great care should be taken to avoid infection; the catheter must be boiled, and no catheter used that cannot be disinfected in this way; the hands of the surgeon must be rendered as sterile as possible. After the bladder has been emptied, the penis should be wrapped in antiseptic gauze.

In the large majority of cases the deformity reduces itself when the patient is placed flat on his back; if there is deformity, it must be rectified by extension under chloroform anaesthesia. The question of immobilization next arises. In fractures in the lower dorsal region, a carefully applied plaster-of-Paris jacket should be employed, but in higher fractures it is unwise, on account of the amount of the respiratory embarrassment produced. Extension by means of weights and pulleys is almost impossible to carry out if a cord lesion is present, on account of the injury caused to the anæsthetic tissues by the necessary strapping, etc., but if it is absent this is the most favourable method of securing immobilization.

If no cord lesion is present, the patient must be kept on his back for six or eight weeks, and then allowed up with his back supported by a poroplastic jacket. With cord injury, the treatment now resolves itself into combating complications, the most formidable being bedsores, cystitis, and pyelitis.

The treatment of bedsores is preventive, and skilful nursing under the direct supervision of the surgeon is necessary. The skin exposed to pressure must be kept dry, and after washing with soap and water, at least once a day, spirit lotion is applied and the parts dusted with boracic acid powder. All pressure must be as far as possible avoided, and after about three weeks a water-bed may with advantage be substituted for the fracture mattress. If a bedsore appears, dry antiseptic dressing will be found useful in most cases; in others boracic acid or eucalyptus ointment may be substituted. The ulcer should be surrounded with a water-pillow or a circle of thick plaster to avoid all pressure. The greatest care must be taken with the dressing to avoid infection; when this occurs, fomentations should be substituted.

Retention of urine must be treated by regular catheterization with aseptic precautions. True incontinence is rare, and in these cases care must be taken to secure the sterility of the urine bottles. But in spite of skilful attention, cystitis followed by pyelitis is almost inevitable. For this reason perineal or suprapubic drainage of the bladder has been advocated as a routine treatment in these cases.

Dislocation of the Spine.—Dislocation unaccompanied by fracture is limited to the cervical region, and takes place usually between the fifth and sixth vertebræ. It is commonly unilateral, and caused by a fall from a horse, or similar accident. It may be overlooked at the time of the accident, and

occasionally the patient does not seek advice until some time has elapsed. The appearance of the sufferer is characteristic. The head is turned to the side opposite the lesion, flexed towards the side dislocated, and fixed. The muscles on the affected side are relaxed. It may be associated with injury to the roots as they pass out of the foramina, and corresponding lesions caused; hæmato-myelia also may occur as the result of the injury, but any injury to the cord is uncommon.

Reduction should be at once attempted under an anæsthetic. The head must be bent laterally and somewhat backwards towards the side opposite the lesion, in order to free the articular process which has passed in front of that of the vertebra below. The head is then rotated so that the face looks towards the side of the lesion. If the injury is bilateral, reduction should be attempted in the same way; after one side has been reduced, a similar manipulation is done on the opposite side. Failing reduction by manipulation, open operation must be resorted to. The seat of the dislocation must be exposed; in most cases it will be found necessary to excise the superior articular process of the vertebra below.

In old cases, reduction by manipulation may be cautiously tried, but no force used; if this fails, open operation must be performed if much disability or pain exists, but some cases seem to be little affected. After reduction, a poroplastic support should be worn for at least two months. *James Sherren.*

SPIKE, LATERAL CURVATURE OF.—(See SCOLIOSIS.)

SPLEEN, WOUNDS OF.—(See ABDOMINAL INJURIES.)

SPLenic ANÆMIA.—Under this name a great number of probably very diverse conditions have been included, and it will hardly be too much to say that every anæmia which is associated with enlargement of the spleen has at one time or other been classified under this title. The first broad distinction which must be made is between the splenic anæmia of infants and children, and that of adults.

Splenic Anæmia of Children.—It must not be forgotten that almost every anæmia in childhood is apt to be associated with enlargement of the spleen. In fœtal life the spleen is a blood-forming organ, and there is every reason to believe that under the stress of anæmia it resumes this function, while it retains its function of destroying the imperfectly formed anæmic corpuscles, and this double increase in function is associated with enlargement of size. It is extremely common to find that rickety, anæmic children—and almost all rickety children are anæmic—have large spleens. The measures advisable for the rickety state will be found to have good effect also on the anæmia and the size of the spleen. One often, however, finds children who are not rickety who are yet intensely anæmic and have large spleens. It is sometimes extremely difficult to come to an exact diagnosis of the blood condition in these cases. Some of them present a picture of pernicious anæmia with more or less accuracy, for in very early life the blood easily reverts to the fœtal condition, which is closely allied in appearance to that associated with pernicious anæmia. In others, the blood picture is not unlike that of an early lymphatic or myelogenous leukæmia, and cases of this sort have been classed as anæmia pseudo-leukæmia infantum. In others again, especially in older children, the blood picture is that of a secondary anæmia. All such cases should, of course, be treated by nourishing food, and by due attention to excretion of all kinds. As regards more special treatment, the rule should be to give iron in all cases, and to give it in large doses; the actual form matters little. Children take the saccharated

carbonate well, and it may be given in doses of 20 gr. and upwards. If this is not well taken, reduced iron, or almost any of the pharmacopœial preparations, will do. Should these not be successful, some of the organic irons which have lately been put on the market may be tried, but they are not usually so satisfactory. In cases where the colour index is high—that is to say, where the blood approaches the type of pernicious anæmia—arsenic should be given in addition. X rays are of no service.

Splenic Anæmia in Adults.—There are many conditions in which enlargement of the spleen occurs whose terminal stages are anæmic, and these are often spoken of as splenic anæmias. Pernicious anæmia in a fair proportion of cases is associated with enlargement of the spleen, sometimes to a considerable extent. Primary splenomegaly, though it may persist for years without anæmia, very often shows it in the late stages. Cirrhosis of the liver occasionally produces sufficient splenic enlargement to have been classed with this disease. Banti's disease is in similar case, while malarial cachexia, primary tumours of the spleen, terminal stages of pseudo-leukæmia, suppurating hydatid, etc., must all be differentiated before a diagnosis of splenic anæmia can be arrived at. The recently described condition of leukanæmia, if it is a real clinical entity, must also be borne in mind. This is a very rare disease of fairly rapid course, where the symptoms are those of a steadily advancing anæmia with enlargement of the spleen; and the blood picture is at first that of pernicious anæmia, to which later the condition of leukæmia is superadded. When all these conditions are excluded, however, there still remains a group of cases with a progressive secondary anæmia, and with enlargement of the spleen, for which no cause can be found during life. It is extremely doubtful whether the enlargement of the spleen is more than a symptom, but the cases are not very numerous and have not been very fully worked out. The treatment must be on the general lines suitable to any secondary anæmia: the administration of iron, rest in bed, and perhaps the use of the x rays in order to reduce the size of the spleen where that is causing pain or discomfort. In one of my cases the spleen returned to the normal size, and the blood became normal, with x-ray treatment. Splenectomy may be tried provided the anæmia is not too great, for in Banti's disease recovery has followed the operation. In 32 cases of Banti's disease collected by Armstrong (*Brit. Med. Jour.*, Nov. 1906), the operation was fatal in 9 (28 per cent); in 22 there was complete recovery; in 1 only was the condition unrelieved. The possible causes of death from the operation are hæmorrhage at the time, gastric intestinal hæmorrhage after a few days, pneumonia, or vague gastro-intestinal symptoms some months after the operation. During the last two years a large number of cases of Banti's disease have been treated by splenectomy, with, on the whole, encouraging results. The blood may return to normal, the general condition of the patient improve greatly. The theory underlying the procedure is that the toxin causing the disease is located in the spleen, and is removed along with it.

G. Lovell Gulland.

SPRAINS.—The treatment of sprains depends upon the nature and severity of the injury, and upon the particular joint or muscle affected; but certain principles in their management are common to all. Our first aim should be to check or limit extravasation; after this to promote its early absorption; then to obtain satisfactory healing of the injured ligaments, muscles, or tendons; and finally to restore the normal movements to their fullest degree.

For the purpose of classification sprains may be divided into two large classes: (I) *Articular*; (II) *Muscular*. The former are concerned with injury to the joints themselves, the latter with the overstretching, dislocation, or rupture of muscles and their tendons.

I. ARTICULAR SPRAINS.

Articular sprains may, for clinical reasons, be arranged into two divisions or classes: (1) *Simple*; (2) *Complicated*.

1. SIMPLE SPRAINS.

These are cases where, as the result of some external violence, the soft parts are overstretched or torn across, and in which no gross lesion of bone is found.

In the simplest form of sprain, that known as *strain*, the soft parts are merely overstretched, and there is no true laceration. No swelling is found nor does it ever supervene, and the symptoms are merely those of pain, stiffness, and some loss of function.

In the more severe forms, in which there has been tearing as well as overstretching, we get swelling in addition to pain and loss of power. When the swelling comes on immediately, it is due to hæmorrhage; when later, it is merely due to serous effusion (deferred swelling).

Strains.—In this, the simplest form of sprain, in which pain and stiffness are the chief symptoms and in which there is no swelling, the patient usually seeks advice for the relief of pain, which may be intense. Absolute rest to the injured part is the first indication for the relief of pain, and this is best attained with the aid of strapping. Any resilient, though elastic and strong, material, such as wash-leather strapping, will serve the purpose. Many of the commercial forms of plaster are convenient and useful, providing they are smoothly, accurately, and carefully applied. As soon as pain ceases or is distinctly lessened as the result of the strapping, gentle stroking massage may be employed twice or even oftener in the day. The plaster need not be removed for this purpose, the massage being applied over it. This plan will usually reduce the pain. *Slight voluntary movements* should be encouraged from the first as soon as strapping has been applied. By these means stiffness, the other prominent symptom of strain, is readily and speedily overcome, and the healthy physiological nutrition of the joint or muscle is promoted, with complete and early restoration to function.

Sprains with "Immediate Swelling."—Swelling as the result of hæmorrhage is usually well established before the attendant is called to the patient. If, however, the case is seen at once or early, an attempt should be made to arrest or diminish further bleeding. Applications of *heat and cold* are seldom of any real service, have certain disadvantages, such as difficulty in application, and are, besides, not often at hand. The most efficacious and at the same time the most readily applied remedy is *firm elastic pressure*. Elastic pressure is suitable for all cases of extravasation, whether of small or great amount, whether immediate or deferred. It has the advantage of being absolutely safe, easily applied, and of universal application; it ensures perfect rest; and, if used at once, distinctly diminishes or completely prevents those secondary effusions that so frequently follow. Furthermore, it promotes to a marked degree the rapid absorption of all extravasated materials, the next urgent requirement in the treatment of every variety of sprain. Thus, by ensuring rest, checking or limiting immediate bleeding, preventing, or at any rate diminishing, secondary effusions, and promoting the absorptions of all extravasated materials, it serves the double purpose of meeting the two first and all-important requirements—checking hæmorrhage and removing extravasations. When properly applied it takes the place of a splint, and ensures rest.

The principle of applied elastic pressure is simple. The pressure applied being greater than that of the blood-pressure, it checks oozing or bleeding from the wounded vessels; and as the pressure exerted is greater than the pressure

of the extravasated material in the tissues, it serves to disperse the local extravasations by driving the fluid contents again into the general circulation, whence they are eliminated by the emunctories. The same principle is at work in relation to the serous effusion which is generally poured out secondarily into the synovial cavities of the large joints as the result of sprain. Personal experience bears out the statement that if elastic pressure is properly and immediately applied to an injured joint, the secondary effusion will be lessened to a certainty, if not entirely prevented, and to a far greater extent than when any other remedial measures are utilized.

Equable elastic pressure may be used for any form of extravasation or effusion, whether diffused or localized, whether of rapid or more gradual formation. It matters little whether the material is pent up within the capsule of the joint, or more loosely collected in the intermuscular and intercellular planes of the trunk or extremities. The action is the same, and its service is invariably efficient.

If the knee is taken as an illustration, and if we suppose that, as the result of a twist, its capsule has become distended with effusion, that most of the swelling appeared immediately after the accident, and that it continued to increase more gradually for some hours afterwards, such a knee will be found to have assumed the posture of slight flexion. In this position the capsule attains its fullest capacity and the surrounding muscles are relaxed so that the sufferer obtains the greatest relief.

This is nature's first attempt at procuring rest, the first requirement in treatment. To extend such a joint, and to fix it on a straight splint as is so often done, not only violates the principle of securing rest, but makes the patient very uncomfortable. The limb should therefore be allowed to assume that position which is most comfortable.

Fig. 72.—To illustrate elastic pressure applied to the knee.

Method of Applying Elastic Pressure.—The limb being slightly flexed and the joint relaxed, thick layers of cotton-wool or gamgee tissue, rolled round or cut into shapes, are adapted to it, and so applied that a complete coating of at least one inch thickness is attained. In regard to length, the material should extend for at least two inches above and below the outside limitations of the capsular ligament. Over this thickness of material a strong roller bandage is tightly drawn; an elastic though resilient material, such as domette or flannel, is all that is necessary. The bandage is drawn as tightly as possible so as to compress the wadding to its utmost, and then fixed so as to maintain and keep up the compression. The wadding should be smoothly applied and all creases avoided, or the pressure will be distributed unevenly (Fig. 72).

For the first few days it is of decided advantage to remove the bandage, even twice in twenty-four hours whenever possible. This enables the attendant to watch the local condition and the swelling, and to note the progress or otherwise of the case. It has been found that those cases in which the intermittent relaxation and compression is regularly carried out progress more rapidly than those in which the pressure is maintained more continuously. When the bandage is removed the joint becomes flushed with fresh oxygenated blood, and on its re-application the veins and lymphatics are once more compressed, so that their contents are emptied into the general blood-stream. The to-and-fro flushing and depletion is most beneficial, both in improving the nutrition of the limb and in assisting absorption.

In most cases the effusion will have disappeared in from four to five days ; but this result will depend largely upon the time at which treatment is commenced, and upon the care and attention that the attendant is able to give in carrying out the details.

Massage.—The writer seldom or never now uses massage until all or most of the effusion has disappeared. In ordinary cases, if it is properly and intelligently used, elastic pressure will effect all that massage can. Early massage often increases bleeding, and so causes delay. When large collections of blood are present in the tissues or joints, the process of absorption will take longer. It is in this class of case that massage combined with elastic pressure is more helpful. If the details in the application of elastic compression are carried out as here recommended, there will be neither complaints of discomfort nor feelings of strangulation experienced in the limb.

Massage is seldom used before the fourth or fifth day, and not till the effusion has nearly or quite disappeared. Gentle stroking massage is used for a few minutes after the bandage is removed, and the bandage reapplied. If at the next inspection the fluid is less and there is no heat, friction massage combined with stroking movements is allowed ; this breaks up coagula and hastens their removal.

A strong elastic rubber bandage should *never* be worn ; it is uncomfortable, causes too much compression, is hot, allows of no evaporation, and starves the joint of part of its blood-supply.

Rigid splints and fixed apparatus, whether of wood, plaster, or other material, should *never* be employed, even in complicated cases such as sprain-fracture. They are unnecessary, are nearly always harmful, and lead to stiffness and atrophy. Having got rid of the effusion, our next care is to restore the strength and mobility of the joint in the shortest time. Weak, stiff, and painful joints result usually from the presence of adhesions within or around the capsule. Much wasting of the surrounding muscles is apt to follow the use of splints and fixed apparatus. This is a serious complication, and must be prevented.

Active voluntary movements may be allowed from the very beginning. However slightly made, they are of primary importance in preventing adhesions and muscle-wasting, and in maintaining the proper nutrition of the structures of the articulation. In most instances they relieve rather than cause pain ; they should be permitted at first only in those muscles that have escaped injury, and their range should be limited.

Passive movements are only mechanical in action, and possess little, if any, physiological merit. By stretching out the synovial membranes and capsular ligaments they may aid in restoring to their natural position fibres that are curled inwards and likely to form new and faulty attachments. They are not to be compared with active movements as regards their influence on nutrition and repair. The normal nerve-impulses, transmitted to the region of the joint through the muscles, will do more than any mechanical means such as massage and passive movements to restore physiological action and maintain the process of repair ; and this is an important fact in dealing with any injured tissue.

Recurrent and Relapsing Cases.—When a distinct interval of hours or days occurs between the time of injury and the incidence of swelling, and in those cases where there is a recrudescence of symptoms after a period of apparent subsidence, the effect is probably due to *secondary inflammatory changes*. The treatment will depend upon whether or not there are present other signs of inflammation, such as pain on local pressure, heat, and increased tension.

In the absence of these acute symptoms, massage and movements may be used. Especially useful are gradually increased voluntary movements and exercises assisted by elastic compression. If there is pain and rise in surface-

temperature of the part, whether of joint or other region, *all movements and massage should cease at once*, and reliance be placed entirely on elastic pressure. The amount of pressure should be regulated according to the comfort or otherwise that it affords. Cotton-wool and a crêpe Velpeau bandage will give all the support and rest required. It is notably in these cases that the use of splints is harmful. The discomfort of the splint leads the attendant to imagine that more complete rest is needed; and so the splint is retained for an indefinite period, with the result that adhesions form, muscles waste, and a painful, stiff, and crippled joint remains. These so-called relapsing cases are not infrequently associated with, and dependent upon, the health of the individual.

Those of a gouty, rheumatic, tuberculous, and even syphilitic tendency are subject to effusion into their joints, the injury being merely the starting and localizing cause. Hæmophilia must not be forgotten. It is of the greatest importance to make careful inquiry into the histories of all recurrent or relapsing cases, to search diligently and carefully for any other clue which may be corroborative of a suspicion as to a constitutional taint. In a large percentage of cases such taint will be readily found, a fact which will greatly influence our views of the local treatment.

These constitutional cases must be treated, according to their nature, by general as well as by local means. In *rheumatism*, the salicylates are usually successful in relieving pain. With a history of *gout*, the iodides or even colchicum exhibited internally are useful, whilst vasogen-iodine is an excellent local application. In *syphilis*, small doses of mercury in pill are preferable to the depressing iodides; and salvarsan would seem to promise well. *Hæmophilia* requires absolute rest; in three recent cases, injection of horse serum was eminently and rapidly efficacious, and far outstripped any results formerly attained by prescribing calcium lactate and other drugs; fortunately this complication is rare. *Tuberculosis* as a sequela and complication is not unknown, and must never be lost sight of; personal experience teaches that it is not, however, as frequent as is generally taught.

Tension in Joints after Sprains.—The “tension in joints” of various writers is a condition which may follow a joint injury immediately, or come on gradually some days or weeks later. The joint becomes distended to its fullest with a fluid effusion. When immediate, it results from hæmorrhage; when later, from secondary and inflammatory processes. Inflammation may follow local injury or any of the constitutional states (gout, rheumatism, etc.) already enumerated. Local heat is always a symptom of tension, but it may be so slight as to escape casual observation; as a rule, the more rapid the incidence of swelling, the more evident the heat locally. Pain, often constant, and readily increased by any form of movement, is complained of. This is often severe, and gives rise to sleeplessness, loss of appetite, and general irritability. In the more severe cases, one of two lines of local treatment is adopted:—

- i. When there is no definite constitutional contra-indication, and in the absence of hæmophilia, the severe pain will be relieved at once by aspiration under a general anæsthetic. An ounce or two of serum withdrawn is quite sufficient, and as a rule recovery follows more quickly after partial removal of the contents than after complete and full withdrawal. Partial removal, followed by elastic compression to the joint, will usually relieve pain at once; and it will establish a condition suitable to rapid re-absorption of the effusion.

- ii. When aspiration or any other form of operation is contra-indicated or objected to, the radiant-heat bath should be tried. In a certain proportion of cases it is useful, whilst it often fails entirely. When dry heat is unobtainable, the old-fashioned application of hot fomentations with laudanum or lead lotion may have a soothing effect. As soon as the tension is subsiding, elastic pressure

followed by gentle massage is indicated. So long as pain and local heat remain, *all movements must be prevented.*

In the long-continued cases, and where there appears every prospect of disorganization or weakening of the joint from its prolonged distention, and subsequently from advancing atrophy of the muscles, arthrotomy and digital exploration of the joint itself may become necessary and even advisable. No open operation should, however, be lightly considered or undertaken when the knee or shoulder-joint is concerned; it is only to be adopted in the worst cases, after all other measures have failed, and where the joints must otherwise be permanently damaged. Digital exploration will often reveal a troublesome adhesion, or other defect, productive of the whole mischief. To open the knee-joint, the clinician must be one who has the fullest confidence in his surgical technique; for unless absolute cleanliness and thorough asepsis can be guaranteed, arthrotomy should never be practised.

2. COMPLICATED SPRAINS.

We may classify these as follows :—

a. Large collections of blood (*hæmatoma*) may form, owing to the lacerations of muscles and other soft tissues, and so complicate an otherwise simple sprain.

b. In a few cases nerve trunks, or their branches, become injured, so that pain, paresis, palsy, and even atrophy and neuritis, may supervene, and lead to crippling.

c. Sprains may be complicated with injuries to the bone or periosteum, as when portions of bone or epiphyses are detached, or when the bones are fissured or even crushed (*sprain-fracture* or *fracture-sprain*).

d. In the joints in which inter-articular cartilages are found, as in the knee, these structures may become loosened or partially detached, torn, and displaced (*sprain-dislocation*).

A sprain complicated with injury to a bone, with displaced, torn, or otherwise detached interarticular cartilage, with gross nerve lesion, or with extensive extravasation, will require special and careful handling.

a. Hæmatomata.—Large hæmatomata, if superficially placed and if some distance from the joint, are best treated either by aspiration or by a free incision, with a removal of clots and immediate suture. Drainage is seldom required. Elastic pressure may be applied with advantage over the absorbent dressing. When the wound is healed, massage to the peripheral parts, whilst avoiding the scar, will expedite the cure. Extensive collections of blood may form in the buttock and upper thigh, axilla, sheaths of recti abdominales, and psoas and iliacus muscles. In articular sprains, the bleeding is generally arterial and from the periosteum; whilst in tears in muscles, it is more usually venous in character.

b. Sprains Complicated with Injury to Nerves.—In the lacerations of muscles as in the overstretching of ligaments, nerves are injured. Nerve injury often escapes the attention of the surgeon at first, and may not be detected until quite late in the management of the case. When pain radiates along a nerve trunk, or there is marked paralysis, nerve injuries do not escape notice as they do when small branches between the muscles of the trunk are overstretched or torn. Numbness and tingling are indicative of pressure; they usually pass off in about thirty hours, and are relieved by massage or the more direct removal of the pressure.

When pain radiates along the course of a particular nerve or group of nerves, absolute and complete rest is imperative. Massage and movements do positive harm, and herein lies the difficulty in treatment. In simple sprains and strains, massage and movements are advocated, and fixation disallowed. In this

particular complication, routine movements and exercises, as recommended by the bone-setter, are the *worst possible treatment*. In this class, absolute rest must be given until the pain is subsiding or has disappeared, though not necessarily with splints. After this, gentle massage should be cautiously tried, and followed by graduated exercises. If the pain should be increased, then movements must cease. A good alternative plan to the employment of massage is the use of Bier's bandage, and in chronic cases it should be applied two or three times a day. At first progress is slow as a rule, but the pain subsides more rapidly later. The repeated and alternating flushing and depletion stimulates the local circulation and overcomes the local neuritis. In the more chronic forms resulting from neglect, static electricity may succeed when massage fails. Blistering, and even the actual cautery, along the course of a nerve trunk has been used to diminish the intensity of the pain. Opiates and similar drugs should be avoided in all such chronic cases. One of the most rapid and obstinate forms of wasting of muscles results from gross nerve lesion; it is more rapid, more complete, and more lasting than any of the forms that result from mere disuse.

c. Sprain-Fractures and Fracture-Sprains.—The treatment of this class differs in certain particulars from that of a simple sprain. With portions of bone detached, or fissured, or crushed, it becomes necessary to give sufficient rest to restore bony union. Elastic pressure is as useful for this purpose as in simple cases, nor is a splint usually necessary. Forcible passive movements *must be avoided*, or stiffness and delayed repair will result; whilst voluntary movements must be confined at first to remote parts and not allowed to play directly upon the injury. It is obvious that any force which will produce separation of fragments, or stretch early union in tissues unduly, will delay repair.

Passive movements will also be harmful unless very limited in their range. Whenever they cause pain they must be discontinued. The teaching that *passive movements and massage* is the correct line of modern treatment in fracture-sprains has led to much mischief; many joints have been made permanently stiff because the attendant, in his anxiety to carry out this teaching, has overdone the movements, and has increased callus formation. The practice of passive movements should be as limited as possible, and used mainly to put the particular joint through its various movements *once*; and whenever this causes pain it should be desisted from and not repeated. When pain is complained of, passive movements do more harm than good. Voluntary movements and more regular exercises are more useful later in the case—that is, after the union is complete. When there is fracture without separation, as in fissures in the lower tibia or fibula or in the metacarpals or small carpal bones, and where there is but slight effusion, strapping as for a simple sprain is convenient and sufficient. The main difference between the treatment of simple sprains and that of sprains complicated by fracture is that, in the former, voluntary or active movements are permitted and encouraged from the *earliest stages*, and are essential to speedy recovery; in the latter, they must be secondary to gentle passive movements and massage, and allowed only in the later stages. Massage is valuable in both classes and, speaking generally, may be begun early. In simple sprains, passive movements are of secondary importance; whilst in those complicated with fracture, they are, perhaps, of greater service than voluntary exercises; especially is this true of the early treatment; active exercises are helpful to both classes in the later stages.

In every case in which there is reason to suspect bone injury, a radiogram should be taken; otherwise a mistaken diagnosis may be made, and unsuccessful treatment result.

d. Sprain-Dislocations.—The treatment of sprains complicated by the presence of loose bodies in the joint is referred to below.

II. MUSCLE SPRAINS.

Muscles and tendons are liable to injury in many ways ; thus, they may be strained or sprained from undue stretching, become herniated through splits in their enveloping fasciæ, displaced or dislocated from the groove in which they normally run, partially ruptured, or even torn across.

The tendons around a sprained joint usually suffer, though to a less extent than the ligaments which bind the bones together. When a muscle is over-stretched or partially torn it is said to be strained or sprained. Athletes suffer more from muscle sprains than labourers. The injury is usually the result of sudden violence when a muscle or group of muscles is taken unawares and brought into action. There are many examples, e.g., "rider's sprain," affecting the adductors of the thigh ; "jumper's sprain," the hamstrings or calf muscles ; "tennis elbow," the pronator radii teres ; "driver's or angler's elbow," the common origin of the supinator extensors of the forearm ; "labourer's back," with which the sacro-lumbalis is concerned ; and "bowler's side," affecting the oblique muscles of the abdomen. Each of these popularly-named injuries is an example. The symptoms are pain, tenderness on pressure, and inability to carry out the particular movement or movements concerned in the injury. As a rule recovery is complete, though it may be long delayed.

The treatment consists in discontinuing the movements which produce pain or spasm when the muscle is examined, and in *strapping* the painful part firmly and completely so as to allow the individual to use some of the muscles freely without putting strain upon the injured ones (*Fig. 73*). Massage and electric vibration may be employed in addition, and applied over the strapping.

Fig. 73.—Strapping for a sprained ankle. It is applied to the skin direct, not over cotton wool.

Strain is meant, in muscular as in articular sprains, to indicate the less severe disability.

Hernia in Muscles is comparatively rare. The protrusion is oftener through a longitudinal slit than through a transverse tear, and as a rule requires little more in the way of treatment than strapping and massage. When the protrusion is large and inconvenient, open operative methods may be required for complete anatomical restitution.

Dislocation and Displacement of Tendons is also comparatively rare. The commonest examples are displacement of the peroneus longus and tibialis posticus tendons, with lodgement on to the external and internal malleoli respectively ; and of the long head of the biceps flexor cubitis inwards or outwards from the bicipital groove of the humerus. The small tendons at the back of the neck are occasionally displaced over the posterior tubercles of the transverse processes of the vertebræ. These are all the result of violent twists during certain specialized movements.

The treatment of these conditions, after the reduction of any displacement, is usually by rest and strapping. When relapses occur, it may be necessary to operate to refix the tendons into their grooves.

Rupture of Muscles and Tendons is fairly common, and usually occurs near to their points of attachment to bone or where the muscle fibres join the

tendinous ; it may result from outside injuries such as blows or crushes, but it is more generally occasioned by sudden, indirect, and involuntary forms of violence.

When a muscle ruptures, its fibres contract and retract so as to leave a gap. The amount of separation depends mainly upon the length of the muscle. The tears are usually only partial. As the result of tearing there may be much ecchymosis and swelling ; the proximal fibres are drawn upwards, and a gap may be seen and felt. The symptoms are not severe, and the diagnosis is often evident on inspection.

Treatment is directed towards supporting the tear with strapping, unless the swelling is great, when elastic pressure should be used at first. As the tears are usually only partial, this line of treatment is generally suitable and efficient.

In severe and complete tears in important muscles, *immediate suture* may be necessary, and gives better results than secondary suture. When the muscle is small and unimportant, position and strapping usually suffices, if supplemented later by massage and exercise.

SEQUELÆ OF SPRAINS.

Many permanent disabilities result from faulty or careless management of sprains, whilst others cannot in any way be laid to the fault of the surgeon. They therefore fall into two groups : (1) *The avoidable* ; (2) *The unavoidable*.

1. **Avoidable Sequelæ.**—Among these are stiff and painful joints, recurring and relapsing synovitis, atrophy and wasting in muscles, crippled and deformed joints, improperly-united muscles and tendons, and ankylosis. Nearly all these disabilities arise from undue and over-prolonged fixation and a disregard for the promotion of early movements. Sprains are often treated as if they were fractures. Joints are designed for movement and not rigidity, and should be treated accordingly.

Ankylosis is rare except in those cases which readily yield to "breaking down" under an anæsthetic. Such a condition usually follows upon a sprain-fracture, the true nature of which was not recognized at the time, and which was probably treated by extensive and ill-advised movements. The enforced and oft-repeated movements give rise to increased formation of callus in the neighbourhood of the articular surfaces ; this not only tends to mechanical locking, but affords opportunity and place for new and strong adhesions to form.

2. **Unavoidable Sequelæ.**—These permanent and remote consequences, though beyond the control of the surgeon as regards prevention, are of interest in so far as they influence prognosis. They consist of local paresis and paralysis, ossifying myositis (muscles), osteo-arthritis (articular), and loose bodies in joints.

Paresis and paralysis may be treated by massage and electrical treatment, which may be of service if continued for a long time.

Ossifying myositis is best kept as quiet as possible. Friction and violent massage is harmful and should be carefully avoided. The tendency is for the bony deposit to be *re-absorbed* in time if the limb is kept quiet, so that violence and continued exercises must be prohibited. If the bone plaque is painful or inconveniently situated, total excision of the muscle may be required.

Osteo-arthritis, the true pathology and nature of which is as yet improperly understood, is of different types. The treatment in the case of elderly people must be adapted to prevention in the first instance, especially by removing every cause of chronic irritation, and later on, to meeting symptoms as they arise. Drugs, baths, vaccines, thermal applications, electricity, various exercises, have all been tried, and with varying success. The outlook is not a bright one when once the condition is fairly established ; and it is only in the early cases that cure is to be expected.

Loose bodies, of whatever nature, whether solitary or multiple, whether occurring as the result of disease or trauma, should be removed by operation as soon as they give rise to symptoms of pain and stiffness, and as soon as the diagnosis is clear. No other means of treatment is curative. The danger of osteo-arthritis supervening from their chronic irritation should always be borne in mind.

SPECIAL FORMS OF TREATMENT.

Bier's Hyperæmic Régime.—This is undoubtedly useful as a method of treating sprains. Its chief therapeutic value lies in promoting the absorption of effusions; and it is highly extolled by some when rapidity of absorption is an urgent necessity. *Active hyperæmia* is superior to prolonged *obstructive hyperæmia*, even when the latter is preceded or followed by massage. Relapses are not uncommon after hot-air treatment, and the result on the whole cannot be compared with those obtained by elastic pressure, either as to rapidity, efficiency, or simplicity.

Obstructive hyperæmia, by removing the effusion, has been of help in a few cases of chronic articular synovitis.

Mechano-Therapy.—The chief application of this form of treatment is for overcoming stiffness and atrophy in the latest stages of injury; it is of but little service in the earlier management. Mechanical exercises encourage patients to persevere in movements when they often would not do so otherwise, and they are helpful in cases that have been mismanaged; but no mechanical exercises are as efficient in overcoming muscular atrophy or promoting regeneration of muscle as are active voluntary movements.

Injections of Fibrolysin.—These injections have not come up to expectations. The softening effects on fibrous tissues is not as great as was at one time thought, and there are some decided disadvantages, such as changes in the blood; even fatal cases of purpura have been recorded as following its administration.

Kataphoresis.—One of the most important results of electrolytic treatment is the resolving influence on cicatricial formations when a kathodal stream of solution of sodium chloride is employed. Joints completely ankylosed (fibrous) have been known to regain their function rapidly without forced movements or pain. The electrolytic method is useful also for the administration of the specific remedies in old sprains complicated with gout, rheumatism, or other constitutional affections. The more superficially placed the joint, the more amenable it is to the method. The use of kataphoresis as a therapeutic measure is daily becoming greater; doubtless it will be found helpful in some of the most obstinate cases, and even in those which were constituted surgical failures.

R. H. Anglin Whitelocke.

SPRAIN-FRACTURE AND SPRAIN-DISLOCATION.—(See SPRAINS.)

SPRUE (Psilosis).—Absolute rest of the body, and as complete rest of the intestinal tract as is possible, are the essentials in the treatment of this disease. Also the strength must be maintained.

The most important part of the treatment is dietetic.

1. *Milk Treatment.*—The milk should be sipped frequently, but in small quantities at a time. It is best to begin with 5 oz. every two hours, and as the motions become less frequent, to increase the amount gradually and also lengthen the intervals. Under this treatment, though the amount of milk taken is large, there should be constant hunger. After a time, the motions, though not normal, become formed. Constipation must be carefully guarded against. If there be

any tendency to it, small doses of castor oil (1 dr.) should be given. This treatment in young adults is highly successful, but the craving for food is so great that many persons will not keep strictly to the diet, and therefore it is best carried out in a hospital, or where the patient is under control. In old persons the digestion is so feeble that, though the severity of the symptoms may abate, the debility and emaciation increase. Such cases are very difficult to deal with, as any increase in the diet brings on a recurrence of the disease. In such cases a combination of this diet with fruit or meat juice may be advantageous.

During convalescence the diet may be varied gradually. Stewed apples, fish, and (later) small amounts of farinaceous food can be allowed. The return to an ordinary diet must be made very gradually, and if any symptoms of relapse occur, the milk diet must be resumed. The patient must never be allowed to become constipated; olive oil or castor oil are the best laxatives to employ. Drastic purgatives must be avoided. Stimulants are contra-indicated.

2. Another dietetic method, which may be employed when a pure milk diet is not tolerated, is the "*fruit cure*." Large quantities of fresh or preserved fruit without sugar, such as bananas, strawberries, pears, apples, grapes, are taken.

3. *Meat Diet* has many advocates. The meat must be either raw or very lightly cooked. In a very severe case, feeding every hour with raw beef juice may be necessary. Ordinarily 5 oz. of pounded meat should be given three times in the day, and home-made beef jelly or calf-foot jelly every two hours between feeds. The jelly should be taken at night also if the patient is awake, and the first thing in the morning. In a few days the diet may be increased and poached eggs given. Strawberries go well with this diet. Three or four pounds of fresh strawberries can be taken between meals. Soup made from liver seems of benefit in some cases.

Drugs are of little value. A preliminary aperient should be given, and subsequently the patient must not be allowed to become constipated. Opium is injurious, and so is alcohol. Any of the digestive ferments—pepsin, pancreatin, papain—may be used, but the result of their administration is not marked.

The use of yellow santonin, 3 to 5 gr. in a teaspoonful of castor oil, for six successive days, has been strongly advocated, and seems to be of value in some cases.

Intestinal antiseptics, such as β -naphthol, are used by some observers. For the anæmia, injections of arsenate of iron (Squire's liq. ferri arsenatis), as recommended for tropical anæmia, may be employed.

The mouth affection may cause trouble, even when the patient is improving otherwise. Weak carbolic mouth washes (1 per cent) or weak boracic lotion (5 per cent) are useful. When the condition of the mouth is very painful, the ulcers may be brushed with cocaine (5 per cent) before food is taken. Chlorate of potash 10 gr. to the ounce as a mouth-wash, and subsequently swallowed, relieves the dryness and often causes a rapid improvement in the condition of the mouth. Oral sepsis from carious teeth or from pyorrhœa alveolaris, and irritation from irregularly placed or broken teeth, must be remedied.

C. W. Daniels.

SQUINT.

Paralytic.—Our efforts must be directed towards treating the cause of the paralysis, potassium iodide, salvarsan, mercury, salicylates, or colchicum being given according to the nature of the disease.

Locally, the constant current may be useful in maintaining the nutrition of the muscle. Prisms occasionally assist the patient, but these only relieve the diplopia in one position of the eyes. The discomfort of diplopia is, as a rule, overcome only by wearing a ground glass or shade over the affected eye. In some old-standing cases an operation may be attempted.

Concomitant.

A. *Convergent Squint*.—Our object must be not only to correct the deformity, but to set up or restore binocular vision whenever this is possible. The cause of concomitant squint being a faulty fusion of the retinal impressions received from the two eyes, combined with imperfect muscular balance, the principles we have to keep clearly before us are : (a) to remove any strain on the accommodation which is upsetting the muscular balance, by ordering glasses to correct any refractive error ; (b) to train the acuity of the squinting eye ; (c) to train the fusion sense. If the acuity of vision in both eyes is good, and the fusion sense established, then, as soon as the eyes are straight, binocular vision will be gained.

When one eye is very amblyopic, and remains so in spite of our attempts at training it, we can never hope to get binocular vision ; again, in certain cases the fusion sense can never be acquired, as in most cases of true alternating squint, and here also binocular vision is unattainable. In these two classes all we can hope for is to cure the deformity. In most cases of squint, however, the attempt should be made to attain binocular vision. *We cannot begin too early* ; owing to neglect we often have to start too late. The best time for training the acuity of the amblyopic eye and the fusion sense is in the first seven years of life, and we should begin as soon as the squint appears.

The order of our treatment should be :—(i) *Test refraction* under atropine, and order correcting glasses for constant wear ; (ii) *Train the squinting eye* by blocking the good eye with a pad or a black goggle, or paralyzing the accommodation of this eye by atropine ; (iii) *Train the fusion sense* with the amblyoscope, stereoscope, or by “bar reading” ; (iv) *Measure the angle of the squint* at regular intervals ; (v) *Operation*, when this is necessary.

i. The full astigmatic correction, and not less than 0·5D below the full hypermetropic correction under atropine, should be worn constantly, except at bedtime. (A baby even under one year may safely wear glasses in special frames. These have short sides which end in loops, to which are attached tapes to tie behind the head. When a baby is too refractory for a retinoscopy to be done, the good eye should be blocked with a pad : *vide infra*.)

ii. If the squinting eye is very amblyopic, the good eye should be blocked all day for at least two months, either with a pad of gamgee placed between the eye and the glass, which is fixed with strapping or a bandage ; or by a special pair of glasses which have a clear lens over the squinting eye and a black opaque goggle over the good one. If marked improvement has not taken place in two months, training of this eye can be abandoned as hopeless. If the eye is not very amblyopic, a useful method of training is to put a little atropine ointment (4 gr. to the ounce) once a day into *the good eye only*, to paralyze its accommodation. Then, when wearing the glasses, the good eye can see in the distance but not close to, while the squinting eye, having its accommodation intact, can see close to, and will therefore be used and trained.

iii. Training of fusion sense. (a) While the squint is present, this can only be done by means of the “amblyoscope,” or where the squint is slight, by a stereoscope provided with a pair of strong rotating prisms, and under the immediate supervision of the doctor himself (see Worth on “Squint”). (b) When the eyes are straight, fusion is trained by means of the stereoscope and Krolls pictures, and by “bar reading.”

iv. If glasses bring the eyes straight, training both of the acuity and fusion sense should be continued till perfect binocular vision is obtained. If the squint persists, the angle should be measured from time to time to see if it is diminishing or remaining stationary.

v. No operation should be performed till glasses have been worn for at least

a year, and not till at least six months have elapsed since any improvement in the squint has taken place.

For squints of less than 25° , either an advancement of the external rectus alone or tenotomy of the internal rectus is advisable. For more than 25° we combine the two operations. *After operation* the training must still be maintained, to acquire, if possible, binocular vision. All operations for squints are much more satisfactory and certain in the results if they are done under cocaine without a general anæsthetic.

B. Divergent Squint.—The refraction should be tested and glasses worn regularly. If the divergence disappears, we try to train the eyes to work together as in convergent squint. Unfortunately cure with glasses is not very common, and an operation then has to be performed; and even if the operation bring the eyes straight, binocular vision is seldom obtained. Tenotomy of the external rectus affords us only about 5° , so that tenotomy of both external recti is only suitable for divergence of 10° or less. For higher degrees, advancement of the internal rectus, combined with external tenotomy, is necessary. It is not advisable to operate for divergence of highly myopic eyes. *W. Tindall Lister*

STAMMERING.

Preliminary Considerations.—In order that the rationale of the treatment of stammering shall be clear, it is necessary to summarize briefly the etiological and pathological considerations upon which it is based. In the circumstances we shall state the facts dogmatically, and refer the reader elsewhere for the evidence in support of them.

Stammering is due to spasm of the respiratory muscles in the act of speech. The over-action of the respiratory nervous centres producing the spasm rapidly spreads into the centres controlling the laryngeal and oral mechanisms, and leads to spasm of the muscles of the throat, mouth, and face. In bad cases the disturbance may spread even so widely as to cause spasmodic movements of the arms and other parts of the body. Thus the spasmodic action of the articulatory muscles, although, as a rule, the most obvious phenomenon of stammering, is, in the great majority of cases, really a secondary event, due to the spread of a disturbance beginning in the respiratory mechanism. This fact must never be lost sight of in treatment; and where the patient is old enough to apprehend it, it should be carefully explained to him; though, when the articulatory difficulty is extreme, it will not be easy to convince him that the primary seat of his trouble is elsewhere.

The causes which lead to stammering are twofold: (1) *Predisposing*; and (2) *Exciting*.

Of the former a neurotic inheritance is one of the most important, and a family history of stammering is not infrequent.

Under the latter head we have anything tending to interfere with and embarrass respiration early in life, as for example adenoids. Such an interference leads to faulty modes of breathing and a low respiratory volume or "vital capacity," which react unfavourably on the controlling centres. The result is an irritability and irregularity in the action of these centres, which are especially manifest during speech, when the demands made on the respiratory mechanism are highly complex and, unless met in the best way, somewhat exhausting.

It will be evident, then, that treatment must be directed to (1) The removal, as far as possible, of respiratory defects, and such of the causes which have led to stammering as may still be operative; (2) The education of the amended mechanism until spasm no longer tends to occur, or, if it does, can be prevented by voluntary control. In other words, treatment must be (1) *Prophylactic*;

(2) *Educative.* These two general indications are of equal importance, although the first is liable to be neglected—and is, indeed, always neglected by the numerous quacks who hold so large a share of the public confidence. It is unreasonable to look for any permanent benefit from educative treatment so long as the causes which have led to the derangement are in active operation. And further, while educative treatment is always difficult, and demands both patience and experience, the necessary prophylactic measures are readily taken, and may alone lead to considerable improvement in speaking.

1. **Prophylactic Treatment.**—The influence of a neurotic inheritance so often lying at the bottom of the trouble cannot, of course, be done away with, but it should be vigorously combated by measures directed to the control of the general health of the patient, and by dealing with any existing causes of nervous irritation or depression. Chronic dyspepsia, for example, is not infrequently a potent cause of nervous irritability, and highly detrimental to a stammerer. A sufficiency of fresh air and exercise must be secured in all cases. Regular work is very desirable. Too little work is probably as bad for stammerers as overwork, as discouraging the development of powers of mental control and concentration, which imply the rigid limitation of nervous discharge to the part of the brain required for any particular action, the very thing the stammerer so egregiously fails in during speech. Moreover, the habits of a daily routine will be very valuable to the patient, in that he will almost certainly have to undertake daily exercises for some years if he is to overcome completely his disability. In a word, it is important to do what is possible to increase the nervous tone and self-control of the patient, and such details of hygiene as the open window at night will well repay the attention given to them.

Having enquired into the general health and mode of life of the patient, and devised the appropriate hygienic measures, the chest and respiratory passages should next receive special attention. There should be a perfectly free respiratory passage through the nose. This may be roughly tested by asking the patient to blow out a match held about a foot from each nostril in turn, the mouth being shut and the other nostril closed by the finger. Adenoid vegetations in the nasopharynx are very common in stammerers, and although since atrophied, were frequently the original exciting cause of the condition. Thus in our analysis of twenty-seven consecutive cases in Mrs. Behnke's clinic, over 50 per cent presented a clear history of some nasal obstruction. Adenoid growths, with or without enlarged tonsils, were the most frequent cause. More rarely a deflected septum, a spur, or chronic hypertrophic catarrh, may be the cause of obstruction. In one case, lately recorded by Mrs. Behnke, a button had been pressed into the back part of the nose by the patient when a child. It had remained there a year or more, during which time the disturbance of speech began. Whenever there is obstruction there can be no doubt that the first thing to be done is to remove it, and then to instruct the patient to keep his mouth closed, and to breathe through his nose. Without removal, experience has shown that exercises of whatever sort are only waste of time.

The lungs should be carefully overhauled. A slight chronic bronchitis, such as is ignored by most people in the winter time, is of great disadvantage to the stammerer. Even a laryngeal catarrh, leading him to spare his voice, will encourage stammering.

Nearly every stammerer has a low "vital capacity" (complemental + tidal + supplemental air): thus, when correlated with stature in a series of 46 male stammerers, it was found to average 35 per cent below normal. This would seem to imply that the amount of "tidal air" which the stammerer has conveniently at his disposal is also small, and perhaps a direct result of this is the not uncommon habit of speaking during *expiration*. The existence of

a low capacity is to be sought for in the type of respiration. It is thoracic (often upper thoracic) rather than abdominal; that is, costal rather than diaphragmatic. Dr. Arthur Keith has shown that it is by the descent of the diaphragm that the lungs are most effectively aerated, and that smaller movements of this wall are required for the respiration of a given quantity of air than of any other wall of the thoracic cavity. It is important for a stammerer to have as much wind as he requires for his sentences with the least possible effort. Hence he must be taught to make full use of his diaphragm in breathing; and in order to secure the maximum degree of efficiency, to this should be added the great thoracic enlargement which accompanies a free elevation of the lower costal wall. As the diaphragm contracts, it forces the abdominal contents downwards, and the muscular abdominal wall relaxes to make room: as the diaphragm relaxes, the contraction of the abdominal muscles restores the parts to their former position; for it must be remembered that expiration is as much a complete muscular act as inspiration, and not merely a passive relaxation or elastic recoil. Thus, in the abdominal type of breathing, the range of movement of the belly wall during breathing is, to an extent, a measure of the descent of the diaphragm. When, on the other hand, there is much expansion of the thorax owing to the excursion of the lower ribs, the upper end of the abdominal cavity becomes considerably widened, and the contraction of the diaphragm now causes less protrusion of the anterior abdominal wall. Experiments with a spirometer show that it is this combined lower costal and diaphragmatic expansion which yields the greatest capacity. For purposes of training it is best at first to direct the patient's attention to the diaphragmatic and the costal movements separately. He should be given the two following exercises, which may be performed either standing or lying flat on the back.

1. *For Diaphragmatic Breathing.*—Placing one hand flat on the epigastrium, take a series of slow deep breaths, blowing out the belly as much as possible at each inspiration, and allowing it to sink in at expiration. In this, as in all the exercises described below, the breath should be taken in through the nose and let out through the mouth, thus imitating the proper manner of breathing in speech.

2. *For Costal Breathing.*—Place each hand so that the backs of the fingers rest on the seventh or eighth rib in about the nipple line, as shown in *Fig. 74 a*, and take a series of deep breaths, magnifying the costal movement as much as possible. In each exercise the attention must be riveted on the motion of the part beneath the hand.

Having practised these exercises separately, the patient should next endeavour to combine the two, and with one hand on the belly and one on the chest, to magnify the excursions of his diaphragm and ribs simultaneously.

When the patient has made some progress in diaphragmatic breathing he should be given a series of exercises which, as experience has shown, will both develop the muscles of his chest and increase his vital capacity. Such a series has been devised by Mrs. Emil Behnke, and fully described in her book on "The Speaking Voice"; but they form such an essential part of the treatment of stammering that it will be well to describe here a few in detail. These exercises may be practised in ordinary attire, provided there is nothing tight (such as corsets) round the waist or chest which can in any way impede the respiratory movements. Light dumb-bells may be used with advantage, but are not essential. While performing each exercise the patient must see that the accompanying respirations are full and deep, with ample diaphragmatic and thoracic play.

1. Stand upright and place the arms at the side in the military position of attention. Now raise both arms slowly into position *b*, *Fig. 74*, and from this

a

b

c

d

e

f

h

k

Fig. 74.

carry them right up over the head ; during the movement take (through the nose) a long inspiration. Now reverse the movement and lower the arms through position *b* back to the side again ; at the same time slowly let out the breath (through the mouth).

2. Raise the arms from the side slowly to position *c* ; at the same time take a deep breath. Swing the arms sharply back in a horizontal plane into position *b*, while forcibly expelling the breath ; then drop them to the side again.

3. Begin with the arms in position *d*. During inspiration slowly extend them horizontally, setting the shoulders well back and "opening" the chest. During expiration, slowly return to the flexed position. The second (extended) position in this exercise is similar to *b*, except that the palms of the hands are turned up.

4. Stand upright with the arms to the side, and slowly swing over into the position shown in *e*. During this movement take a full breath. Now slowly swing back again and let out the breath. Repeat the movement on the opposite side.

5. Standing in position *f*, swing the arms right over the head back into position *h* while drawing a deep breath and letting it out again. Swing back again into position *f*, and again take a breath and let it out.

6. Lie at full length prone on the floor. Flex the arms and, keeping them close to the side, place the hands on the floor, palms down. Press the body up to arm's length into position *k*, keeping the trunk rigid the while, and draw a deep breath. Lower again to the floor while breathing out. Those patients for whom the exercise is too arduous in this form may practise it leaning forward against a wall or the back of a chair.

Each of the above movements should be repeated six to twelve times ; and at first the exercises may be practised with advantage three or even four times a day. When the patient has reached a stable condition with little or no stammer, the performance of the exercises for a few minutes night and morning may be sufficient.

Before considering the education of the vocal mechanism in the act of speech, we would strongly urge the advisability of applying to all cases, at an early age as possible, some such prophylactic treatment as we have indicated. And we would most emphatically protest against the common practice of withholding all treatment from stammering children until they are old enough to appreciate and profit by educative treatment. Stammering usually begins at about the fourth or fifth year, and it is probable that the removal at this age of large tonsils or adenoid growths, and the exhibition of simple breathing exercises, would in many cases be sufficient to lead to the disappearance of the habit before the channels of vicious nervous discharge had become firmly established.

2. Educative Treatment.—The treatment that we have so far described tends only indirectly to lessen stammering, and we have still to consider measures for directly preventing the respiratory spasm which, spreading from the vocal to the articulatory mechanisms, is the immediate cause of the disturbance in speech. The rational methods which have been devised to attain this end aim at establishing, by suitable exercises, a voluntary control by the higher centres of the whole or part of the mechanism of speech. Such exercises fall into two distinct classes.

1st Class.—Exercises in which the attention of the patient is directed towards the result produced ; the method of producing it being thus indirectly controlled.

2nd Class.—Exercises in which the attention is directed to the actual movements of some part of the mechanism of speech, so as to predetermine the result produced.

For example, if a passage be read aloud slowly and with exaggerated clearness

and precision of enunciation, it would form an exercise of the first class in articulation. If, on the other hand, the reader has acquired a knowledge of the exact position that the tongue and lips should occupy for the pronunciation of each letter, and in reading the passage he were consciously to put his articulatory apparatus through the requisite movements, then the exercise would be one of the second class. The value of exercises of this latter class is very great, provided always *they are of that part of the mechanism of speech which is the seat of the primary disturbance*. Exercises of the first class may at the outset be very difficult for a stammerer, the indirect subconscious control of the seat of the disturbance being insufficient to prevent spasm. From exercises of the second class, however, he soon acquires voluntary control of the disturbance at its point of origin, and can in this way deliberately prevent it.

In the great majority of cases stammering begins, as we have stated, with a delay in the action of the respiratory mechanism, and hence the exercises we should naturally seek are such as will control especially the respiratory function. The patient must be told from the outset to ignore his articulatory difficulties, and to attend only to his respiratory movements and to the character of his vocalization, with the assurance that his articulation will then look after itself.

Now, there is a quality of speech which is solely determined by a proper and orderly management of the breath, namely rhythm. It has long been observed that stammerers read verse with greater facility than prose, and advantage has been taken of this fact in their treatment. Colombat, Merkel, and, in recent years, Mrs. Behnke, have taught the advantage of emphasizing the natural rhythm of all speech. A rhythmical mode of speech is neither offensive nor *b zarre*, indeed it is characteristic of the best speakers. "The more natural and flowing the diction," says Mrs. Behnke, "the more evenly and regularly falls that pulsation to which the name of 'rhythm' is now usually applied." The observance of rhythm implies the raising of the intensity of the sound on the syllables on which the accent falls, and the maintenance of a certain time relation between those syllables. This rise in intensity is solely dependent on a more powerful blast of air at the moment, that is, on an instant acceleration of the expiratory act. In the adoption of a rhythmical in place of an arrhythmical mode of speech, the demands on the respiratory muscular system are much simplified, for the variations in its rate of movement are reduced from an irregular to a regular series, i.e., to a series which the stammerer subconsciously forecasts independently of the words, and which is, therefore, less readily disturbed. Thus, whenever the patient accentuates and prolongs the rhythmical syllables in his speech, he is indirectly exercising the respiratory act in a series of augmentations and retardations—an exercise of the first class. In the slighter cases this form of practice may be sufficient to give the necessary respiratory control. And in order that this rhythmical control may be thoroughly acquired, the patient must read, first verse and then prose, with great exaggeration of the rhythm, the rhythmical syllables being both *accentuated* and *prolonged*. As the actual marking of the rhythm in prose occasionally presents some difficulty to those whose attention has not been previously drawn to it, we have accented, for example, the following passage from Stevenson:—

"He was loved and respected by some of the best and wisest men in England. He was President of the Royal Society; and when he came to die, people said of his conduct in that solemn hour—thinking it needless to say more—that it was answerable to the greatness of his life. Thus he walked in dignity, guards of soldiers sometimes attending him in his walks, subalterns bowing before his periwig; and when he uttered his thoughts they were suitable to his state and services."

Now, with many stammerers this mode of control may be insufficient and

may fail them at critical moments. The very power to accentuate the rhythm seems on occasion to vanish. Hence it is well in any but very slight cases to give also exercises of the second class, in order that a more direct control may be obtained over the source of the disturbance. Let the patient stand with his hands resting against the lower ribs (position *a*, *Fig. 74*) and utter any prolonged vowel sound—*ah*, for example—maintaining an even intensity of tone throughout. Bid him notice and fix his attention upon the even and continuous collapse of his thorax beneath his hands. Next let him say a long *ah* with rhythmical accentuations, about one a second, allowing his voice to die away between the accentuations, but not to fail altogether. He will then observe that the motion of the thoracic wall beneath his hands undergoes corresponding rhythmical accelerations and retardations. The difference between the former and the latter expiratory phase is well shown on the pneumographic tracing in *Fig. 75*. The first up-stroke describes the motion of the thoracic wall during

Fig. 75.—Respiratory tracings showing the effect of alterations in the intensity of the voice uninterrupted by consonants, and the pitch remaining constant. The tracing reads from left to right. The expiratory part (up-stroke) of the first curve represents the vowel sound "*ah*" sung with (fairly) constant intensity, and at a constant pitch. The second curve shows the effect of raising the intensity of the tone on the beats of a metronome, and letting it die away between the beats. The small dots indicate approximately the points at which the intensity was raised. The finer undulations on both curves are due to the heart-beat. (It is to be noted that the pressure exerted by the respiratory muscles varies as the square of the velocity of the out-driven current of air, so long as the laryngeal aperture is constant. Hence the variations in pressure which produce variations in the intensity of the voice are proportional to the square of the amplitude of the accompanying waves in the pneumographic tracing. Thus very slight undulations in the tracing may be evidence of quite appreciable variations in the muscular activity.)

an even *ah*, the second (undulatory) up-stroke exhibits the same during a rhythmically accentuated *ah*. The stammerer should practise this until he becomes acutely conscious of the variations in the rate of collapse of his thorax and abdomen which correspond to variations in intensity of the sound, and until he can alter the intensity by deliberately altering the rate of motion of his chest wall and diaphragm. He should next take some piece of simple poetry with a well-marked rhythm and learn it by heart, until he can say it almost subconsciously. He should then practise reciting it, again with an exaggerated rhythm, but now voluntarily directing the respiratory movements which predetermine the accentuations. If he can do this he will be giving his respiratory mechanism a perfect exercise of the second class in speech. The undulatory character of the expirations which he must recognize and consciously accentuate

are illustrated in the pneumographic tracing in *Fig. 76*, recording the respiratory movements as a line of Longfellow's "Hiawatha" was being recited with a greatly accentuated rhythm. This poem is particularly well adapted to early practice, for (1) The lines are short; (2) The rhythm is obvious; (3) The first syllable in every line is accentuated. The patient will do well, however, not to confine himself to verse, but to extend this form of practice to the reading of prose; always reading with a full voice, and a highly, even grotesquely, exaggerated rhythm.

If, then, the stammerer will practise these forms of exercise, he will, in the event, become possessed of two means of control in ordinary speech with which to check the onset of spasm—first, by attending to the rhythm of his sentences, and, secondly, by consciously directing his respiratory movements. The first should become his regular habit of speech. The second is not practicable for continuous use, but should be relied upon in case of emergency and a sudden inclination to stammer.

Fig. 76.—Pneumographic tracing of the line *With the odours of the forest*, spoken slowly and with the rhythmical syllables accentuated and slightly prolonged. Reading from left to right, the first up-stroke shows a series of four undulations which correspond to the four accented syllables of the line. These variations in the rate of expiration may be readily appreciated by a hand laid on the epigastrium.

The above represents a general scheme of treatment for a typical case. Modifications, such as experience directs or necessity compels, must be made for individuals. And a careful study of the idiosyncrasies may reveal special indications for the application of educative methods. A brief reference to two or three further points will serve to illustrate this.

Many stammerers speak habitually in a thin voice, with little volume of sound. This may be partly due to an improper mode of delivery, but it is also due to the use of a feeble air-blast in vocalizing. And if, during expiration, the tension of the expiratory muscles is only just greater than that of the inspiratory group—as will be the case if the air-blast be feeble—there would appear to be a greater tendency to spasm than if the two groups of muscles were less nearly in balance. Hence, it is well to encourage all stammerers to speak in a full, resonant voice. The increase in loudness may, however, necessitate the voice being pitched in a lower key, lest it should become unpleasant.

Again, anything which acts as a mechanical check to the breath stream is a

stimulus to spasm, and so we find the explosive consonants are the most common excitants of trouble. But, as we have shown with the pneumograph, the time that the breath is arrested varies considerably, according as the consonant is firmly articulated or only lightly touched on. It may, therefore, be advisable in certain cases to pay some attention to lightness of articulation. But it must not be forgotten that the articulation is not the primary seat of the trouble, and any attention paid to it is liable to be at the expense of a more fundamental control.

Some patients stammer very severely on initial vowels, and it may be necessary to draw their attention to the fact that there are two distinct ways of initiating a vowel sound, one of which is easy to stammerers, and the other difficult. In the first (easy or smooth method) the vocal cords move up at once into exactly the position required for the note, leaving a narrow slit between them. In the second (the difficult or explosive method) the cords move up, meet, and press against each other, and then open again into the position required for the note. In this way a consonant formed in the larynx itself precedes the vowel, and, similarly to other consonants, acts as a mechanical check to the breath. Now in ordinary speech it is usual to employ the second way in the case of vowels standing at the beginning of phrases; but when the vowels present difficulty, even after vigorous respiratory training, it may be well for the stammerer to practise the smooth method.

Finally, a word on prognosis. It should be impressed upon patients that, in the main, their improvement will be slow, but that its rate is chiefly dependent on their own perseverance and exertions. As their first progress is rapid, so surely will it be short-lived, and their downfall early, should they kick away the ladder of practice by which they ascended. Again, having reached a certain point of improvement, they are liable to stand still for a time, blame the system, and seek another. It were as reasonable for a cricketer to forswear the game because he finds himself "stale" at the end of the season. Let the stammerer, giving up all practice for a time, return to it later, when he will find the effect of exercises surprisingly renewed. Let him also seek variety in practice. A few minutes' pure respiratory gymnastics night and morning will at times restore a lost control, when hours of reading fail. With regard to the ultimate prognosis, a stammerer cured is rarely the same as a man who has never stammered. Without incessant watchfulness on his part, his malady is certain to recur. These aspects of treatment are not unimportant, and it is well that the patient should be forewarned.

Robert Worthington.

STERILITY.—It is important, before undertaking the treatment of sterility, that the practitioner should have a thorough knowledge of the physiology and mechanism of conception; he will then better understand and appreciate the causes of sterility, such knowledge will enable him to arrive at a proper diagnosis, and as a consequence he will be in a better position to treat the lesion, should one exist, which is the factor in the prevention of conception.

It is outside the scope of this article to discuss anything but actual treatment. There are, however, certain points which must be mentioned before dealing with therapeutics.

Sterility due to the Male.—Before treating a woman for sterility, and it is nearly always the woman who seeks advice on this question, it is essential in every case that a thorough investigation should be made of the husband's fertility; it by no means follows that because a man is capable of having intercourse he is fertile, or that a man who is impotent is infertile. The sole proof of a man's fertility can be obtained only by a proper microscopical examination of the seminal fluid. It is essential that living sperms should be demonstrated, and in

order to make sure of this, it is necessary that the fluid should be examined as soon after emission as possible, certainly within the hour. If this is done, there should be no difficulty in recognizing motile sperms.

TREATMENT.—The treatment of sterility in the male is very unsatisfactory.

Congenital malformations, such as hypospadias, undescended testicle, etc., may be remedied by surgical procedure. Acquired defects, such as nodules in the globus minor the result of old-standing epididymitis, should be treated by short-circuiting the vas deferens and globus major (Martin's operation).

Dyspareunia is a condition that the male rarely suffers from, but such a condition can occur, and is usually due to a very tight prepuce; the pain may be so severe as to prevent coitus. Circumcision is, of course, the proper treatment.

Too frequent intercourse is another and an important cause of sterility associated with the male; the man may be perfectly fertile, but owing to excess the quality of the seminal fluid deteriorates; this is particularly the case in the newly-married. The remedy is obvious.

Ignorance in both parties is sometimes met with; it seems incredible that the man should be ignorant of his marital duties, but the writer has met with cases in which both husband and wife were absolutely ignorant. A little judicious talk and advice from the practitioner will soon put matters right.

Awkward connection is another not infrequent cause; in many cases penetration has not taken place, and it is only after careful questioning that it will be discovered that the position assumed by the husband and wife makes it impossible for penetration to occur. Here again a simple explanation suffices.

Sexual incompatibility may exist; that is to say, the couple may be sterile with each other, but either of them may be fertile with someone else. This is a condition which is not amenable to treatment.

Impotence is frequently a cause of sterility, but in many instances can be cured. It is by no means a condition always associated with age and decrepitude; quite a large number of cases occur in young men. In the majority of these the impotence is produced by nervousness; in such cases a temporary separation and tonic will put matters right. In others it may be necessary to treat the patient by suggestion, and the writer knows of many successfully treated by this means.

Impotence as a result of organic lesion cannot be treated, and impotence in the aged very rarely yields to treatment by drugs or suggestion. Artificial insemination is the only possibility in these cases.

Sterility due to the Female.—The treatment of sterility in the female resolves itself into the treatment of the associated condition.

Displacements should be rectified. Backward displacements are usually associated with acquired sterility, and in a condition of retroversion or retroflexion there is frequently descent of the uterus as well.

Of forward displacements, acute antelexion is very often met with in women who are sterile; it is associated with conical cervix and stenosed os; dysmenorrhœa is a frequent symptom in these cases. It is absurd to suggest that the flexion offers mechanical obstruction to the passage of the sperm; but there is no doubt that simple dilatation of the canal not only relieves the dysmenorrhœa, but pregnancy frequently follows the operation.

Congenital abnormalities, such as imperforate hymen, tumours, etc., can be treated surgically; if, however, imperforate hymen is associated with hæmatocolpos and hæmatometra, pregnancy is not likely to result. Unruptured hymen should be dealt with surgically; digital or mechanical stretching is not sufficient; the hymen should be excised and the introitus vaginæ widened.

Vaginismus, which is one of the common causes of sterility, requires careful treatment. Any tender tags of the hymen (carunculæ myrtiformes), should be removed under anæsthesia, the introitus vaginæ should then be well dilated,

and a glass vaginal dilator left *in situ*; the patient should be instructed to introduce dilators of gradually increasing size every night, and should be advised to wear one all night. Finally, when the biggest dilator has been passed quite easily, the vaginal orifice should be well vaselined, and coitus attempted.

Pelvic inflammation should be treated with a course of hot douching and tamponage, either with glycerin or ichthyol and glycerin; or the patient may be advised to have a cure at one of the many watering-places, e.g., Woodhall Spa, Ems, or Kreuznach.

The secretions of the vagina will not infrequently be found to be more acid than normal; an alkaline douche, given some hours before coitus is attempted, is very frequently successful. In the gouty, the normal uterine and vaginal secretion may be altered: there is no doubt that pregnancy frequently follows a course of treatment which the patient may have undertaken with a view to alleviating the gouty symptoms.

Obese women rarely become pregnant, and in these cases the obesity should be treated before any local treatment, should this be necessary, is undertaken.

Artificial Insemination.—The cases in which this treatment may be resorted to are few. It is only in malformation such as hypospadias, disproportion of the sexual organs, and in impotency. In these cases it affords the only possibility of pregnancy. The results are very disappointing, but success is sometimes possible.

Jervois Aarons.

STIFF NECK.—(See RHEUMATISM, CHRONIC.)

STOMACH, CARCINOMA OF.—The radical treatment of cancer of the stomach is undoubtedly surgical, and there is reason to believe that if the diagnosis could be made sufficiently early, the results would be more encouraging than they are. Better results can only be looked for if practitioners will consider the propriety of surgical interference so soon as the presence of carcinoma is suspected. Even where removal of the disease has proved to be impossible, the performance of a gastro-enterostomy has often afforded great relief to symptoms, and has prolonged life. In cancer of the cardiac opening, a gastrostomy is obviously indicated when the difficulty of swallowing becomes great, and will, in these circumstances, if successful, prolong life. Apart from surgery, the means at our disposal are the use of liquid, nutritious, and non-irritating diet, which must in the main be composed of milk, eggs beaten up, soup, gruel, milk tea, coffee made with plenty of milk, or cocoa, and, if any alcohol is necessary, a little good champagne.

In order to relieve the pain, it may be necessary to give anæsthesin (5 to 10 grs. dissolved in olive oil or liquid paraffin), or opium in the form of hypodermic injections of morphia ($\frac{1}{4}$ to $\frac{1}{2}$ gr.), and if, as is often the case, there is some gastritis, we may use the same remedies as in chronic catarrh.

Orexin tannate (4 to 8 grs.) may be given in cachets; magnesium peroxide, $\frac{1}{2}$ to 1 dr., or bitters such as condurango, calumba, quassia, and gentian.

Robert Saundby.

STOMACH, CARCINOMA OF (Surgical Treatment).—Every case of suspected carcinoma of the stomach should be subjected to operation. If the condition can be certainly diagnosed, the most favourable time for removal has been allowed to pass. Cases of dyspepsia in adults which do not yield to rest in bed and diet, after the mouth has been attended to and bad habits corrected, should be submitted to exploration after thorough investigation. Every case of organic gastric disease that fails to yield to medical treatment, or that relapses, should submit to surgical treatment; only on these lines will cancer of the stomach

be 'cured' and prevented. The greatest difficulty arises in the pre-operative diagnosis of cases of the appendix-dyspepsia type. Many of these have been sent to me as cases of gastric carcinoma.

Operation should be undertaken in all cases of suspected or proved carcinoma of the stomach unless obviously inoperable by reason of secondary growths, the surgeon being prepared to do a partial or a complete gastrectomy. The surgical treatment can be summed up shortly : the operation of choice is partial gastrectomy ; in certain cases total gastrectomy may be necessary. *Simple gastrojejunostomy should only be performed when the growth is producing pyloric obstruction.* If cardiac obstruction is present, gastrostomy may be done ; in certain cases jejunostomy may be advisable.

The results of operation by partial gastrectomy are extremely encouraging. The immediate death-rate should not be more than 10 per cent at the present time. The chance of freedom from recurrence for five years and over is at least a 25 per cent one. When recurrence takes place, the average duration of time is eighteen months from the date of operation, and the quality of life is much better than if gastrojejunostomy had been carried out.

Palliative Operations.—*Gastrojejunostomy* is of striking service in the relief of symptoms when the growth is causing pyloric obstruction, and in the rare cases of malignant hour-glass stomach. Its performance should be limited to these, for it affords little or no relief when the growth is not causing mechanical obstruction. The immediate death-rate is much higher than when the operation is carried out for simple conditions. The average duration of life is about six months. The relief afforded is striking, and the operation is certainly one to be recommended. The patients are usually able to resume ordinary life.

Gastrostomy and Jejunostomy.—These operations do not stand on the same plane as gastrojejunostomy. As routine procedures in inoperable carcinoma of the stomach they are inadvisable. They belong to the class of operations that must be left to the choice of the patient, remembering that the quality of life is not good, and that the discomfort of artificial feeding is very great to some individuals. The immediate death-rate of gastrostomy is low. As a rule, life is not prolonged more than six months.

James Sherren.

STOMACH DILATATION.

1. Primary or Atonic.—As this condition depends as a rule upon serious derangement of the general health, it is of far more importance to use means to improve this than to apply any local measures to the digestive organs. In general, we should aim at giving relief from work and worry, with good and abundant food, and change of air to a bracing place. It should be borne in mind that sea air is often not bracing ; this is especially true of the south and west coasts of England during the summer and autumn months ; these patients often do better at upland stations like Buxton or Braemar. In many cases it is necessary to give prolonged rest by a course of Weir-Mitchell treatment, with massage and faradism, and it is desirable not to hold out any prospect of a permanent cure being effected by less than a three months' course. Galvanism and high-frequency currents are both used by some as aids to this method, but I have not been impressed by the results ; in cases where benefit has followed it has not been more than I have seen where no such means were used. The diet may need to be modified if there is gastritis, but not on account of the dilatation ; and when the patient is going about, and, as is commonly the case, there is complaint of pain or oppression after food, he should be made to lie down for three-quarters of an hour after each meal. A well-fitting abdominal belt is often a great help to these patients.

As such dilated stomachs are always able to empty themselves, there is no need for the use of the stomach tube, and still less for any surgical interference.

Medicinal tonics are often of service, such as the following :—

R	Acidi Nitrohydrochlorici Diluti	℥x	Succi Taraxaci (B.P.)	℥i
	Tincturæ Nucis Vomicae	℥xxv	Aquæ Destillatæ	q.s. ad ℥j

Two tablespoonfuls three times a day after meals.

These patients are very often constipated, and require the regular use of an aperient. If they are going about, it is better to avoid giving them saline aperients, which often seem to increase the feeling of exhaustion; glycerin enemata, or doses of liquid paraffin, cascara evacuant, or senna, suit them better. (See also NEURASTHENIA; GASTROPTOSIS; and DYSPEPSIA, ATONIC.)

2. Secondary.—As this form of dilatation is due to structural changes which are not readily susceptible of modification by medicinal means, treatment must be surgical. Klemperer's thiosinamine (fibrolysin) treatment may be tried for a few weeks, but should not be unduly prolonged when surgery is ready and able to effect a cure. It is only where surgical aid is refused that the case should be treated by the stomach tube: the patient should be taught the use of the stomach tube, with which he should empty and wash out his stomach once a day. This may be done either the last thing at night or the first thing in the morning; the advantage of the latter time is that it gives longer for the passage of food through the pylorus, but on the other hand it also allows the contents of the stomach to remain unduly long in contact with the gastric mucous membrane, thereby frequently setting up gastritis; so that on the whole it is preferable to use the tube the last thing at night. Secondary dilatation may, of course, be complicated by gastritis, and may call for appropriate treatment by diet and drugs. (See GASTRITIS.)

The most serious complication of dilated stomach is tetany, the most successful treatment for which is gastro-enterostomy; but other means that have been tried are infusions or enemata of normal salt solution, enemata of chloral (1 to 2 dr.),* and morphine ($\frac{1}{8}$ to $\frac{1}{2}$ gr.) hypodermically.

Robert Saundby.

STOMACH, DILATATION OF, ACUTE POST-OPERATIVE.—This condition is by no means uncommon. Its recognition is of the utmost importance, as unless treated early and energetically it is inevitably fatal.

Although it may arise after operation in any part of the body, it most often occurs after those upon the kidney and gall-bladder. As soon as the condition is suspected, the patient should be placed lying down and the foot of the bed raised. The stomach tube should be passed, and the stomach kept empty by tube as often as necessary. In persistent cases, the patient should be on the face, or even in the knee-elbow position. Operative treatment is never indicated. The condition may arise after, and in spite of, gastrojejunostomy.

James Sherren.

STOMACH, FOREIGN BODIES IN.—The treatment will depend on the form, consistency, and size of the article swallowed. If it is thought that the foreign body is likely to pass, a diet of porridge or mashed potatoes should be given, but no purgatives. The patient should be x-rayed, and the exact location of the foreign body determined. It must be remembered that its weight may displace the stomach, and it may be necessary to examine after a bismuth meal. If the foreign body is giving rise to no symptoms, no hurry is necessary.

If natural discharge is impossible owing to the size, shape, or number of the foreign bodies, or if symptoms are produced, immediate operation should be resorted to.

In most cases it will be necessary to open the stomach. The incision in the

* Doses of this size should be given with extreme caution.—AMERICAN EDITOR.

stomach should be transverse to its long axis, and after removal of the foreign body it should be closed with a continuous stitch of fine chromic gut through all its coats, and buried with a continuous Lembert stitch of fine silk or thread. It may be possible to remove the foreign body, after the abdomen has been opened, by means of forceps such as Brüning's or Bilton Pollard's.

If the foreign body is in the duodenum, an attempt should be made to push it back into the stomach and extract it from there: only if this fails should the opening be made in the duodenum.

James Sherren.

STOMATITIS.—The mouth cavity under normal conditions contains many varieties of micro-organisms. Should the local resistance be decreased from any form of trauma, these organisms may attack the tissues and give rise to inflammatory changes. In other cases, specific organisms may gain entry through the intact or injured mucosa and be the cause of a definite series of pathological changes. As a general rule, however, there is some underlying condition, such as bad hygiene of the mouth, exhaustion following infective disease, or the absorption of some poison, which specifically lowers the resistance in the mouth. The forms of stomatitis are usually classified according to the form of pathological lesion present; the following are the principal varieties:—

1. Catarrhal Stomatitis.—This is dependent upon many causes, such as oral sepsis, especially around the teeth, the presence of injury, irritation from tobacco and spirits, and gastric disorders. It may also appear in the course of various specific fevers.

In the treatment, it is necessary first of all to attend to any underlying cause. Any carious teeth should be removed, the teeth sockets made as aseptic as possible, and any irritant which has been administered should be stopped. The bowels should be kept freely open, and a mouth-wash of potassium chlorate ordered. This latter drug, which has a remarkably beneficial effect in cases of stomatitis, may also be given internally.

2. Aphthous Stomatitis.—This condition is more commonly seen in poorly-fed children and in those in ill health, being especially found in association with gastric disorders.

The treatment should be chiefly directed towards the improvement of the general health, whilst potassium chlorate may be given internally and locally. The application of boro-glycerin will relieve the pain; but if only one patch is present and is associated with much pain, the greatest relief often follows the application of silver nitrate. (See also THRUSH.)

3. Ulcerative Stomatitis.—This condition is not uncommon in young children, especially among the poorer classes, and not infrequently follows some infectious disease such as measles. It may follow a catarrhal stomatitis. In certain cases it occurs as an epidemic, and thus appears to be due to a specific organism.

In the early stages, attention to the general health, the use of cleansing mouth-washes, and the application of potassium chlorate, locally and internally, is sufficient to bring about a cure. In more advanced cases, especially those associated with marked general disturbances, it is often better to administer an anæsthetic and to cleanse the teeth, and even the ulcers on the mucosa, by scrubbing them with a soft tooth-brush and a solution of potassium chlorate. In the after-treatment, a generous diet should be given, and the administration of potassium chlorate continued.

4. Mercurial Stomatitis.—(See JAW, NECROSIS OF.)

5. Gangrenous Stomatitis.—This condition, often described as *cancrum oris*, is fortunately uncommon. It is most frequently seen in debilitated children, and follows one of the exanthemata, especially measles. It may commence as an ordinary form of ulcerative stomatitis, which rapidly extends and leads to

destruction of the cheek. Often, however, the earlier stages are overlooked. When the inside of the mouth is examined, the mucous membrane, usually of the cheek, close to the angle of the mouth, is seen to be red and swollen. The centre may be ulcerated and show the presence of sloughs. The condition rapidly spreads, so that the whole cheek becomes swollen and hyperæmic. The mucous membrane becomes black and gangrenous, or shows a large adherent grey slough. In a short space of time the overlying skin also becomes gangrenous, and if the child survives sufficiently long the whole substance of the cheek is destroyed. At first there is marked pyrexia, but the patient rapidly passes into a state of collapse and profound toxæmia.

The treatment must be energetic from the commencement, and must not be limited by any consideration of the amount of the deformity produced. Under a general anæsthetic, which must be sparingly administered, the whole cheek is split from the angle of the mouth to the anterior border of the masseter muscle. By this means good access to the diseased portion is obtained. The mouth being protected by a piece of gauze, all sloughs and necrotic tissues are cut away. The remaining portions must be swabbed with a strong antiseptic, pure carbolic acid being best for this purpose. Care must be taken that none of this falls on the healthy tissues. After it has been allowed to act for five or ten minutes, it should be carefully swabbed away with a weak carbolic lotion. The wound at the side of the mouth must then be lightly plugged with gauze, and a large fomentation applied. Subsequently the mouth is frequently dressed and syringed with Sanitas or weak carbolic lotions. The general health must be maintained as far as possible; and should the child survive, a plastic operation will have to be performed at a later date in order to overcome the deformity.

STRYCHNINE POISONING.—(See CRAMP; POISONING.)

STYES.—(See EYELIDS, DISEASES OF.)

SUBMAXILLARY ABSCESS.—(See ABSCESS.)

SUBPHRENIC ABSCESS.—This condition, depending as it does in most cases upon failure to recognize the necessity for the early surgical treatment of the disease originating it, is undoubtedly becoming less common. Its usual causes are acute appendicitis, perforation of duodenal and gastric ulcers, and suppurative affections of the liver and biliary passages.

Treatment consists in free drainage. When complicating acute appendicitis, it is sometimes possible to drain through the abdominal incision employed for removal of the appendix. In some of the cases of right anterior subphrenic abscess due to perforation of a duodenal or pyloric ulcer, this may be done from the front. The majority, however, are best treated by posterior drainage in a line with the angle of the scapula. After pus has been found by the exploring needle, three inches of the rib below the needle should be removed. If the pleural cavity is not obliterated, the diaphragm is firmly sutured to the intercostal pleura with catgut, and the diaphragm incised and the abscess drained by a large tube.

James Sherren.

SUFFOCATION.—(See DROWNED, TREATMENT OF THE APPARENTLY ; LARYNGEAL OBSTRUCTION ; POISONING.)

SUNSTROKE.—In all countries exposure to excessive heat, and where ventilation is bad, may result in vertigo, nausea or vomiting, and attacks of syncope, particularly in alcoholic subjects. In these cases of heat exhaustion, the patient should be placed on his back in as cool a place as possible, all clothing loosened, and cold water dashed on the face and chest. After recovery from the immediate effects, a brisk purge should be given, and errors in clothing, diet, and ventilation remedied, as attacks are liable to recur. It is of special importance that the lining of the helmet should be red or orange, both for prevention of original attacks and of recurrence.

In the graver forms there is hyperpyrexia, and more active measures are required. Cold, or if possible iced, baths should be given. If no bath is available, the patient should be rubbed with ice or placed in an ice pack. The rectal temperature must be constantly observed, and the treatment stopped when it falls to 104° F., as the fall will continue, and collapse may occur.

After the bath or pack, the patient should be wrapped in blankets, and stimulants given if required. In cases where the respiration ceases during the hyperpyrexia, artificial respiration should be carried on, as recovery may be possible even then.

Venesection is rarely of any value, and is often injurious.

In the mild forms, as well as in the severe, there may be troublesome sequelæ. Of these, mental irritability, insomnia, loss of memory, and headache are the more common. Careful regulation of the course of life, including restricted diet, prohibition of stimulants and opiates, moderate exercise, and mental rest, are of most importance. Any, even the slightest, errors in refraction must be corrected by the use of suitable glasses, and any causes of "eye strain" avoided. Smoked or tinted brown or yellow (not blue) glasses should be worn outside the house, even if the glare is not noticeable. Drugs are better avoided, but small doses of potassium iodide 1 to 5 gr. may be useful. (See also COMA.)

SUPPRESSION OF URINE.—(See URINE, SUPPRESSION OF.)

SWEATING, EXCESSIVE.—(See HYPERIDROSIS.)

SWEATING, OFFENSIVE.—(See PERSPIRATION.)

SYCOSIS.—It is necessary in the first place to exclude the important imitators of this disease—ringworm and impetigo. That being done, the writer's experience is that the particular reason for the want of success which so often attends the treatment of this disease is want of vigour. The disease is treated with too much respect. The value of antiseptics is practically very much diminished by the fact that it is almost impossible to get them to penetrate to the bottom of the follicles in which lie the germs which cause the disease. Antiseptics have their uses in preventing the spread of the disease from one part to another along the surface, but they are powerless to destroy the germs at the bottom. For these counter-irritation is indicated, and it is to their counter-irritative powers that many antiseptics owe their reputation in sycosis. Blistering fluid is often most useful. Strong solutions of sublimate in spirit of wine really act as counter-irritants rather than as antiseptics, and the counter-irritating ointments, such as the acid nitrate of mercury, are often useful.

Although it cannot be claimed, and is not claimed, that these methods are always successful, they are at all events infinitely more so than the older methods of mild antiseptics.

Along with these applications there is no doubt that treatment is facilitated if the hairs growing from the diseased follicles are removed. This is generally comparatively easy to do, but it is questionable whether much benefit results from wholesale epilation, except it be that it is a rather severe form of counter-irritation.

In the x rays we have a remedy which has the power of producing both epilation and counter-irritation. There is no doubt that far too much has been claimed for the treatment; the improvement is often so striking at first that one regrets all the more that it is so often only transitory. All the same, we have in the x rays a valuable addition to our means of attack, and sometimes the continuance of the rays up to the production of a considerable reaction is followed by satisfactory results.

In the writer's opinion, there is probably no disease, with the possible exception of lupus, in which so much may be hoped from vaccine therapy, as sycosis. Probably the best results are got from a vaccine prepared from the patient's own cocci; but if this cannot be procured, a mixed staphylococcal vaccine may be used instead. The disease is sometimes apparently aggravated by the first injection, but improvement soon sets in, and is in the writer's experience much more thorough than that following, for example, the x -ray method. The doses should not be too numerous. Opinions differ, and each should only record his own experience without criticizing others. The writer allows at least ten days to elapse between the injections, and he has no faith in enormous doses.

In the majority of cases no general treatment is indicated, but there is a form of sycosis occurring in a delicate class of young men in whom the administration of cod-liver oil is most beneficial. It is to these cases, probably, that cod-liver oil owes a reputation in sycosis.

Norman Walker.

SYNOVITIS, TRAUMATIC.

1. Acute.—The treatment of acute synovitis depends, to a large extent, upon the cause, the correct diagnosis of which is essential to success. Simple synovitis due to traumatism will alone be dealt with here; for the treatment of the other special forms the reader is referred to the articles dealing with gonorrhœa, rheumatism, syphilis, tuberculous joint disease, and pyæmia.

The treatment detailed below is that appropriate to all cases of sprained joints, though it must be remembered that in a severe sprain, when the joint is rapidly distended with blood—as opposed to the more gradual distention with slightly blood-stained fluid which occurs in less severe wrenches—and acute synovitis results therefrom, it is often advisable to have an x -ray picture taken. The discovery of an unsuspected fracture in the neighbourhood of the joint may call for considerable modification of the treatment. The first essential is immobilization of the affected joint upon a splint, in the position which will render the limb most useful should irremovable adhesions form. This position must vary with the particular joint affected: in the knee, the commonest joint to be the subject of synovitis, a position of slight flexion is the best. The pain is often relieved, and the effusion perhaps limited, by the application of cold, by means of ice-bags, Leiter's tubes, or evaporating lotion. If the limb, when first seen, is in a faulty position, this must be corrected, either gradually by weight extension, or rapidly under anæsthesia. If the knee is the joint affected, and "locking" has occurred, removal of the loose body or displaced cartilage from between the bones must be accomplished by further flexion and manipulation, before the limb can be extended. After twenty-four or forty-eight hours, warmth, in the form of fomentations, will be found most comforting. In rare instances accompanied by great effusion, the fluid may be withdrawn by an aspirator, the joint being afterwards covered with a thick layer of wool and

firmly bandaged. As soon as the swelling begins to recede, massage may be commenced. The time that should elapse before massage is begun must necessarily vary with the severity of the case, the pain, etc., but in the severest cases skilfully performed massage may be of benefit after two or three days. In most cases massage may be commenced after twenty-four hours. The safest guide is the effect produced by the massage. If the pain is aggravated and the swelling increased, it is obvious that the application of this active treatment must be further delayed. Though the pain produced by the first sitting may be considerable, it is often followed by relief, and the next sitting is found most comforting. In order to prevent the formation of, or to stretch, adhesions before they have become firm, passive movements should be commenced as early as possible, though not so early as massage; and here again the surgeon must be guided by the result of such treatment. If some increase of swelling is produced, the movements should be discontinued for a few days, and then recommenced. When much pain is produced by the movements, it has been recommended that a local anæsthetic should be injected around the joint, or even into the cavity thereof. Gradual stretching of adhesions is always to be preferred to forcible breaking down of the bands; but when, owing to their resistance or the nervousness of the patient, such is found to be impossible, the joint may be forcibly manipulated under general anæsthesia. Such a proceeding should very rarely be necessary in cases properly treated from the first. After such manipulation the joint should be kept at rest and cold applied for a few days, when the passive movements may be recommenced. Firm pressure should be applied continuously in the intervals till the joint is well, and may be advantageously continued for some time after the patient has resumed his occupation. In the case of the wrist, active and passive movements of the fingers and thumb must be insisted upon from the very first. A Carr's splint gives comforting support for a few days. A radiogram should be taken in all severe or doubtful cases to exclude fracture of the radius or a carpal bone. Active movements of an inflamed articulation may be encouraged as soon as massage is commenced, i.e., somewhat before passive movements are begun.

2. Chronic. — It is again essential that any aggravating cause, such as a displaced cartilage, loose body, or hypertrophied synovial fringe, which may have given rise to repeated attacks of acute or subacute synovitis, should be discovered, as when one of these is present a cure can be obtained only by operation. In the absence of these, reliance must be placed on strapping the joint over some Scott's dressing, the use of blisters, and massage by a skilled masseur, any or all of which must be combined with rest. Massage to the joint and the muscles around it is the surest of all forms of treatment, but it must be done by a skilled person. It must be remembered that chronic effusion into the knee after an injury is due, not so much to a continued inflammation, as to a laxity of the ligaments and muscles about the joint. It is, therefore, advisable to support the joint capsule by a crêpe or other bandage till all the fluid has been absorbed, after which massage alone should be persevered with for two weeks longer. Rest need not be carried, as a rule, to the extent of immobilization upon a splint. In some cases the application of a Martin's bandage may promote absorption of the fluid and prevent its re-accumulation. In others, particularly in rheumatic patients, hot-air baths, which produce active hyperæmia, combined with massage, may effect a cure. If all these fail, the fluid may be withdrawn by means of a fine aspirating needle, and firm pressure applied. This failing, the joint may be emptied and washed out through the aspirating needle with normal saline or some irritating and stimulating fluid such as 1-2000 sublimate solution. If the latter is used, a final irrigation with

sterilized water is necessary to prevent a too violent reaction. If yet again the treatment fails, the joint should be opened and examined for the presence of thickened synovial fringes. If nothing of this nature is discovered, a tube may be inserted and the joint drained for a few days. If hypertrophied fringes of synovial membrane are present, they should be clipped away; if very extensive, the largest only should be removed, the rest swabbed over with sublimate lotion, and the joint drained for a few days. Since removal of the whole of the synovial membrane must necessarily lead to considerable impairment of movement, this should be undertaken only when it is of paramount importance that the joint should be firm and reliable, even though such can be obtained only at the expense of much of its mobility.

H. A. T. Fairbank.

SYPHILIS.—Syphilis first manifests itself in a local sore or chancre, indicating the locality where the virus was first introduced, and the chancre is subsequently followed by various cutaneous and other manifestations which signal the general infection of the blood and the invasion of the whole system with the poison.

The initial lesion of syphilis usually presents itself in the form of an indolent ulcer, the local treatment for which is the application of some antiseptic powder or lotion. But local applications should be withheld, in cases in which the diagnosis is in doubt, until some of the secretion of the sore has been obtained with a view of ascertaining the presence of the spirochæte, since this organism is driven from the surface by antiseptic powders or lotions. Iodoform was formerly much employed as a dressing for the syphilitic chancre, but owing to its characteristic odour this substance was apt to arouse the suspicions of those familiar with its uses, and is now usually discarded, and replaced by other equally efficient substitutes, amongst which may be instanced dermatol, iodol, resorcin, euophen, xeroform, and orthoform. The sore having been carefully cleansed in warm water, the powder is dusted lightly over its surface, and a piece of lint is superimposed with a view of retaining the powder in contact with the sore, and of absorbing its secretion, while if the sore is on the outer aspect of the prepuce or on the sheath of the penis, the dressing may be secured in position by adhesive plaster.

The lotions usually adopted as a dressing for the chancre are the *lotio nigra* and the *lotio plumbi* (B.P.C.), to which may be added some tincture of opium (40 min. to 1 oz.) if much pain is present. Excision of the chancre may be practised in situations in which no undue mutilation is involved, such as the preputial orifice in men and the labia majora in women; if this can be effected early, the subsequent course of the disease may be considerably modified thereby, and in some cases its further progress is arrested by this operation.

Neglect, privation, alcoholism, and debility may give rise to an unhealthy condition of the chancre, manifested by sloughing or phagedæna, which may cause serious destruction and mutilation of the affected parts. Treatment of this condition must be prompt and energetic, and nothing is more effective than the continuous application of hot water; this is best effected by the immersion of the patient in a hip-bath into which fresh supplies of water are constantly introduced in order to maintain the temperature. The stay of the patient in the bath may be regulated by the severity of the destructive process, and in an acute case immersion for twelve hours daily is advisable. In the intervals between the baths, the application of a lotion of tartarated iron; 20 gr. to 1 oz. water, is a valuable adjunct.

Of far greater importance than these local measures is the constitutional treatment by means of which the syphilitic virus is eliminated from the system. This treatment resolves itself into the administration of three remedies, arsenic,

mercury, and iodine, of which the two former are far the more important, since they seem to act as an antidote to the syphilitic virus, whilst the latter is used to alleviate certain symptoms, and to promote the absorption of some of the products of the disease.

Since the appearance of the last edition of this work, a notable advance has been made in the treatment of syphilis; the value of salvarsan has become more fully recognized, and the modification neo-salvarsan has been introduced; these preparations have been relegated to their proper position in the treatment of the disease, and it is now realized that salvarsan *per se* is not a cure for syphilis, but that it must be supplemented by some form of mercurial treatment. On its first introduction, salvarsan was administered intramuscularly, but it was found that this method had many counterbalancing disadvantages, principal amongst which were intense pain, severe constitutional disturbance accompanied by pyrexia, and possibly the formation of an indurated mass at the site of the injection, requiring incision or perhaps excision. The preparations salvarsan and neo-salvarsan are now almost universally introduced by the intravenous method, which has the advantage of being painless except for the prick of the hypodermic needle, and of giving rise to very little constitutional disturbance. Of the two preparations, the original salvarsan appears to be the more efficacious, but it takes somewhat longer to prepare, as it requires the addition of some caustic soda solution, and has to be administered at a temperature of at least 100° F.; neo-salvarsan is freely soluble in water, and is introduced at the ordinary room temperature, 60° to 70° F. The maximum dosage of salvarsan is 0.6 gram, and of neo-salvarsan 0.9 gram. Formerly the injections were followed by considerable reaction, as manifested by pyrexia, rigors, and intense mental depression, but it is now recognized that these symptoms were due to some impurities in the water in which the preparations were dissolved, and if the water is distilled and re-distilled shortly before use, reaction is either absent or is insignificant. The apparatus for the introduction of the solution into the vein should be as simple as possible; I am in the habit of using a glass receptacle fixed to a metal stand, with a telescopic rod by means of which the glass vessel may be raised or lowered; to the vessel is attached about six feet of india-rubber tubing, in the end of which is inserted a metal tube with a stout hypodermic needle attached to it; about a foot from the termination of the india-rubber tubing a glass "window" is inserted, by which the presence of air in the tube can be ascertained. Some of the distilled water is introduced into the glass vessel, and passed through the india-rubber tube in order completely to empty it of air, a very essential precaution, since the introduction of air into the circulation is productive of serious symptoms such as intense precordial pain and embarrassment of breathing. The skin at the bend of the elbow is rendered aseptic by the application of a solution of iodine and alcohol, and an india-rubber band is applied round the middle of the arm sufficiently tightly to obstruct the venous return, and is secured with Spencer Wells forceps; the needle is then introduced through the skin into the vein which stands out most prominently, usually the median basilic, and the india-rubber band promptly removed; about two ounces of distilled water are first introduced, this is succeeded by the solution of salvarsan or neo-salvarsan to the amount of about six ounces, and this is followed by a further two ounces of distilled water. If the needle misses the vein, a swelling of the subcutaneous tissue ensues, and the needle must then be withdrawn, and introduced into another vein either in the same arm or in that of the opposite side. After the completion of the injection, a small pad of cotton wool is placed over the puncture, and over this collodion is applied. For these injections the same preliminaries must be observed as for a surgical operation; a purge must be administered on the

previous evening, and no food should be taken for four hours previously ; after the injection the patient should rest in bed for three or four hours, at the expiration of which time, in the absence of any reactionary symptoms, he may be allowed to go home. In some cases, especially in the female sex, it is impossible to bring any vein into sufficient prominence, and then it is necessary to make an incision through the skin, for which purpose cocaine may be injected subcutaneously. It is hardly necessary to state that a certain amount of experience is requisite before these injections should be ventured on, but the technique can easily be acquired after witnessing its employment by one who is thoroughly conversant with the method. Opinions vary as to the number of injections to be introduced, but our custom is to commence with four injections of salvarsan at weekly intervals, and to follow them with a course of three months' mercurial treatment, preferably in the form of intramuscular injections ; then should follow a remission of all treatment for a period of three months, after which a Wassermann test should be taken, and if this proves to be positive, two or three further salvarsan injections should be administered, and followed by a further mercurial course.

Mercury may be introduced into the system in various ways : by injection, either intramuscular or intravenous ; by the skin, in the form of inunction ; by the mouth, in the form of pills or mixtures. For intramuscular injections, both the insoluble and soluble mercurial salts are utilized ; but the former are far more effective than the latter, and are more convenient both for the surgeon and for the patient, seeing that only one injection is required weekly, whereas the soluble preparations have to be injected daily. The most powerful and undoubtedly the most effective of the insoluble salts is calomel, suspended in sterilized oil or vaseline, the dose being $\frac{3}{4}$ gr. calomel to 17 min. olive oil injected once a week. The principal objection to its use is that it occasionally gives rise to very severe pain. Another efficient insoluble preparation is "grey oil," consisting of hydrarg. pur. 1 oz., adipis lanæ anhyd. 4 oz., liquid paraffin (carbolisat. ad 2 per cent) ad 10 oz. ; the customary dose of this preparation is 10 min. injected weekly ; this is the formula which is mostly adopted for the treatment of syphilis in our military hospitals.

In the absence of any symptoms of urgency, and where prolonged treatment is indicated, the basic salicylate of mercury has been recommended ; the strength of the solution is 10 gr. suspended in 100 min. of liquid paraffin, of which the weekly dose is from 10 to 15 min. ; it has the advantage of being less painful than the other insoluble preparations, but on the other hand its action is slow and uncertain.

Amongst the soluble salts may be mentioned merc. perchlor. $\frac{1}{3}$ gr. dissolved in 17 min. of distilled water, to which is added sodii chlor. $\frac{1}{3}$ gr. ; merc. succin. $\frac{1}{3}$ gr. ; merc. biniod. $\frac{1}{3}$ gr. ; and merc. sozoiodol. $\frac{1}{3}$ gr., with sodii iodid. $\frac{2}{3}$ gr. The disadvantage of these soluble salts is that they have to be introduced daily or every other day ; but this is to some extent counterbalanced by their comparative painlessness.

Whichever preparation is adopted, whether the soluble or the insoluble, every precaution must be taken against sepsis, and against injecting into blood-vessels or in the region of large nerve trunks. The skin of the patient, the hands of the surgeon, the syringe, and the material to be injected must be treated with the same precautions as regards asepsis as would be deemed necessary in any important surgical operation. The region usually selected is the buttock, the exact spot being the centre of a line drawn from the anterior spine of the ilium to the upper end of the intergluteal fold, this point being well above and to the outer side of the important vessels and nerves emerging from the pelvis through the great sacro-sciatic foramen.

Intravenous injections of 20 min. of a 1 per cent solution of cyanide of mercury into the median basilic vein have been used with great success, but can hardly be recommended as a routine procedure.

Should treatment by intramuscular injections be decided upon, a primary course of from 12 to 15 weekly injections may be prescribed with the insoluble salts, or if the soluble salts are preferred, from 25 to 40 injections, at first daily, then every other day, and finally twice a week.

The inunction treatment consists in the rubbing into the skin of a varying amount of mercurial ointment, according to the condition, age, and sex of the patient, an average daily dose for an adult being 1 dr. The procedure may be carried out either by the patient or by a skilled rubber, preferably the latter, each application lasting for about twenty minutes, by which time all the ointment will have been absorbed by the skin. It is advisable to vary the locality of the applications as much as possible, in order to avoid irritation of the skin, and the hairy parts of the body should be avoided, since the ointment is liable to set up eczema if applied in those regions. An average course of treatment consists of a daily inunction for thirty to forty days, but its duration will materially depend upon the condition of the patient's mouth and gums. The advantages of this method of treatment are, the rapidity with which the mercury is usually absorbed, and that it does not as a rule interfere with the digestive functions; its disadvantages are, that the amount of mercury absorbed is variable and uncertain, that the treatment is uncleanly and consequently distasteful to many, and that its success depends upon the manipulative skill of the rubber or the patient; it is contra-indicated in the presence of a general pustular syphilide, or in patients with a delicate and sensitive skin.

The simplest method of administering mercury, and the one which proves satisfactory in a large proportion of cases, is ingestion by the mouth. At the outset of the disease this is usually effected by means of pills in the form of pil. hydrarg., pil. hydrarg. cum creta, pil. hydrarg. tannatis, pil. hydrarg. salicyl., in doses of 1 to 2 gr., three times a day, with a small quantity of pulv. opii in addition, should their ingestion be followed by colic or diarrhoea. Capsules of mergal or cholate of mercury (gr. $\frac{3}{4}$), with tannate of albumin (gr. $1\frac{1}{2}$), may be given at any stage of the disease; at first one capsule three times a day, the dose to be gradually increased to two five or six times daily. It is quite as efficient in its action as the more familiar preparations above described, and is seldom followed by any gastric or intestinal derangements, and so is specially indicated in mild cases of syphilis where it is desired to prolong the treatment over a considerable period. In the later stages of the disease, a pill combining mercury and iodine may advantageously be prescribed, such as pil. hydrarg. ioidid. virid. $\frac{1}{2}$ gr., or pil. hydrarg. ioidid. flav. $\frac{1}{4}$ gr. The liquor. hydrarg. perchlor. (1-900) may be given in doses of 1 dr. three times a day, and is indicated in cases of relapse, or where it is desirable to continue the use of the drug for a prolonged period. A mixture of biniodide of mercury—1 dr. liq. hydrarg. perchlor. (1-900) with 5 gr. potass. iod.—is valuable in the later stages of the disease, in cases with a gouty diathesis, or when superficial ulceration of the tonsils and fauces is present. Mercury also may be administered in combination with arsenic, in the form of Donovan's solution, in 10-min. doses, in obstinate cases of syphilitic skin eruptions, especially in chronic desquamating papular syphilides.

In whatever form mercury is administered, the greatest attention must be paid to the hygiene of the mouth: before the commencement of the course, any decayed teeth should receive the attention of the dentist, and all tartar should be removed from the teeth by scraping. The teeth should be carefully cleansed with some antiseptic tooth-powder or lotion after each meal, and the mouth should be frequently rinsed out with an astringent lotion, such as alum

10 gr. to the ounce, or a 20 per cent solution of listerine. Moreover, every patient should be instructed at the commencement of treatment that his diet should be simple but nourishing, that exposure to cold and wet should be guarded against, and that the avoidance of stimulants is also advisable, since the therapeutic effect of mercury appears to be greatly modified if alcohol in any quantity is being taken at the same time. Smoking may be allowed in moderation in the absence of any lesions of the buccal mucous membrane, but should there be traces of syphilitic ulceration in that region, it should be given up entirely. The patient should also be informed as to the serious nature of the disease, the various methods by which it can be communicated to others, and as to the length of time during which the treatment should be continued.

In a large proportion of cases the administration of mercury by the mouth is productive of a perfectly satisfactory result, and as it does not entail any pain or inconvenience, it is probably the most suitable form for general adoption. But there are some patients who are intolerant to mercury taken in this manner, amongst whom may be mentioned those suffering from gastric derangements, such as gastritis, dyspepsia, or dilatation of the stomach, also those in whom the drug gives rise to intense colic and diarrhœa which are not counteracted by the addition of opium. Further, since the absorption of mercury thus administered is slow and often uncertain, some other method must perforce be adopted in cases of severe and malignant syphilis, and where it is desirable to get the patient under the influence of the drug with as little delay as possible. More energetic and effective measures are at our disposal in the form of mercurial inunctions and intramuscular injections.

The extent and duration of the mercurial treatment will materially depend upon the constitution and idiosyncrasies of the patient, and also upon the form of treatment adopted; since the introduction of salvarsan, the length of the mercurial treatment has been materially shortened, and it is seldom necessary to prolong it for more than three or four years; occasionally one year's treatment will suffice, if the salvarsan treatment has been carried out thoroughly as a preliminary to mercurial treatment. The best guide to the duration of treatment is the Wassermann test, which if found negative on three occasions taken at three months' interval, will be an indication for the cessation of treatment. The condition of the gums will give some indication as to the duration of the mercurial course, and as to whether the drug is producing the desired effect; a slight gingivitis and increase in the flow of saliva is not always an unwelcome sign, since it indicates that the remedy is affecting the system. The bodily weight of the patient should be carefully noted during the course, and any material diminution will indicate some modification in the treatment. The presence of albumin in the urine will necessitate smaller doses given under very careful supervision, and any gastric and intestinal derangement will call for an interruption in the treatment.

There are cases in which the treatment above indicated fails to subdue some of the symptoms, and here recourse must be had to some of the preparations of iodine; this drug is as a rule required only in the later stages of the disease, when it is of value in promoting the absorption of the products of syphilitic inflammation; thus, it may be administered with advantage in cases of syphilitic ostealgia involving the cranial or other bones, such as the clavicle, ulna, or tibia, in tuberculous and ulcerative syphilides, in syphilitic glossitis, and in tertiary affections of the brain, the eye, the viscera, and the bones. It is usually given in the form of iodide of potassium, but the iodides of sodium and ammonium are equally efficacious and less depressing. It may also be administered in the form of intramuscular injections of iodipin, 25 per cent, of which $\frac{1}{2}$ oz. may be

introduced on alternate days until the quantity injected amounts to from 30 to 40 oz.; this heroic treatment is applicable only in severe and destructive tertiary lesions; iodipin may also be administered by the mouth in doses of $\frac{1}{2}$ oz. of the 25 per cent solution three times a day.

Brief allusion may be made to a method of treatment known as Zittmann's, which consists in the imbibition of a large quantity of a decoction of sarsaparilla, mixed with other ingredients, including calomel. Two quarts are taken in the course of the day; the patient is kept in a room at a temperature of 80° F., is purged, and kept on a light diet. The treatment is depressing, and is only adopted in intractable cases which will not yield to the ordinary measures, and the ingestion of the same quantity of hot water will produce a very similar result.

In addition to the general treatment outlined above, the majority of the symptoms of the disease may be treated on general surgical principles, but there are certain manifestations which may call for special local measures. Ulcerating condylomata must be kept dry, and treated by a dusting powder consisting of equal quantities of calomel and starch; ulceration of the tongue, throat, or any part of the buccal mucous membrane should be painted over with a solution of hydrarg. perchlor. 4 gr. to the ounce, and as a mouth-wash or gargle a weaker solution of hydrarg. perchlor., $\frac{1}{2}$ gr. to the ounce, may be used. Palmar and plantar psoriasis and the chronic desquamating papular syphilides may be treated by the application of oleate of mercury in strength of 5 to 10 per cent.

J. Ernest Lane.

SYPHILIS OF THE NERVOUS SYSTEM.—Syphilitic processes in the nervous system, as in other localities, respond readily, as a rule, to antisymphilitic remedies. This statement does not, however, hold good for those neurone degenerations in the etiology of which syphilis plays an essential rôle (tabes, general paralysis of the insane); nor can these remedies be expected to replace nervous tissue which has been destroyed by the disease, as is the case in cerebral softening, a consequence of thrombosis of a syphilitic vessel, and in so-called syphilitic myelitis, which is of similar causation. The administration of large doses of iodide, in a case of syphilitic cerebral thrombosis, will not restore the softened area, and may indeed do harm by lowering the blood-pressure and facilitating the extension of the thrombus. In such cases, antisymphilitic remedies should only be employed after the acute process has passed off, when they are indicated with the object of influencing the changes in the arterial walls, and thus diminishing the risk of similar accidents in future.

When syphilis of the nervous system is recognized, energetic treatment is called for. Anyone who has had much experience of cerebral syphilis can probably recall cases of gummatous meningitis which have been treated for weeks with small doses of antisymphilitic remedies without improvement, and in which the administration of larger doses was at once effective. If the diagnosis is correct, the drug will almost always be well borne.

Mercury, the iodides, salvarsan, and neo-salvarsan are the known remedies which have a pronounced influence upon syphilitic processes. The principles in the treatment of syphilis of the nervous system are similar to those adopted in relation to syphilis elsewhere. Since the relative efficacy of the iodides and mercury is a matter of uncertainty, it is advisable to administer them simultaneously.

Mercury may be given by the mouth, by inunction, or by intramuscular injections. Oral administration is convenient, but has the disadvantage that the drug is somewhat uncertain in its action, and may cause gastro-intestinal disturbance. Corrosive sublimate, in the form of liquor hydrargyri perchloridi,

(1-900) $\frac{1}{2}$ to 1 dr. thrice daily, may be given in a mixture, together with potassium iodide. Grey powder, combined with Dover's powder if there is any tendency to diarrhœa, is useful in the case of children suffering from congenital syphilitic lesions. Inunctions of mercury are on the whole more effective, while they are not so liable to derange digestion. A drachm of unguentum hydrargyri, or of the unguentum cinerei, should be used daily. The ointment is to be rubbed into the skin for twenty minutes each day, the locality being varied in order to avoid local irritation; this procedure should be continued for a month. Intramuscular injections have the advantage that they act more rapidly, and that the exact quantity of the drug introduced into the system is known. When the symptoms do not respond to the methods above described, injections into the muscle may be employed. Salicylate of mercury, gr. $\frac{1}{2}$, made up to a 10 per cent solution in liquid paraffin (10 gr. in 100 min.) may be injected into the gluteal region. Six injections should be given at intervals of four or five days. Needless to say, rigid aseptic precautions must be employed. Optic atrophy is, according to some authorities, a contra-indication to mercurial treatment. Nonne's plan, when optic atrophy is present, is to take the field of vision and make an ophthalmoscopic examination at frequent intervals, and if either the visual acuity or the ophthalmoscopic appearances show signs of progress, to discontinue the treatment.

Iodides are of the greatest value in syphilis of the nervous system. The potassium salt is commonly employed. It is well to commence with 5 to 10 gr. thrice daily, the dose being rapidly increased to 90 gr. in the twenty-four hours; larger doses than this do not appear to be attended with any special advantage. Two or three drops of Fowler's solution, if added to the iodide, will help to counteract any ill effects produced by the drug.

When iodides and mercury are being administered, the patient should be enjoined to pay special attention to the condition of his gums and teeth. The effects of treatment are usually apparent within a few days if the remedies are given in sufficiently large doses. Symptoms which still remain after the drugs have been given for a period of from six to ten weeks will probably be permanent (Gowers). Very occasional cases are met with in which both mercury and the iodides are ineffective; indeed, cases have been recorded in which syphilitic lesions have developed during an antisyphilitic course.

Salvarsan has now been given an extended trial in syphilis of the nervous system. It is of undoubted use in cerebral and spinal syphilis, though the results obtained in tabes and general paralysis are disappointing. Intramuscular injections were, in the first instance, employed; but of late the intravenous method has been almost exclusively used, the advantage of this method being the absence of pain and the possibility of measuring the exact dose. The technique of salvarsan therapy is described elsewhere. Advanced cardiac and vascular degenerations are regarded as contra-indications to its use. At one time, salvarsan therapy was looked upon with considerable suspicion, for numerous instances of relapse, and of subsequent auditory and facial paralysis, were observed, while occasional fatalities were recorded. It is now generally recognized that there is little danger if the drug is given with due precautions. The circumstance that the peripheral palsies disappear during salvarsan administration clearly indicates that they are due to the disease and not to the remedy. A dose of from 0.2 to 0.6 gram should be given once a week for a period of six weeks. It is doubtful whether the results obtained by the use of salvarsan are more pronounced than those observed in cases thoroughly treated with mercury and iodides, but there can be no question as to the more rapid action of the former. Mercurial treatment should be simultaneously administered.

Edwin Bramwell.

TABES DORSALIS (Locomotor Ataxy).—It will be convenient to consider treatment under the following headings: (1) Antisyphilitic treatment; (2) General therapeutic measures and drugs which appear to influence favourably the course of the disease; (3) Symptomatic treatment.

1. Antisyphilitic Treatment.—The existence of a very close relationship between tabes and previous syphilis is almost universally acknowledged; indeed, an increasing number of observers go so far as to say that without syphilis there would be no tabes. It is unnecessary here to do more than refer to this very intimate association. The circumstance that in only a very small proportion of those who have been infected by syphilis does tabes subsequently develop, shows that other influences must play a part in determining its incidence; although there is evidence which suggests that differences in the character of the syphilitic virus may be a factor of importance in this connection.

The establishment of this etiological relationship has hitherto not proved of great therapeutic value, for cases of tabes are rarely met with in which very striking improvement is attained by the exhibition of mercury and the iodides. In some, however, these remedies certainly do good, and there is pretty general agreement that an *antisyphilitic course is indicated*: (i) When syphilitic manifestations are present; (ii) When there is a history of comparatively recent syphilitic infection (say within five years), especially when the patient has never undergone a thorough syphilitic "cure"; and (iii) In doubtful cases in which it is difficult to exclude a true syphilitic process giving rise to symptoms closely simulating tabes (pseudo-tabes).

There is still some difference of opinion as to the advisability of mercurial treatment in all cases of tabes. The opinion, however, seems to be gaining ground that in all cases which have not previously undergone a thorough mercurial course this drug should be used. The existence of optic atrophy must be regarded as a contra-indication to the treatment, since it is affirmed that mercury has a prejudicial effect upon the degenerative process in the optic nerves.

Mercury may be administered by the mouth, by inunction, or by intramuscular injection. If the first method is adopted, the liquor hydrarg. perchlor. (1-900) may be given in doses of half to one drachm. The disadvantages of oral administration are the somewhat uncertain action of the drug and its tendency to produce gastro-intestinal derangement.

The action of mercury is more certain when it is administered in the form of unguentum hydrargyrum, $\frac{1}{2}$ dr. of which should be used as an inunction twice daily. The inner aspect of the thighs and the axillæ are the most suitable places for the application. The ointment is to be rubbed in for twenty minutes at a time, the same piece of lint being used for successive inunctions. It is advisable so to apply the ointment that the same region of skin is not used oftener than once in two days. A tepid bath may be taken immediately before the evening inunction, since it appears to assist absorption. The mercurial treatment should be continued for a fortnight, but stopped on the appearance of redness or soreness of the gums, pronounced salivation, or marked loss of weight. This "course" may be repeated at intervals of two months.

If tertiary symptoms exist, potassium iodide should be given, and continued for six weeks in increasing doses of 10 to 40 gr. three times a day. In some cases, gastric disturbance is set up by the iodide, and may interfere with its administration; it is therefore important to correct, so far as possible, any pre-existing gastric irregularities before the iodide treatment is commenced. Aromatic spirits of ammonia, or ammonium carbonate, may be added to the iodide with advantage, with the object of counteracting the depressing effect of this drug when administered for a lengthened period. If the iodide is given

in large doses, the patient should be confined to bed. Toleration of large doses may be regarded as an indication that the remedy is doing good.

Salvarsan may be used in tabes, although there is as yet no proof that it is more effective than mercury in this disease. The writer has seen several cases, however, in which the beneficial effect upon the lightning pains has been pronounced. Optic atrophy is not a contra-indication provided that small doses are given (Nonne).

The intrathecal administration of salvarsanized serum and of neosalvarsan has been recently advocated, but the available data are as yet scarcely sufficient to justify an expression of opinion as to the efficacy of these methods.

2. General Measures and Tonic Treatment.—Statistical enquiries, as well as individual observations, have demonstrated that certain factors in addition to syphilis may take a share in determining the development of tabes. Thus chills, over-exertion, sexual excesses, and trauma appear in certain cases to have acted as exciting causes of the disease. It follows that special precautions should therefore be adopted to avoid these influences, which, since they may excite the disease, are no doubt capable of accelerating its progress.

The necessity of freedom from the worries of business should be emphasized and the avoidance of over-fatigue insisted upon.

The peculiar susceptibility to falls in the barometric pressure, which is so often manifested in increased severity of the pains, is an indication for warm clothing. A warm, dry climate, such as that of Egypt or Northern Africa, is very suitable during the winter months for those who can afford it.

Loss of weight, which cannot but predispose to the development of complications and associated lesions, is a common accompaniment of severe cases of the disease; hence the need for a nutritious and fattening diet and of careful attention to the organs of digestion. Alcohol, if allowed at all, is to be strictly limited. Moderate smoking is permissible. The tabetic should be strongly advised not to marry, and he must be warned of the bad effect which indulgence in sexual excesses may have upon the disease.

General massage is of distinct service in cases in which there is much wasting. Faradism may be used with advantage when the muscular nutrition is defective; it is also sometimes of use in the treatment of certain subjective sensory disturbances. In the opinion of some authorities, the application of a weak galvanic current to the spine, for five to ten minutes at a sitting, one pole being placed between the shoulders, the other over the sacrum, has been attended with benefit. A course of hydrotherapy at some of the German baths, e.g., Wildbad, St. Moritz, may be worthy of trial by those to whom money is no object.

The suspension treatment, introduced some years ago, has been almost entirely abandoned, later observations having failed to corroborate the favourable impression at first created by this procedure.

Nerve stretching is no longer employed.

Drugs which have obtained some reputation in the treatment of this disease, as in so many of the degenerative affections of the nervous system, are arsenic and strychnine. Twelve minims of tincture of nux vomica, combined with from 2 to 5 min. of Fowler's solution, is a convenient form of administration. Strychnine must be given with caution, since in some cases it appears to increase the severity of the pains. Aluminium chloride, in doses of 2 to 4 gr. thrice daily, has been specially commended by Gowers; it may be given in combination with arsenic. Nitrate of silver, a remedy the efficacy of which was at one time greatly lauded, still has a few adherents. It may be given in the form of a pill, $\frac{1}{4}$ gr. twice a day, made up with unguentum kaolin. Gastric disturbance is apt to be produced, and discoloration of the skin results if the drug is long continued; therefore after a fortnight its administration should be stopped, to be again

resumed after a month's interval. Other remedies, such as iron and quinine, may be of value from their general tonic action.

3. Symptomatic Treatment.—A peculiar feature of tabes consists in the multiplicity of distressing symptoms to which the disease may give rise, and the almost unrivalled variety of types which it may in consequence present, according to the predominance of one or more of these symptoms in the clinical picture.

Lightning pains which present great variations both in their intensity and in the frequency of their occurrence, and which affect especially the lower limbs, are rarely absent; indeed, they constitute the most common symptom of the disease. When the pains are not severe, 5 to 10 gr. of phenacetin will often disperse them. If they are more intense, phenacetin (20 gr.), antipyrin (20 gr.), or exalgin (2 gr.), may be exploited. Pyramidon (5 to 10 gr.), and acetyl-salicylic acid (20 gr.), have been highly recommended by Oppenheim, and may be tried. Potassium iodide is sometimes of use, as is salicylate of soda. Osler finds that nitroglycerin, given in increasing doses and continued over a considerable period, is of undoubted value where the blood-pressure is raised.

Hot fomentations, massage, and a gentle faradic or galvanic current to the affected part, are sometimes beneficial. The local application of lint sprinkled with chloroform and covered with oiled silk, according to Gowers, may relieve superficial pain. Counter-irritation is occasionally useful. High-frequency currents have at times a temporary beneficial effect.

All these measures may be of use when the pains are not of great intensity; but in those cases in which their excruciating character is unbearable, morphia is usually the one drug which will bring relief. Only as a last resource should morphia be used, and the patient should not be allowed to give himself hypodermic injections; for not only is there a great risk of the development of the morphia habit, but, in addition, the drug has such a lowering effect upon the will and emotional control as to render the fight against the pains when they recur still more difficult. The effect of salvarsan upon the pains in some cases has already been referred to.

Ataxia occupies a prominent place among the serious symptoms of the disease. It has long been recognized that an increase in the ataxia is apt to follow confinement to bed, but it is only of recent years that any real success has been obtained in the treatment of this symptom. To Fraenkel we owe the introduction of a plan of treating the ataxia which has been attended with most encouraging results.

The appreciation of the rationale of the method is essential to its successful application. The procedure consists in the re-training of co-ordination, the possibility of which is shown by the observation that if an ataxic patient repeats a movement several times in succession, the ataxia in connection with that movement becomes less pronounced. Before the treatment is commenced, it is advisable to point out to the patient that his difficulty in walking is not due to weakness of the muscles, but to an inability to co-ordinate—i.e., that as a consequence of destruction of certain afferent neurons, he receives a defective and erroneous idea of the movement which he is performing, with the result that the movement is at fault. The tabetic must learn to forget the "movement memories" which served his purpose while in health, and proceed to acquire a new series of "movement memories" corresponding to the impressions which he now receives through those neurons which remain intact. The patient must realize that it is the care and precision with which the movements are carried out, rather than their very frequent repetition, which are so essential to success. Suitable exercises will suggest themselves to the physician. Even when the ataxia is slight, the value of simple exercises, such as walking along a straight

line, is considerable. The exercises should be practised systematically two or three times a day, for half an hour at a time, stopping at once, however, if the patient's attention begins to wander, or if there are any indications of fatigue. A course of general massage and faradism is a valuable adjunct when the muscles are flabby and weak from disuse.

Such complications as grave cardiac disease, bladder trouble, a disorganized joint, or a perforating ulcer of the foot, may contra-indicate this treatment. Again, mental changes interfering with the patient's power of concentration may render the treatment unsatisfactory; while severe and prolonged attacks of lightning pains and gastric crises, because of the confinement to bed which they necessitate, may counteract any improvement derived.

Hyperextension of the knees, which gives rise to difficulty in walking, may be materially benefited by suitable orthopædic appliances.

Disorders of micturition are among the most serious symptoms to which the tabetic is liable. Difficulty in emptying the bladder is very common, incontinence is of frequent occurrence, while occasionally complete retention is met with.

In every case of tabes it is necessary to impress the patient with the importance of passing water at frequent and short intervals (every two hours), and of attempting at each act of micturition to expel all the urine the bladder contains. It is well to keep in view the possibility of a co-existing stricture of the urethra, a complication not uncommonly overlooked in tabes, which, when present, calls for appropriate treatment. When there is difficulty in passing water, 5 min. of liquor strychninæ (1 per cent), thrice daily, is sometimes of use. Incontinence of urine is at times distinctly benefited when a like quantity of tincture of belladonna is taken three times a day. If there is reason for believing that the bladder is being imperfectly emptied, a catheter should be passed after the act of micturition, and the residual urine estimated; should it exceed ten ounces, it is probably best, as Sir William Gowers suggests, to draw off the urine at regular intervals, treating the case, in fact, exactly like retention dependent upon an enlarged prostate, and with the same object in view, viz., the prevention of cystitis and its dreaded sequela, pyelonephritis. The residual urine should be drawn off two or three times in the twenty-four hours, with the hope that in the course of a short time it will diminish in quantity. There is little, if any, additional risk of producing a cystitis in passing a catheter in cases of tabes, provided that rigorous aseptic precautions are taken. When cystitis actually exists, the bladder should be washed out twice daily with weak boracic solution; while remedies such as hexamethylenamine, acid phosphate of soda, etc., may be given internally, according to special indications.

Constipation is often a troublesome symptom. Fluid extract of cascara, 5 to 20 min., combined with tinct. nucis vom., 12 min., three times a day, may be sufficient to produce a daily evacuation of the bowel. It is often necessary, however, to employ enemata.

Crises.—Visceral crises may be a source of great distress to the tabetic. Among these, gastric crises are most often met with. During an attack, the patient should be fed per rectum. Oxalate of cerium, 5 to 10 gr., given in a wafer paper, has been said to do good, and may be tried. A minim of spirit of nitroglycerin may be given, three times a day, in cases where the blood-pressure is raised. But, as a matter of fact, if the crises are severe, morphia given hypodermically is usually the only drug found to be of any real value. The problem of the administration of morphia in these cases is a most difficult one, for in the writer's experience there is no patient so likely to become a morphomaniac as the tabetic who suffers from gastric crises. It is of great importance to feed up the patient in the intervals between the attacks, in order that he may recover

his strength and make up the loss of weight which is produced thereby. In several cases of tabes with very severe gastric crises, the seventh to ninth dorsal posterior roots have been divided. This operation, which was originally proposed by Foerster, has been attended with promising results. The procedure is a severe one, and only to be undertaken in extreme cases.

Laryngeal crises may sometimes be relieved by the inhalation of nitrite of amyl; if this fails, painting the vocal cords and neighbouring parts with a weak cocaine solution may be found to be of service.

In the case of rectal, vesical, and intestinal crises, the application of a mustard leaf or hot fomentation to the abdomen is worthy of trial. The various analgesics above mentioned may also be employed, but when the crises are severe, morphia, given in the form of a suppository, will usually be found to be the only effective remedy.

Optic atrophy, when present, frequently goes on to complete blindness. In these cases ataxia is often absent or ceases to progress if the amaurosis becomes complete, while the pains are usually slight. Mercury and potassium iodide are contra-indicated in these cases. Strychnine given hypodermically tends, it has been affirmed, to retard the atrophic process in the optic nerves. An initial dose of $\frac{1}{100}$ gr. per diem should be gradually increased until the physiological action of the drug is apparent.

Pain in the back may sometimes be relieved by counter-irritation. Failing this, the remedies previously mentioned as effective in the treatment of the lightning pains should be resorted to. Girdle pains are to be treated on similar lines. Cutaneous hyperæsthesia, a somewhat uncommon symptom of the disease, is at times markedly benefited by the application of a weak faradic current with a fine wire brush electrode. The effect of a warm bath may also be tried in these cases.

The treatment of perforating ulcers or tabetic arthropathies which are giving rise to inconvenience may be relegated to the surgeon.

From these remarks on the symptomatic treatment of tabes, it will be seen that the physician has considerable therapeutic scope, with a distinct prospect that his endeavours will not be altogether in vain.

SUMMARY.—We may say that the first question demanding solution is a decision as to whether an antisiphilic course is called for; this must be decided from the indications already laid down. In addition, the patient should be advised, in the words of Erb, "to live the life of an old man, simple, abstemious, quiet, and regulated." If the case belongs to the category of early stationary tabes with unobtrusive symptoms, prophylactic precautions alone are required; if, on the other hand, the case is more advanced, active general measures and suitable symptomatic treatment must be adopted, according to the special indications present.

Edwin Bramwell.

TACHYCARDIA.—This is a term used rather loosely, signifying a considerable increase in the frequency of the heart's action. It is a condition far from uncommon, and though in the majority of instances it is a temporary manifestation, it may be continuous.

Before considering the treatment in any case, it is imperative to have clearly in mind the cause of the acceleration. In some patients a frequent heart action is normal; in others of an emotional nervous temperament, very slight stimuli produce marked changes in the rate of the heart. Whatever causes enfeeblement or irritability of the myocardium, such as exhausting diseases, influenza, diphtheria, cachexia, or anemia, induces a liability to attacks of tachycardia. In such patients the accelerated action of the heart is the result of an increased stimulus production at the sinus, or an increased excitability and irritability

of the cardiac musculature. Pyrexia and certain toxins such as alcohol and atropine act similarly by diminishing the inhibitory influences. Over-secretion of the thyroid gland is an important factor, tachycardia being in some instances the first manifestation of Graves's disease. In an enfeebled heart, physical exertion may produce a tachycardia which persists for hours, instead of quietly settling down within a few minutes of the exertion. One notices also a peculiar liability to undue frequency of the heart in cases of mitral stenosis, a condition very little influenced by drugs. If no reason for the tachycardia can be discovered, one should suspect some obscure toxæmia, such as pulmonary tuberculosis without pyrexia or physical signs, or an infection by the *Bacillus coli* or other organism.

In the above instances of tachycardia, the manner of the heart's action is normal though frequent, and the contraction of the heart starts in the usual site; but there is another series of important groups in which this is not so.

Auricular fibrillation, the tachycardia being continuous, or in paroxysms with normal intervals. There is no co-ordinate contraction of the auricle—its muscular wall is in a condition of fibrillation or fine tremor.

Auricular flutter, characterized by enormously increased frequency of the action of the auricle, the contractions originating in an unusual site, the ventricles responding to every second or third systole of the auricle.

Paroxysmal tachycardia, or enormously increased frequency of the heart, the contraction originating in some abnormal place in the auricles, in the ventricles, or in the auriculo-ventricular node.

The tachycardia in the first group generally shows some slight irregularity. In the second and third groups the pulse is unusually frequent, 120 to 250, and quite regular in time. Alternation may be observed. The paroxysms begin suddenly and cease abruptly. The rate is not influenced to any degree by emotion, pyrexia, or exercise.

TREATMENT.—In many instances frequent heart action is associated with palpitation, and the treatment described for the latter complaint will be equally helpful for the tachycardia.

In the nervous patient, a cold sponge down in the morning, followed by skin-rubbing exercises, will give tone to the vasomotor system. For these patients gentle exercise in the open air is to be recommended.

When the tachycardia appears after exhausting diseases such as influenza or diphtheria, or when it is associated with anæmia, rest is essential and gentle massage should be employed, together with some preparation of iron, quinine, and strychnine, such as Easton's syrup.

In the tachycardia of mitral stenosis ammonium bromide should be given at night as:—

R Ammonii Bromidi	gr. xxx	Liquoris Potassii Arsenitis	℥ij
Spiritus Aromatice Aromatici	℥xv	Aquam Menthæ Piperitæ	ad ̄ss

All alcoholic and other stimulants must be avoided, and coffee and tea should only be taken in the greatest moderation. It is well to curtail the amount of tobacco smoked, and sexual excess must be avoided.

In any obscure case, corroborative evidence of hyperthyroidism should be carefully sought for.

The apyretic tachycardia of some cases of pulmonary tuberculosis is extremely ominous, and the general condition must be vigorously attacked by complete rest, free diet, and the tentative administration of minute doses of tuberculin.

The treatment of the tachycardia due to *auricular fibrillation* is fully described in another article (see HEART, IRREGULARITY OF). The essentials are rest and the exhibition of some member of the digitalis group until the heart is slowed down, any marked hypertension being modified.

Similar treatment is necessary for the cases of *auricular flutter*. Tincture of digitalis, 80 minims daily, increases the block at the junctional tissues, and the ventricular rate is diminished. The flutter may give way to fibrillation; and this may be looked upon as a step towards recovery, as the fibrillation sometimes ceases and a normal action of the heart supervenes. When the tachycardia is due to fibrillation or flutter of the auricle, life should be taken very easily; confinement to bed is necessary for some patients if the discomfort is considerable, and more particularly if digitalis is being administered in large doses.

In *paroxysmal tachycardia* nothing gives consistently good results. The attacks begin and end suddenly, apparently independently of treatment. As a result of the paroxysm the heart may dilate and evidence of cardiac distress may follow, though often there is nothing more than slight discomfort. It is better for the patient to rest, and this becomes imperative if the heart shows signs of dilatation. Vigorous slapping of the chest, counter-irritation, or pressure on the vagus has at times appeared to terminate an attack. Small doses of digitalis appear to be of some service. The mode of life between the paroxysms should be carefully regulated. Coffee, tea, alcohol, and tobacco should be used in great moderation, and the heart should not be subjected to any undue stress.

John Hay.

TÆNIA.—(See WORMS, INTESTINAL.)

TALIPES, ACQUIRED.—The term talipes, or club-foot, signifies an abnormal attitude of the foot, with consequent disturbance of its relationship to the leg or of that of its component parts to one another. The expression “acquired club-foot” indicates that the faulty attitude has developed at some period after birth, and contrasts the condition with the congenital deformity which is present when the child is born. The deformity may occur in any one of the four directions in which the foot can be moved, or it may be compound, in two directions at the same time. The subjoined table will show the more common varieties of acquired club-foot, and briefly indicate the attitude in each variety.

Simple Talipes	{	Equinus. Foot pointed—heel drawn up.
		Calcaneus. Heel dropped—front of foot raised.
		Varus. Foot inverted.
		Valgus. Foot everted.
Compound Talipes	{	Equinovarus. Foot pointed and inverted.
		Calcaneovalgus. Heel dropped—foot everted.
		Equinovalgus. Foot pointed and everted.

Another deformity which falls within the scope of our definition of club-foot, but is not included in the above classification, is the condition called claw-foot, or *pes cavus*.

Acquired club-foot is essentially due to prolonged maintenance of a faulty attitude by the affected limb. There are many conditions which result in this maintenance of abnormal position, but granted that any one of them has come into action, the nature of the deformity produced will depend more upon the habitual attitude assumed by the foot in the new circumstances than upon the circumstances themselves. For example, if the muscles of the leg be paralyzed from poliomyelitis, and the foot be allowed to hang down habitually, the deformity will be one of equinus or equinovarus. If, on the other hand, the patient attempts to walk on the paralyzed limb, the superincumbent body weight will in all probability produce a condition of calcaneus or calcaneovalgus. The maintenance of the foot in bad position is soon accompanied by contraction of such structures as the tendo Achillis, plantar fascia, tibialis posterior, or ligaments such as the plantar ligaments and the posterior and internal lateral ligaments of the ankle-joint. This contraction fixes the foot in its abnormal position, and it is impossible to rectify the deformity until the tight structures have been divided or stretched.

By far the commonest cause of acquired club-foot is infantile paralysis affecting the muscles of the leg to a greater or less extent and as a consequence the condition is often

called paralytic talipes. But club-foot can also be acquired as the result of contraction following burns, or during the course of disease of the ankle-joint or of the bones of the leg; it is a constant accompaniment of the central palsies of infants, i.e., spastic paraplegia and infantile hemiplegia. Again, talipes equinus can be acquired during the treatment of fractures, or of any disease, because the bed-clothes have been allowed to weigh upon the foot and keep it in the extended position long enough to overstretch the flexors of the ankle while the tendo Achillis contracts; this condition has been called talipes decubitus. Acquired talipes may result from peripheral neuritis, or may be produced by accidental section of, or pressure upon, one of the popliteal nerves, or by forcible straightening of a flexed knee without section of the tendo Achillis. Lastly, the condition may be hysterical.

The only point in the diagnosis is the differentiation from the congenital deformity. The distinguishing features, such as the absence of deformity at birth, the history of symptoms suggesting an attack of poliomyelitis, the fact that movement of the foot is limited in one direction only, whereas the congenital club-foot is a rigid one, the wasting of the calf, the poverty of the circulation, and the under-development of the part, clearly indicate the paralytic talipes, and should the deformity be due to any of the other causes mentioned above, the history and general features of the case will usually throw light upon the origin of the mischief. The hysterical club-foot is usually, but not always, an equinovarus, and is associated with much spasm and rigidity while the patient's attention is fixed upon the foot. The deformity disappears under anæsthesia, or even if the attention can be attracted to other things.

As a rule, acquired talipes is not accompanied by much osseous change in the foot, unless the deformity is an old-standing one or has been produced by actual bone or joint disease.

TREATMENT.—In the treatment of acquired club-foot the deformity must be corrected, and steps must be taken to prevent it recurring. Thus the means at our disposal fall under two heads: (1) Operative; (2) Mechanical. The operative measures are tenotomy, with or without forcible correction with the wrench, tendon transplantation, removal of portions of redundant skin, and joint fixation or arthrodesis, with or without removal of portions of the tarsal bones. Mechanical apparatus has two great functions—it may be used to prevent the development of an acquired club-foot, and it is of the greatest value in the post-operative treatment of the club-foot once the deformity has been corrected—it cannot replace operation if the deformity has already developed. Splints and irons should combine simplicity with effectiveness; they should tend to correct the deformity for which they are employed, and they should be designed so that they may be applied without interfering with the circulation in the affected limb.

In the detailed account of the treatment of each variety of talipes it is assumed that the condition is paralytic; mention, however, is made of any modification necessary in dealing with cases due to other causes.

Paralytic Talipes Equinus is a simple deformity. The tendo Achillis is shortened, and the patient walks upon the heads of the metatarsal bones or even upon the dorsum of the toes; the flexors of the ankle and often the extensors of the toes are overstretched and useless.

Tenotomy of the tendo Achillis usually allows the foot to be brought up to a right angle; if the posterior ligament of the ankle-joint is shortened, the shortening can be overcome by the use of the Thomas wrench. As a rule, if the foot be kept in good position in a light rectangular splint for a sufficiently long time, and efficient massage be employed, the anterior tibial group of muscles will recover their tone and will themselves prevent the deformity recurring. As this process is often a tedious one, and it is difficult to keep a splint applied for a long period of time, the foot can be more efficiently splinted by removing a good piece of skin from the front of the ankle, and stitching the edges of the raw surface together so as to tighten up the skin and suspend the foot in good position.

If it is thought that the anterior muscles will not recover, it is advisable to perform an arthrodesis of the ankle by removal of the cartilage covering the bones entering into the articulation, this resulting in a short fibrous ankylosis

being produced with the foot in good position. It is not advisable to resort to this measure in a young child, nor indeed is it often necessary in the case of simple talipes equinus, as the muscles frequently recover when the stretching effect of the deformity has been removed. In order to ascertain whether they will recover, it is only necessary to increase for the moment the equinus deformity, and observe if any extending movement of the toes can be performed voluntarily or even reflexly; if there is the slightest flicker of extension the muscles will recover their tone, provided the foot be kept at right angles for a sufficiently long time and the limb be well massaged. In talipes equinus due to spastic paralysis, simple tenotomy is not advisable, as the proximal end of the divided tendon will retract up the leg, and a condition of calcaneus will develop. The best procedure in such a condition is division of the tendon through an open incision, and mooring the two ends with strands of chromic catgut after the foot has been brought to a right angle. Talipes equinus due to old disease of the ankle or tarsus, with ankylosis in a faulty position, is best dealt with by removal of a wedge of bone from the dorsum of the foot as near the ankle-joint as possible.

If a walking-iron is necessary in the post-operative treatment of talipes equinus, a simple and effective mechanism is a light iron running down the back of the calf and turning at right angles at the heel to run forwards for a short distance in the substance of the boot. This iron is secured at its upper end by a leather strap and buckle, and another strap should be applied round the ankle, so that the heel may fit into the angle of the iron.

Talipes Calcaneus is a condition which varies in severity with the age of the patient, and the treatment consequently depends upon the same factor. In the baby a few months old, the deformity may be corrected by shortening the tendo Achillis through an open incision—the tendon being split longitudinally, and stitched up so that the wound becomes transverse; the wound in the skin may be treated in the same way. The foot must be kept pointed for several weeks by means of a short straight splint applied over the front of the ankle, and massage of the muscles of the calf must be thoroughly carried out. The child should be allowed to walk only in a back-iron such as described above, but bent at an angle rather greater than a right angle at the heel. This method of treatment will fail if the child is old enough to walk before the surgeon is consulted. In such a case an arthrodesis of the ankle—the joint being attacked on the posterior aspect—will secure a much more permanent result. In performing this operation, in addition to removal of the cartilage from the bones, a wedge is taken from the back part of the body of the astragalus. This procedure results in an ankle-joint with an immeasurably strong posterior ligament which retains the foot in good position, and the long prominent heel which is such a feature of talipes calcaneus is shortened. In older cases still, there is not merely calcaneus, but the foot is arched and the plantar fascia contracted; this deformity is sometimes termed **Calcaneocavus**, and there may be superadded an element of varus or valgus. For such cases two distinct operations are indicated:—

1. Tenotomy of the plantar fascia and removal of a wedge from the dorsum of the foot. In this way the hollow-arched condition of the foot is removed, even if the calcaneus deformity be made to appear more exaggerated.
2. Posterior arthrodesis, as described above, is performed, and the straight foot moved down at the ankle-joint into good position.

It is hardly necessary to add that some weeks ought to intervene between the two operations. Other measures which have been tried for this talipes calcaneocavus are implantation of the peronei and flexor longus hallucis tendons into the tendo Achillis, but the results obtained by the procedure first described are much more satisfactory.

Equinovarus is a common combination of deformity in two directions ; the foot is pointed and inverted, the tendo Achillis is shortened, as is the plantar fascia, and possibly the tibialis posticus and the internal lateral ligament of the ankle-joint ; the head of the astragalus usually forms a marked prominence on the dorsum of the foot. The flexors of the ankle are either permanently paralyzed or overstretched, and so weak as to be useless. Treatment here depends on the condition of the muscles ; if they give any indication that they will recover their tone when the deformity is corrected and the foot has been kept in good position for the necessary period of time, then tenotomy of the plantar fascia and tendo Achillis is sufficient. The foot must be kept overcorrected in a club-foot shoe, and the muscles be well massaged until such time as they can hold in good position without aid. This interval can be shortened by employing the operation of tendon transplantation. A slip of the tendo Achillis may be fixed to the peroneus longus tendon, but a better method is to shift the tendo Achillis to the outer side of the os calcis and to take a functioning tendon at the front of the ankle, say the tibialis anticus or the extensor proprius hallucis, and reinsert it into the outer side of the foot. In this way the foot is braced up in a good position, and the muscles, in virtue of their new insertions, serve to keep it right. If the extensor muscles be considered useless, the treatment to be adopted is an arthrodesis of the ankle-joint, with excision of the wedge from the outer side of the body of the astragalus ; this operation is usually the one adopted in adolescent or adult cases, and the results are extremely satisfactory. It is sometimes necessary to combine tendon transplantation with arthrodesis in order that a good and permanent correction of the deformity may be obtained.

Whatever be the operative measure in a case of talipes equinovarus, the after-treatment is the same. At first the foot must be kept overcorrected in a club-foot shoe, or in a plaster-of-Paris dressing reaching from the toes to below the knee. Later on, when the patient is allowed to walk, he should wear an iron running down the inside of the ankle, and turning to fit into a brass socket which crosses the heel of the boot ; the play which takes place between the iron and the socket allows movements of flexion and extension of the ankle. The upper end of the iron is fastened to the leg by strap and buckle, and an additional strap round the ankle holds it snugly to the iron and ensures that the foot is kept everted. In addition a strap of metal is worn along the outer edge of the sole of the boot, to lift up the front part of the foot. The patient should continue to wear the club-foot shoe at night, even though he is walking with a boot and iron in the day-time, as the foot tends to relapse into the old position during sleep.

Talipes Calcaneovalgus is one of the most common varieties of paralytic club-foot. In the child six months to two years old the condition looks more like flail ankle, or at any rate pure valgus ; the foot can be overflexed at the ankle and everted and abducted. In such cases the surgeon is tempted to perform an arthrodesis of the ankle, with removal of a wedge from the inner side of the body of the astragalus, but this operation will surely fail if performed at an early age—the ankylosis will not be a firm one, and so the deformity will recur. Therefore, if arthrodesis seems necessary, it is better to fit the child with a walking-iron until he reaches the age of six or eight years, when the operation can be performed with much greater likelihood of success. If investigation of the muscular power leads the surgeon to consider that a tendon transplantation will suffice, good results are obtained by shifting the tendo Achillis to the inner side of the os calcis, and at a subsequent operation implanting the extensor proprius hallucis tendon into the periosteum of the inner side of the neck of the first metatarsal bone. This procedure will only serve for pure valgus deformity. Calcaneovalgus will require the treatment described under calcaneocavus.

Talipes Equinovalgus is a not uncommon variety of acquired club-foot. Here the foot is pointed and abducted, the toes are often dorsiflexed, and there may be a condition of hallux valgus, resulting from attempts at walking on the deformed foot. The tibialis anticus and posticus are the muscles which are not acting, and the tendo Achillis is contracted. Excellent results can be obtained in this condition from treatment, which is carried out in three stages: (1) Shifting the tendo Achillis to the inner side of the os calcis; (2) Some weeks later, elongation of the Achillis tendon; (3) Later still, implantation of the extensor proprius hallucis in to the inner side of the foot.

In all cases of valgoid deformity the foot must be kept inverted for several weeks after the operation. This can be done with an outside straight splint or by means of a plaster dressing. The iron with which the patient walks is planned in the same way as the iron for talipes varus, but is placed on the outside of the ankle. In addition, the heel of the boot should be elongated, so that it comes under the instep, and it should be made deeper on the inner than on the outer side; this throws the body weight on to the outer side of the foot.

Pes Cavus, or Claw-foot.—This condition, not falling under any of the headings mentioned above, is still included in our definition of club-foot. It is a deformity which causes extreme pain, and interferes with locomotion to a very grave extent. The foot is short, thick, and stubby; there is enormous exaggeration of the normal antero-posterior arch, so that the under surface of the foot presents in bad cases little more than a deep cleft between the prominent heads of the metatarsals. The toes are dislocated backwards at the metatarsophalangeal joints, and acutely flexed at the first row of interphalangeal joints; there are usually large corns over the prominent heads of the metatarsal bones, and pressure here causes exquisite pain. The plantar fascia and plantar ligaments are much shortened, as are the extensor tendons of the toes and the glenoid ligaments of the interphalangeal joints. There is often a degree of equinus or even varus associated with claw-foot. No condition leads to greater disablement of the foot, and in none does the treatment demand more from the ingenuity and skill of the surgeon. The etiology of this deformity is obscure; it has been attributed to infantile paralysis causing paresis of all the muscles, especially the flexors of the ankle and the lumbricales and interossei; but no explanation has been found for this particular deformity after the muscular paresis.

Treatment varies with the severity of the deformity. Division of the plantar fascia and correction of the overarched foot with the wrench are necessary preliminaries in every case. The tendo Achillis may have to be divided, but this must not be done until all the wrenching is finished, as the resistance of the Achillis tendon is necessary while the arch is being straightened out with the wrench. In milder cases this is all the operative treatment necessary; the patient may be allowed to walk in a boot, the heel of which has been lowered, and which has a bar of leather half an inch thick running across the sole opposite the necks of the metatarsals. Some splint, e.g., a club-foot shoe, which will keep the foot straightened out, must be worn at night.

In certain cases benefit has been obtained from implantation of one or more extensor tendons into the heads of corresponding metatarsal bones. Severe cases, and those which tend to relapse, are best treated by removal of portions of metatarsals near their bases. This should be done through separate incisions on the dorsum of the foot over each bone. Tenotomy of the extensor tendons and of the tight structures on the plantar side of the interphalangeal joints will allow the toes to be straightened. On no consideration should there be any operation wound in the sole of the foot. The after-treatment is the same as that described above.

Robert Jones.

TALIPES, CONGENITAL.—It is well to remember that in most instances congenital talipes is a distortion pure and simple, unaccompanied by paralysis of any of the muscles, and capable of complete cure if treatment is commenced sufficiently early. Certain muscles are, however, abnormally short, while others are too long; the shortened muscles are stronger than the opposing and stretched ones, which tend to become still weaker from disuse and over-stretching, if the deformity is left untreated. Certain ligaments and bands of fascia are too short, but are capable of being stretched or divided. The bones are more or less deformed, but these will gradually acquire their normal shape if the deformity is corrected and the foot retained in its corrected position for a sufficient length of time. The earlier the case comes for treatment the more cartilaginous are the bones, the less distorted are they, and the sooner will they assume their normal shape.

There is no deformity which calls for a greater amount of patience and perseverance from both surgeon and parents than does the one under discussion.

Two points must never be forgotten: (1) Treatment must be commenced as early as possible; and (2) Treatment and supervision of the cases must be continued till all tendency to relapse has disappeared, i.e., in the majority of cases, for years. Many patients have to wear apparatus of some sort till they have reached the age of six or seven.

All varieties of this deformity are treated on the same general lines, and, since three-quarters of the cases fall under the head of equinovarus, this class of case may be taken as the type, and its treatment considered in detail. Equinovarus cases are usually more severe than those of other varieties; they possess a greater tendency to relapse, and they therefore call for most care in treatment. In this deformity, the foot is inverted and adducted, as well as plantar-flexed. The two former movements take place at the sub-astragaloid and mid-tarsal joints, the latter at the ankle-joint. The longitudinal arch of the foot is usually somewhat increased, and the plantar fascia contracted, particularly its inner part.

To obtain a complete cure the surgeon has to do three things:—

1. To correct, and to over-correct, the deformity.
2. To retain the foot in the over-corrected position till the muscles have regained their balance and the bones have acquired their normal shape.
3. To correct any accompanying deformity, such as rotation of the leg, genu-valgum, etc., the presence of which may prejudice the result of the treatment of the foot. In all but the mildest cases of equinovarus there exists an internal rotation of the foot and leg. This rotation may take place anywhere in the leg, most commonly in the tibia and fibula. So long as this rotation persists, though the distortion of the foot be fully corrected, the child will walk with the toes turned in, and there will exist a constant tendency to recurrence of the varus portion of the deformity.

We may consider the treatment under four heads, arranged according to the severity of the cases to be dealt with. Thus we have (1) The mild cases, which can be cured without any operative procedure; (2) The severe cases, the most numerous, which require tenotomies, fasciotomies, etc.; (3) The relapsed and neglected cases; (4) The inveterate cases in adolescents and adults.

1. *Mild Cases.*—In these cases the foot can be brought into line with the leg, or even slightly everted, but the moment the foot is released it springs back to its faulty position. The equinus is also slight, i.e., dorsiflexion is but slightly limited. These cases may be treated successfully by manipulation and fixation on a simple tin shoe (*Fig. 79*). The mother or nurse is taught to manipulate the foot in two definite directions. For the first manipulation the heel and ankle are grasped firmly with the fingers and thumb of one hand,

while the other grasps the forepart of the foot; the latter is then gently but firmly turned outwards, at the same time everted as far as possible, held in the corrected position for some moments, and then let go. This movement is repeated again and again, the utmost possible correction being obtained each time. The second manipulation is then performed as follows: the malleoli are grasped in one hand, while the other seizes the foot and dorsiflexes it as far as possible, holds it in the corrected position, and then lets go. This movement also is repeated many times. During this manipulation the foot must be held in the position of slight eversion, i.e., the varus must be corrected at the same time, or some of the muscles will escape proper stretching. The foot should thus be forced towards the position of calcaneo-valgus. The foot and leg are then carefully massaged, special attention being paid to the muscles on the outer side of the leg. The splint is now applied to the leg with a calico bandage, the foot being held in as good a position as possible. Two or three times a day the splint is removed, and the manipulations and massage are

Fig. 77.—Malleable Iron Splint.

Fig. 78.—Adams' Varus Splint.

repeated. Day by day the foot is further corrected, until full over-correction is obtained, but the treatment must be continued till all tendency for the foot to return to its faulty position has disappeared. The angle the foot-plate makes with the leg-piece can be altered from time to time as the over-correction becomes more and more complete.

In the mildest cases the child may be completely cured before he learns to walk. In others the foot may still need watching after walking has commenced; in such cases it is well to manipulate the foot every night, and to let the child wear the splint during sleep, and to have the outer edge of the tread of the boot that is worn by day thickened by the addition of a slice or two of leather, while in a few cases a boot with the sole and heel thickened on the outer side, and with an inside iron and varus T-strap, may be required.

2. *Severe Cases.*—No hard and fast line can be drawn between mild and severe cases, but it will be found a good rule to make use of tenotomy in any case in which the foot cannot be brought into line with the leg by ordinary pressure with the fingers. The varus should be corrected first, the equinus left till later, as the tendo Achillis serves as a useful *point d'appui* for the stretching of the contracted tissues in the sole of the foot. During the first week or two of life simple manipulations may be employed; and in the third week, if the child is in good condition, tenotomy may be performed. What structures will require division? It is usually necessary to divide the tibialis anticus tendon, the inner band or the whole of the plantar fascia, and the anterior part of the internal lateral ligament of the ankle-joint. These may all be divided subcutaneously, sometimes even through the same puncture in the skin. The tibialis posticus may also require division, but this is by no means always necessary. This tendon is best divided above the internal malleolus, through an open incision. Occasionally it may be found necessary to divide this tendon after the equinus has been corrected. Other structures which may require division are the abductor hallucis, and the astragalo-scapoid and the inferior calcaneo-scapoid ligaments. As a rule all these structures can be

Fig. 79.—Tin Shoe with Quadrant. Special pattern for equinovarus.

stretched sufficiently by forcible wrenching at the time of doing the other tenotomies, and by the daily manipulations afterwards. After tenotomy a pad of gauze is placed over the puncture and a rather firm bandage applied; the foot is then fixed in a partially corrected position (Fig. 77) by the iron splint, bent to a suitable angle round the outer side of the foot.* The foot should be held in as good a position as is possible without undue pressure. The usual position will be with the foot in line with the leg, a position which it could not before be made to assume; to hold the foot in this position the splint must be slightly bent outwards. It is not wise to attempt full over-correction at once, as if this be done the pressure of the splint is liable to damage the skin. After four days the splint is removed, bent further outwards, and reapplied, the correction of the deformity and the daily manipulations being continued till the varus is fully over-corrected and the contraction of the sole unfolded.

This will occupy some four weeks, after which the second stage of the treatment is proceeded with. The tendo Achillis is divided subcutaneously, and the foot is forcibly dorsiflexed to stretch the posterior ligament of the ankle-joint; the foot is then put up at a right angle, with the varus corrected, for four days, after which time the daily manipulations and massage may be recommenced. Two splints are in common use. The better is Adams' varus splint (Fig. 78), which is quite simple and yet absolutely controls the foot. The other is a tin shoe, with a quadrant and screw on one side (Fig. 79), so that the degree of flexion of the ankle may be altered. The author prefers that the sole-plate should be slightly everted, and should not lie in a transverse horizontal plane when the leg-piece is held vertical. The sole-plate should have its inner margin convex and its outer concave. These modifications of the simple rectangular shoe will be found of great service in holding the foot in an over-corrected position. This latter instrument has the advantage of being cheap, and is suitable for all the milder cases and the youngest infants; but for severe cases and older children Adams' apparatus is the better. Although more complicated,

* This splint is *not* for equinus, but for varus.—H.A.T.F.

it can be removed, replaced, and even adjusted by the mother or nurse. It has also some control over the internal rotation of the leg. The strap passing over the front of the ankle is fixed first, so that the heel is well down. It is also useful to have the sole-plate extended while the apparatus is being applied, and to screw it up after the heel is fixed, especially in the early stages of treatment. The sole-plate is best set in a position of slight eversion as in the case of the tin shoe. The tin shoe is fixed to the limb by a strong calico bandage. Whatever apparatus is used, it is removed two or three times each day, and massage and manipulations are performed as before. This treatment is continued till the child is allowed to walk, i.e., till about the end of the second year, though the correction of the equinus takes only from four to six weeks. If the case proves obstinate or is allowed to relapse, the foot may need wrenching under anæsthesia. Lorenz's padded wedge will be found useful, or the hands may be aided by some form of wrench, e.g., Thomas's.

In all cases it is advisable to order a surgical boot and irons for walking purposes. A varus T-strap is always used. In the worst cases a light toe-elevating spring may be added, with a "stop" to prevent over-dorsiflexion, while in the mild cases a "back-stop," to prevent plantar flexion, may be sufficient. In the majority of cases the inner iron should reach to the upper part of the thigh, while the outer iron is continued to a pelvic band, and double knee-caps and a ring-catch are added at the knee. By means of this large apparatus (*Fig. 80*), the internal rotation of the limb, wherever this may have taken place, is controlled, and, as the child grows, gradually corrected. Laxity of the ligaments at the knee, genu valgum, and genu retrorsum, can all be dealt with by this apparatus. The irons should be worn for a year at least, and often for much longer. If difficulty is experienced in preventing the rotation inwards of the whole leg and irons, the pelvic band may be prevented from slipping round by the addition of a short iron reaching to a broad band around the thigh of the sound leg. When both legs are affected, the rotation of the feet can be easily adjusted by straps at the front and back of the pelvic band. At night a tin shoe or Adams' splint must be worn, the daily manipulations being carried out as before. The cause of relapse is leaving off treatment too early: the more severe the case the longer must it be watched. Something may be done for the rotation of the leg even before the child walks, if the twist occurs below the knee. The upper and lower ends of the tibia and fibula are seized by the two hands, and an attempt is made to twist the lower end outwards (Robert Jones). Osteotomy of the tibia is not uncommonly necessary in children—not infants—for correction of this inward rotation. The fibula does not require division. Adams' varus splint, if properly constructed, holds the leg and foot in a position of external rotation whenever the knee is bent.

3. *Relapsed and Neglected Cases.*—General rigidity of the foot is a feature of these cases, particularly of those that have relapsed. Only too often no bands of fascia stand out, inviting division by the tenotome. Some of these feet can be successfully treated by the methods already detailed. Forceful wrenching under anæsthesia will probably be necessary on more than one occasion. While plaster-of-Paris casings are not permissible in the youngest infants, in children of a year and upwards, where difficulty in retaining the

Fig. 80.—Walking Apparatus.

foot in the over-corrected position is experienced, or the case has been neglected, plaster-of-Paris is of the greatest service. It has the advantage of holding the foot in a proper position continuously ; but it prevents all exercises and massage, and should therefore not be employed for longer than two or three months. After the major operations, when these are necessary, plaster should always be used. In spite of all we can do by these methods, some cases will still remain imperfectly corrected, chiefly owing to the deformity of the bones. Many operations have been devised for these cases, not one of which can be said to free the patient entirely from the possibility of a relapse. Phelps' operation, which involves division of all the resisting structures on the inner side of the foot down to the bones, has not found much favour in this country, owing to the frequency with which it is followed by relapse, even when the wound has been covered by skin flaps or grafts.

Subcutaneous division of the chief resisting structures will form part of the treatment in all cases. Beyond this, three operations appear to offer the best prospect of restoring the foot to a fair shape without interfering unnecessarily with its functions. These are (a) partial astragalectomy, with removal of part of the cuboid, (b) complete astragalectomy, and (c) Ogston's operation. Complete astragalectomy is called for in cases in which equinus forms the chief part of the remaining deformity. Ogston's operation is based on the fact that for the first few years of life each tarsal bone consists of a shell of cartilage surrounding a bony nucleus. The operation consists in incising the cartilaginous envelope and scooping out the contained bone. The foot is then forcibly corrected, the shells being crushed. It should be noted that in this operation the small joints of the foot are not interfered with. The astragalus, cuboid, and anterior part of the os calcis are treated in this way. This operation may be performed up to the age of six or even later. Each case must be treated on its own merits, the major operations being more often resorted to in hospital than in private practice.

4. *Inveterate Cases.*—Of these little need be said in a work of this kind. The best we can hope for is a more or less unshapely foot on which the patient can walk with comfort. If time is no object, tenotomies and frequent wrenchings with the use of a Scarpa's shoe may give a successful result. In most cases one of the major operations will have to be undertaken. Of these there is a great variety, but only two need be mentioned, namely, astragalectomy and cuneiform osteotomy. In the latter a wedge, with the base outwards, is removed from the tarsus, irrespective of the articulations. For a detailed account of the various methods which have been adopted in these difficult cases the reader is referred to works on orthopædics. It must always be remembered, however, that, whatever operation is done, a relapse is possible, and must be guarded against by the use of retentive apparatus.

It should be remembered that in adults the adaptation of the bones and other tissues to new lines of pressure and strain takes place far less readily than it does in childhood, and that a foot after correction may be the cause of even greater discomfort than was experienced before operation. In adults, therefore, amputation is a procedure which must be taken into consideration.

Of the other varieties of congenital talipes, the valgus, calcaneovalgus, and calcaneus cases are, as a rule, of a mild type, and rarely call for tenotomies. In these cases the tendency to relapse is small. Manipulations in the direction of inversion and plantar flexion, with or without the use of a malleable iron splint, will generally suffice to cure the deformity before the child is old enough to walk. In cases of pure valgus the peronei may require division, if the deformity is severe ; and when the child begins to walk, a boot with an outside

iron and valgus T-strap should be ordered. In mild cases the deformity is often overlooked till the child begins to walk. In such cases the heel of the boot should be carried forwards on the inner side, and the whole of the inner edge of the sole and heel should be thickened so as to throw the ankle outwards. Massage and the use of the special shoes or boots should effect a cure in a year or so. Sometimes a valgus is sufficiently severe to call for the use of a tin shoe with the sole-plate inverted. Occasionally congenital valgus and varus are associated with partial or complete absence of the fibula or tibia respectively. The fibula is more commonly at fault, and in this case the valgus should be corrected, and a boot-iron, and T-strap ordered for walking. The affected leg will be considerably shorter than the other. When the tibia is deficient the chance of obtaining a useful limb is extremely small.

TAPE-WORM.—(See WORMS, INTESTINAL.)

TEETH, CARIES OF.

Dental caries is a bacterial destruction of the hard tissues of the tooth. It is pre-eminently a disease of young life, and makes most rapid progress in "young" teeth: e.g., of two teeth, the first and second permanent molars, attacked about the age of 13, the second molar will be far more rapidly destroyed. It begins invariably on some part of the exposed oral surface of the tooth, the sites of election being the pits and fissures of the crown, normal or abnormal, the interstitial surfaces of the teeth, and the bucco-cervical margins—any spot, in fact, where free cleansing is impracticable or not practised; hence caries at the necks of the teeth, by the gum-edge, is common in cases of prolonged illness, where careful cleansing of the teeth is a great difficulty. At some undisturbed spot acid-forming bacteria gain a lodgement. Starches and sugars, which undergo an acid fermentation, form their pabulum, and in a longer or shorter time the enamel at the spot is destroyed, dissolved by the acid products of bacterial activity, and a way is opened into the dentine. This, though calcified, is largely composed of organic matter. The acid-forming bacteria continue their work of destruction, decalcifying the dentine and attacking the enamel on its under surface; while other bacteria, whose activity is chiefly manifest by the production of liquefying enzymes, dissolve the decalcified dentine. The enamel, unsupported by dentine and thinned from inside, eventually gives way under the stress of mastication, and a large cavity is suddenly revealed. Since bacterial activity varies greatly with even the slightest changes of environment—e.g., the culture medium, the species of bacillus growing in association—many variants of dental caries are to be found, e.g., rapid, slow, pigmented, and arrested caries.

The minute differences between the saliva of health and of disease are probably enough to account for the absence or presence of dental caries, while the permanent absence of starch and sugar from the food would be an insuperable bar to its onset. (Meat and albumins undergo an alkaline fermentation.)

When the dentine is reached there may be pain, varying from discomfort to a severe neuralgia minor, but it is when the tooth pulp becomes involved that the most severe pain is felt. Inflammation of the pulp is set up either by the access of bacteria or their products along the dentinal canaliculi, or by exposure of the pulp in the course of extension of the carious process. Acute inflammation of the pulp is soon followed by its death, due to strangulation of blood-supply from pressure of inflammatory exudation, and by equally sudden cessation of pain.

The intensity of the inflammation and the period of time during which the pulp survives its onset are very variable—from an acute process ending suddenly in death of the pulp in two or three hours, to a chronic condition resulting in a polypus of the pulp, analogous to the "hernia cerebri" of older authors—the differences depending on the intensity of the infection and the extent of exposure as leading to greater relief of pressure.

In general the dead pulp rapidly decomposes, and, via the apical foramen of the root, the bone becomes infected, leading to an "alveolar" abscess.

Thus, in the course of dental caries "tooth-ache" may be due to: (1) Lesion of dentine; (2) Inflammation of pulp; (3) Periodontitis and alveolar abscess. Usually the first of these conditions will cause only a moderate amount of pain and discomfort, but the symptoms vary from nil to a true neuralgia minor.

The distinction between the second and third may in general be made by consideration of the following points:—

Inflamed Pulp.—Pain intermittent, of a sharp, shooting character, often referred to other parts of the distribution of the fifth nerve, to the ear and down the neck in the

case of lower premolars and molars; from a lower to an upper tooth, or vice versa, of the same side; made worse by changes of temperature, or by such chemical stimuli as sugar or salt. Tooth not tender on pressure; but if pressure is made on the exposed pulp a paroxysm of pain is set up.

Alveolar Abscess.—Pain constant, localized to site of lesion. Tooth very tender on pressure, and feels raised above its fellows, so that biting becomes impossible. Later there is swelling of soft parts, usually accompanied by relief of pain. As with an acute pulp-inflammation, pain may cease suddenly, the cessation being due to the relief of intra-osseous pressure sequent on perforation of the outer plate of bone by the pus. Hence the pain of a dental abscess usually becomes less as the swelling of soft parts increases.

Though an alveolar abscess is usually an acute abscess of bone, palpable central necrosis is almost unknown.

Palliative Treatment of "Toothache":—

1. *Due to Lesion of Dentine.*—Clear the cavity of débris and try to cover in with gutta-percha; failing this, insert frequently-renewed plugs of cotton-wool dipped in an alcoholic solution of gum-mastic, after applying oil of cloves to the cavity in each case.

2. *Due to an Inflamed Pulp.*—(a) If the pulp is not exposed, treat as in the first case. Relief is not certain, but may follow when peripheral irritation is prevented by an antiseptic plug. (b) When the pulp is exposed, syringe the cavity clean with warm water, insert gently over the pulp a pledget of cotton-wool soaked in oil of cloves, pure carbolic acid, or creosote, and over this a containing pad of cotton-wool soaked in an alcoholic solution of gum-mastic. The first pledget must be large enough to prevent the gum solution reaching the pulp, and the containing pad must be put in without making any pressure on the pulp. While pressure exists there can be no relief of pain. Before there is room to insert any plug it will generally be necessary to clear away some of the softened dentine.

3. *Due to Periodontitis and Dental Abscess.*—In the early stages and in mild cases, painting the gums with tincture of aconite and iodine may give relief. Dry the gum over the affected part and beyond, and the cheek—this prevents the spread of the reagent. Hold the cheek aside, and with a pledget of cotton-wool held in the conveying forceps, paint the gum with the "aconite and iodine." R. Lin. Aconit. (B.P.), Tinct. Iodi Fort. (B.P.), aa ʒj.

Extraction of the tooth is the quickest and surest way of cutting short periodontitis or a dental abscess. The source of infection is removed and exit given to pus. Swelling of soft parts is no bar to extraction.

If extraction has been delayed, a subperiosteal, subcutaneous, or glandular abscess may need evacuating, whether or no the tooth be removed. In opening a subperiosteal abscess, keep close to the bone. A subcutaneous abscess should be opened early from outside. The scar of an early incision will be scarcely visible. A glandular abscess must be suspected when the trouble has existed for several days; it is frequently masked by the general swelling of soft parts.

If the patient desires to save the tooth, after syringing out the cavity insert a light plug of cotton-wool steeped in 5 per cent sol. carbolic acid, in the hope that some may soak up the root canal and cut short the supply of infective material. Give opium if pain is severe, and release pus when detected.

In the case of a single-rooted tooth it may be possible to perforate the bone opposite the tooth-apex and so relieve tension, but with multi-rooted teeth this is seldom practicable.

In the absence of all else, frequently renewed, lightly inserted plugs of cotton-wool soaked in carbolic acid, oil of cloves, or creosote may be used in any of these forms of toothache; but when using these drugs, put in a small plug of the reagent first, and cover this with a simple cotton-wool plug to prevent burning the mouth.

A gum-mastic plug will be foul by the end of twenty-four hours, hence such temporary stoppings should be renewed every twelve hours.

Septic Socket.—After extraction of a tooth, severe pain may exist owing to the presence of septic osteitis. This may have been due to: (1) Infection by forceps; (2) Infection from the mouth at the time of operation—germs lying round the neck of the tooth may be carried up into the tissues by the forceps; (3) Persistence of osteitis already present; (4) Subsequent infection from a septic mouth, especially when local anæsthesia has been obtained by means of a solution containing suprarenal extract. In the absence of bleeding, the aseptic (or antiseptic) blood-clot which normally fills the vacated socket is not formed, and infection from the mouth contents readily takes place.

To prevent infection, forceps must be boiled, the neck of the tooth well cleaned with an antiseptic just before extraction, and a septic tooth extracted early.

In many cases infection is to be expected, especially after difficult extraction of a lower third molar. When a socket becomes septic, the only treatment consists in thorough syringing at least twice daily. Between-whiles a light plug of cyanide or sal-alembroth gauze may be left in the socket. Care must be taken to syringe to the bottom of each separate socket. A small metal nozzle connected to a bulb syringe by two feet of light rubber tubing forms the best syringe. The nozzle is to be put down to the bottom of the socket and a slight to-and-fro motion given to it during syringing. In bad cases six weeks of syringing may be needed.

As a general rule, at all ages every tooth which cannot be rendered aseptic and painless should be extracted.

Prevention of Dental Caries.—Well-cleansed teeth cannot decay. Bacteria may be present, but their food supply is cut off. Both natural and artificial cleaning should be made use of. Natural cleansing is obtained by thorough mastication, during which the scouring action of food particles, tongue, and cheeks is supplemented by a free flow of saliva flushing the interdental spaces. Firm meat, hard farinaceous food, and such fruit as apples will best promote this natural cleansing; and it is worth remembering, as bearing on many cases of indigestion at all ages, that thorough mastication also means thorough insalivation, and that salivary digestion of starches goes on for a long time in the stomach in a well-made bolus.

Starches and sugars, which undergo an acid fermentation, are the food-stuffs which promote dental caries. They are injurious according to their tendency to cling to the teeth when moistened with saliva. Dry stale bread, or bread made of coarsely ground wheat, will be found to leave a far cleaner mouth than the white bread in ordinary use. Indeed, to this food-staple must be attributed the greatest share of the causation of dental caries.

Artificial Cleansing.—Brush the teeth, inside, outside, and on the coronal surfaces, with a small firm tooth-brush (child's size) night and morning, especially night, and pass waxed dental floss silk between the teeth. On the brush use soap, or a weakly acid or alkaline tooth-wash.* Use a tooth powder only occasionally, to remove any more adherent stains.

After cleaning the teeth at night, eat nothing more—especially not sweets and biscuits.

Wherever possible, skilled dental attention for children should be secured early. They should early be accustomed to having their teeth examined, and the confidence gained by a painless visit to the dentist is of great value.

Hæmorrhage after Tooth-extraction may be expected whenever from

* The use of weak acids daily will in no way damage the teeth. Both weak acids and weak alkalies are solvents of mucus, but the acids are the more potent removers of "dirt."

long-standing sepsis the gums are chronically engorged. The blood-vessels have lost their tone and power of contraction, and oozing is to be expected for some hours. Should the amount of blood lost call for interference, a soft pad of antiseptic (sal alembroth or cyanide) gauze, wool, or lint, shaped so as to press on and overlap the bleeding part, on to which the patient bites with the jaws bound together, will always stop the hæmorrhage. Bleeding definitely from a socket may be arrested in the same way, or by approximating the edges of the gum by cross stitches of horsehair or silk, which form a network entangling the blood and inducing clotting. There is no need to plug a socket, or to use astringents. In some cases a broken edge of alveolus or tooth frets the part with each movement of the tongue or cheek and keeps up hæmorrhage.

Joseph Geo. Turner.

TENDONS, INJURIES OF.—We must here consider: (1) *Section*; (2) *Rupture*; (3) *Dislocation*.

1. **Section.**—We must emphasize the fact that the division of a tendon need not lead to any deformity, and the test for division is that the movement normally carried out by that tendon and its muscle is now impossible. The most common site of division is in the region of the wrist-joint or fingers; the amount of separation between the ends, due to the retraction of the upper end by the muscular belly, is greater in the region of the wrist than in the fingers.

The treatment may be considered under the following heads:—

a. Full asepsis must be used in the repair. Tendon being a tissue of low vitality, it is unwise to use strong antiseptics. The wound may be cleaned with turpentine and 1–80 carbolic; but it is safer to simply paint the finger and swab the wound with a 2 per cent solution of iodine in rectified spirit. A carbolic compress must never be applied to a finger.

b. Immediate repair must be undertaken. There is no advantage, to my mind, in treatment by saline baths for three days, and then secondary suture of the tendon.

c. Signs of division of nerves must be thoroughly looked for before administering an anæsthetic to the patient.

d. To find the two ends. The operator may be fortunate enough to see these in the wound, but usually they have retracted. The upper end may sometimes be squeezed down by manipulation of the forearm through the sterile towel. Another plan is to stretch a tendon on each side—e.g., if the flexor of the ring finger be cut, then hyperextension of the middle and little fingers may cause the upper end of the divided tendon to come along its sheath into the wound. Failing this, the forearm may be bandaged firmly from above downwards by a sterile bandage. As a last resort, the incision may be extended along the line of the tendon till the upper end be secured.

e. In suturing, chromic gut is preferable to silk. In suturing small tendons, it is wise to place a ligature tightly upon the cut ends, and then with a round needle insert the chromic gut sutures close to these ligatures but distal from the side of the section. The object of the ligatures is to prevent the chromic gut sutures splitting the tendon as they are tied.

f. Cargile-membrane, if at hand, may be used to wrap round the sutured segment. It is infinitely easier, when working with Cargile-membrane, to work with dry hands and dry instruments. Whether Cargile-membrane be used or not, the sheath should be closed as completely as possible with catgut.

g. A splint must be applied to relieve tension upon the sutured tendons.

h. Movement and massage. In the after-treatment, we have to regulate the length of the tendon and prevent adhesions. Tendon unites by fibrous tissue, which is very strong by the end of a couple of months; therefore shortening of the tendon must be prevented in the early stages of the after-treatment. The

surgeon himself should test the finger on the sixth or seventh day, giving very slight passive movement. If the bond of union seems firm, the passive movements are very slightly increased each day until, by the end of the fifth or sixth week, full movement is carried out. If at any time the bond of union seems weak, it must be allowed complete rest for four or five days. The splint may be removed at the end of the third week. Massage is commenced as soon as the stitches are removed and the wound is healed. Active movement is allowed when the splint is removed.

I have never been able to trace any benefit from fibrolysin during the after-treatment.

i. *If the proximal end cannot be found*, our only resort is to anastomose the distal end to a neighbouring tendon. If the section be old, and it is impossible to bring down the proximal end into apposition with the distal, a Z-shaped lengthening of the proximal part of the tendon may be carried out; better still, the gap may be bridged by silk prepared by Lange's method.

2. **Rupture.**—The term explains itself. It may be divided into (a) Disinsertion, a sub-variety of rupture in which a tendon is torn from its insertion into the periosteum; and (b) Actual rupture. Rupture of the tendon, in my experience, is not so common as disinsertion.

a. *Disinsertion.*—This is seen most frequently in connection with the extensor tendons of the fingers or thumb, giving rise to the condition known as "mallet finger" or dropped-phalangette. The so-called rupture of the ligamentum patellæ is, in the majority of cases, really a disinsertion.

Dropped-phalangette is seen in men and women. In men it is due (e.g.) to a blow from a cricket ball on the tip of the finger catching the patient unawares and suddenly flexing the finger. In women it is due (e.g.) to forcing a tight stocking over the heel with the tips of the fingers.

In treatment, the mental picture we must have should not be, as a matter of fact, a complete tearing of all the tendinous fibres, but rather a condition comparable to the appearance of a portion of thick cloth which has been overstretched—i.e., a few fibres torn, the rest merely separated. There are two methods of treatment:—

i. The majority of cases get better by keeping the extensor tendon completely relaxed by the application of a splint which maintains the terminal phalanx in hyperextension. This must be persevered with for at least six weeks, and must be used even although the deformity is of some months' standing. The splint must be applied continuously; and if removed for washing or massage, the terminal joint must not be allowed to flex.

ii. Should splint treatment fail, the alternative is repair by suture. The peripheral stump is never long enough in a true mallet finger to afford a hold for stitches. It is difficult to sew the proximal stump to the periosteum of the terminal phalanx. The best plan is to suture the tendon to the thick subcutaneous tissue in the region of the nail bed, the patient being warned beforehand that a temporary interference with the nail growth may be a sequel of the operation.

The after-treatment is essentially the same as that of a cut tendon.

b. *Actual rupture.*—The commonest sites for this are:—

i. The quadriceps tendon above the patella. I have seen only one case, and this was followed in twelve months by a similar lesion on the opposite side. Complete restoration of function followed the application of a splint to keep the knee extended, and massage. Should it happen in a young man, I should advise primary suture if the retraction of the quadriceps were marked. In the case I saw, judging from the repeated effusion into the knee-joint, the synovial membrane must have been torn with the tendon.

ii. Rupture of the tendo Achillis. Diagnosis from the separation of the ends should be easy, and I should advise primary suture; but I have never seen a case.

iii. Rupture of the long tendon of the biceps is, in my experience, the commonest variety of ruptured tendon. It is nearly always bilateral. To my mind the lesions are pathognomonic of bilateral osteo-arthritis of the shoulder. The ruptured tendon usually becomes fixed secondarily in the bicipital groove, and I should refuse to open an osteo-arthritic shoulder for the sake of secondary suture of the ruptured tendon.

iv. The patellar ligament tears away from either the tibia or the patella. If near the tibia, the synovial membrane of the knee is intact. If near the patella, the synovial membrane is torn and the knee-joint full of blood. The treatment depends upon the amount of separation. This, again, depends upon the extent of the tear laterally. If the separation be slight, then good results are said to follow relaxation upon a splint; while if the separation be marked, I should advise suture.

v. Rupture of the plantaris tendon is described as the cause of sudden very acute pain occasionally taking an athlete in the calf of the leg. Two points may be noted: first, there is more bruising than is usually associated with a ruptured tendon; and, second, the condition has been known to recur in the same leg. So far as I know the rupture has never been accurately demonstrated; an alternative explanation, that the sudden pain is due to the rupture of a small vein, is equally feasible, and strongly suggested by the two points mentioned. Treatment is relaxation and immobilization.

3. **Dislocation.**—The only dislocation of tendons at all common is that of the peroneal tendons from behind the external malleolus. The only other dislocated tendons I have seen were two cases of dislocated extensor tendon of the index finger. Dislocation of the peroneal tendons is not at all rare in cases of paralytic calcaneovalgus, but I have seen it once in apparently a perfectly developed foot.

In the paralytic, the slipping of the tendon is painless. It is easily seen on dorsiflexing and everting the foot, and the treatment is the treatment of the calcaneovalgus—viz., keep the foot inverted, and prevent the heel dropping, by a walking instrument double to the knee, a valgus T-strap, and a toe-depressing spring.

In traumatic cases, the symptoms are pain, swelling, and bruising in the region of the external malleolus, and the tendons are palpable. For treatment, the tendons must be replaced by extension and inversion of the foot, redislocation prevented by the application of a pad and strapping, and the foot put in a plaster splint for three weeks. The tendency to redislocation is marked; therefore, on removal of the plaster case, it is wise to fit an outside iron to the knee, with a valgus T-strap, for two or three months. Should the condition become chronic, the tendons being repeatedly dislocated, they must be fixed in place by first of all deepening the bony groove, and then turning a flap of periosteum with spicules of bone from the outer surface of the fibula and suturing it to the periosteum of the os calcis.

Robert Milne.

TENDONS AND TENDON-SHEATHS, INFLAMMATION OF.—So far as we can tell, inflammation is never limited to the tendon itself. Either (1) Areolar tissue surrounding it is involved—a condition of *tenocellulitis*; or (2) The synovial sheath is involved—a condition of *tenosynovitis*.

1. **Tenocellulitis.**—This occurs in the tendo Achillis. It follows excessive use, but is not due to rubbing by the upper part of the shoe, being above this level. Clinically, there is pain above and behind the heel, and the patient may have discovered that a high heel gives relief. The tendon may be swollen and

tender, and on moving the ankle-joint slight friction may be palpable over the tendon. The condition is not common, and it has been confused with inflammation of the bursa between the tendo Achillis and the os calcis, in spite of the fact that the swelling and tenderness are above this level.

TREATMENT.—This consists in firm pressure; a piece of strapping starts just behind the toes, and passes over the heel and up the calf, with the ankle in a position of slight plantar flexion. It is fixed in position by a firm bandage, and the patient rests the foot as much as possible. Potassium iodide should be given, 5 gr. three times a day.

2. Tenosynovitis.—This is of two kinds—traumatic and infective.

Traumatic tenosynovitis may be of three types: Plastic; accompanied by serous effusion; or proliferating.

Infective tenosynovitis may also be of three types: Accompanied by serous effusion; suppurative; or tuberculous.

We have thus to consider the following forms: (i) Plastic; (ii) Accompanied by serous effusion; (iii) Proliferating; (iv) Suppurative; (v) Tuberculous.

i. Plastic.—This most frequently occurs in connection with the extensors of the thumb, more rarely in the extensors of the fingers. The onset is usually sudden, and the disease is seen after a bout of hard work in a person of a rheumatic tendency.

TREATMENT.—The limb should be fixed by a splint for at least two weeks. For the first week it may be painted with weak tincture of iodine (B.P.) every second day, and firm pressure applied by bandaging over wool. During the second week massage should take the place of counter-irritation. Occupation can be resumed gradually after the end of the third week.

ii. Accompanied by serous effusion.—This may follow a plastic tenosynovitis, or it may be infective, due to gonorrhœa, secondary syphilis, or rheumatism.

TREATMENT.—Having excluded tubercle in a chronic case, the treatment consists of rest on a suitable splint, counter-irritation, pressure, and massage.

iii. Proliferating (simple ganglion).—

TREATMENT.—The best treatment is complete excision, but it must be complete. Alternative treatment is to try the effect of rest and counter-irritation in the form of a blister. Ganglia are sometimes ruptured subcutaneously, either accidentally or intentionally by the surgeon or patient; the material escapes from the interior of the cyst into the subcutaneous tissue, and may often take from seven to ten days to be absorbed, remaining underneath the skin moving from place to place like a lump of jelly. If the ganglion be very thick-walled, subcutaneous rupture may be assisted by a puncture with a tenotomy knife; but all these methods are uncertain compared with excision.

It may be noted that cysts comparable to ganglia have been seen in the substance of a tendon, and not infrequently in connection with the external semilunar cartilage. (See also **GANGLION**.)

iv. Suppurative.—This may be due to a punctured wound, spread of infection from a subcutaneous whitlow, or infection by the blood-stream.

The great danger is sloughing of the tendon. The explanation of this is that the tendon receives its blood-supply mainly by the vincula, which correspond to the mesentery of the small gut. The rise of intrathecal pressure due to the formation of pus cuts off the blood-supply, and coupled with the action of the toxins in the pus, leads to the death of the tendon.

TREATMENT.—The essential treatment, therefore, is to relieve tension at once. This is best done by multiple small incisions, either on the palmar aspect or at the sides of the finger. To incise the sheath from end to end certainly relieves tension, but it allows the escape of the tendon from its sheath, and this is rapidly

filled up by granulation tissue, rendering replacement impossible and leading to a useless finger. Having made multiple small incisions and relieved tension, the finger must be kept either in a continuous hot saline bath, or a Bier's bandage must be applied around the upper arm. The bandage is worn for twenty hours out of the twenty-four, and if it causes pain, either the tension in the sheath has not been relieved or the bandage is too tight. In the case of the thumb or little finger, if there is any tenderness above the annular ligament of the wrist, an incision must be made directly over the spot of maximum tenderness, avoiding the median and ulnar nerves. Incisions in the palm of the hand must be below the level of the outstretched thumb. If above this level, the deep palmar arch may easily be injured, and the upper ends of the synovial sheaths of the index, middle, and ring fingers will be missed. Pus in the upper part of the palm must always be evacuated by Hilton's method. As soon as the condition of the wound permits, passive movement and massage of the finger must be commenced. If the tendon becomes adherent it must be freed, and an attempt made to prevent the re-formation of adhesions by Cargile-membrane, early movement, and massage. If the tendon sloughs, an attempt may be made to replace it by strands of silk prepared by the method advocated by Lange. Amputation may be necessary for septicæmia, for prolonged suppuration, or for a useless or stiff finger which incommodes the patient.

v. *Tuberculous (compound ganglion).*—There are two forms: (1) Associated with melon-seed bodies; (2) Associated with excess of granulation tissue.

TREATMENT.—

1. Melon-seed body type.—Systemic treatment for tubercle—viz., open air, sunshine, and cod-liver oil. I have no experience with tuberculin in these cases. If the typical crepitation has been obtained, open the sheath above and below any constriction, remove or wash out with saline the melon-seed bodies, sew up the sheath, and keep the part at rest for six months after the operation.

2. Fungating type.—General treatment as above. Counter-irritation with Scott's dressing, and fixation in plaster-of-Paris for twelve months. If, in spite of fixation, pain continues, the plaster must be removed. If the swelling has increased, then operative treatment is indicated. The whole of the wall must be removed, and the part lying under the annular ligament must be treated by passing a strand of gauze from the opening above to the opening below and thoroughly wiping out all traces of granulation tissue. Any granulations on the tendons themselves must be removed by scraping. The condition is more serious than the melon-seed body type.

Robert Milne.

TENOCELLULITIS AND TENOSYNOVITIS.—(See TENDONS AND TENDON-SHEATHS, INFLAMMATION OF.)

TESTICLE, UNDESCENDED, and ECTOPIA TESTIS.—The following questions are usually asked by the parents of a child with a partly descended testicle, and as they directly bear upon treatment, they will be answered here.

(1) Will the testicle come down as the child grows older? (2) Is the undescended testicle a useful organ? (3) Are there any risks in leaving it alone?

1. Non-descent of the testicle into the scrotum cannot be looked upon as permanent during the first year, but after that the organ will not descend.

2. The retained testicle is usually a useless organ. It is believed that the testicle may sometimes develop if placed in the scrotum. It will not develop if left alone.

3. The risks of leaving a partly descended testicle alone are: (a) Hernia; (b) Recurrent attacks of inflammation from mechanical injuries; (c) Torsion

of the cord, and gangrene : this is specially dangerous from the proximity of the peritoneum ; (d) Malignant disease of the testicle.

The treatment is operative. No form of massage or truss is effectual.

Operation may consist in :—(1) An attempt to bring the testicle into the scrotum and keep it there (orchidopexy) ; (2) Replacing the testicle in the abdomen ; (3) Castration.

1. Attempts to bring the testicle down into the scrotum and to retain it there are sometimes successful, and the testicle has been known to develop after the operation. Atrophy of the testicle follows this operation in about 16 per cent of cases. If the testicle is very small, and if it has repeatedly been the seat of inflammation, it is useless to attempt to bring it down. The operation, if performed, should be done about the age of four or five years.

2. If the imperfect descent of the testicle is bilateral, it will be better to replace within the abdomen a testicle which is lying in the inguinal canal than to remove it. Castration is preferable in unilateral cases when orchidopexy is inadmissible or has failed.

3. Castration will be required in most cases. It is especially indicated when (a) The testicle is atrophied and a hernia is present ; (b) Recurrent attacks of inflammation have occurred ; (c) Torsion and gangrene have taken place ; (d) A new growth of the organ has appeared.

In **Ectopia Testis** the organ is misplaced. It may be found on the pubis (pubic ectopia), in the groin (crural or femoral ectopia), or in the perineum (perineal ectopia). In crural ectopia the testicle has escaped from the abdomen through the crural canal, and castration is necessary. In pubic and perineal ectopia the testicle should be replaced in the scrotum.

J. W. Thomson Walker.

TETANUS.—The treatment of this disease falls naturally under two headings : (1) *Prophylactic*, certain measures that should be taken in all cases of wounds that have been contaminated with soil or manure, especially crushes and compound fractures ; (2) *Systematic*, the actual treatment required when symptoms of the disease have made their appearance.

1. **Prophylactic Treatment.**—Modern bacteriology has shown us that not only is an incubation period usual before the development of symptoms after infection of a wound, but that this period is the most favourable for the employment of that valuable remedy, antitoxin, in those cases where, from the nature of the accident, there is a possibility of tetanus supervening.

Although we now know that tetanus can develop without actual suppuration in the damaged area, nevertheless crushed limbs where suppuration is profuse are specially liable to this dangerous complication.

Apart, therefore, from the ordinary measures that would be undertaken for the cleansing of any contused or lacerated lesion, such as washing, irrigation, removal of foreign bodies and of dead or dying tissue, and the provision of adequate drainage, it may be urged that in all cases where soil, cinders, refuse, etc., have obtained access to a wound, protective or immunizing doses of antitoxic serum should be given. Although tetanus is one of the few organisms for which we possess a specific antitoxic serum, this serum is not particularly potent or satisfactory when once symptoms of the disease are manifest ; and granting that, under the above conditions, the serum will be administered unnecessarily in a certain number of cases, the noxious effects are not serious, and such treatment will undoubtedly lead to the saving of life and to the successful control of severe types of the disease. The mode of administration and action of the serum will be considered later.

2. **General Systematic Treatment.**—When once the appearance of typical symptoms has placed the diagnosis beyond doubt, the patient should be moved

to a quiet room, or surrounded by screens, and be protected as far as possible from sudden noises. Rest and quiet are very important factors in dealing successfully with these cases. The banging of a door or the falling of a tray will often bring on a painful convulsion which might have been avoided.

In tetanus, as in strychnine poisoning, the nerves and nervous system generally are hypersensitive, and every effort should be made to avoid sudden or violent stimulation of the senses. The blinds should be drawn, or curtains hung so that the bed is in the shade, and no gas or other light should shine on the patient.

As the result of the violent contractions of the muscles, profuse sweating occurs, and it is advisable to bear this in mind, since the bed linen must be changed frequently.

Diet.—Milk and fluids generally will be found most suitable. In mild cases the patient may be fed through the mouth—a tooth if necessary being extracted, though in cases of moderate severity this is often not required. Where the spasms are severe, nasal or rectal feeding will be called for, and in the worst types of cases the disturbance created by attempts to pass the nasal tube is so great that the operation must be performed under chloroform anæsthesia. In all instances the greatest care must be exercised in this matter of feeding since the spasm of the constrictor muscles greatly interferes with swallowing, and the patient often shows a tendency to choke if the food is given too quickly.

The Wound must be treated on ordinary antiseptic principles. Free incisions should be made for drainage, and antiseptic lotions and dressings applied. When once the symptoms have appeared, the local treatment of the wound seems to have little influence on the course of the disease. Amputation for tetanus is not called for as far as the tetanus itself is concerned, though it may be necessary for other reasons. It has been shown that during their period of incubation the tetanus bacilli produce the toxins in the wound, and that these toxins are rapidly taken up into the nervous system, where they combine with the nerve cells. Afterwards the bacilli die; they do not remain and manufacture fresh poison. This being the case, it is necessary to deal with the wound on ordinary principles only, cleansing it thoroughly and swabbing it out with strong antiseptics.

Micturition and Defæcation.—Owing to the spasm of the muscles of the perineum, a catheter may be required, and some trouble will be experienced in obtaining satisfactory actions of the bowels.

Medicinal Treatment.—Nearly every drug that can exercise a sedative action on the nervous system has, from time to time, been vaunted as a valuable remedy in cases of tetanus. Calabar bean, curare, hyoscine and others of the belladonna group, have been employed. On the whole, chloroform and chloral combined with bromide of potassium have given the best results.

Chloral, since it diminishes the activity of the anterior nerve-cells and diminishes the conductivity of the nerve fibres, is most valuable. It is, however, a poison, and a powerful cardiac depressant, and therefore must be used with care. In the case of a strong adult, chloral 25 gr., brom. potass. 30 gr., should be given per rectum as soon as possible, and this should be followed by 15 gr. of each drug every four hours. There is no doubt that this combination affords the greatest possible relief to the unfortunate sufferer.

Chloroform should be reserved for those very severe cases where the spasms threaten the patient's life by asphyxia, or where the chloral and bromide do not control the convulsions.

It has recently been suggested as an alternative to the above treatment that anæsthesia of the spinal cord should be induced by the injection of cocaine into the spinal canal. In severe cases this might be given a trial, but there are not

sufficient data to hand to allow of our pronouncing definitely upon the method at present.

Antitoxin Treatment.—When the specific toxin and its neutralizing antitoxin were isolated, great hopes were raised of curing all cases of tetanus by this serum. Unfortunately, insufficient knowledge of the mode of action of the tetanus toxin led to the employment of this remedy in an entirely empirical manner. Doses of varying amounts were given beneath the skin, injected into the subdural space, and even into the brain itself.

Recent investigation, especially the valuable work of Schmiedeberg, has cleared up many debated points in connection with the spread of the disease. During the latent period, or period of incubation, the toxin is slowly spreading, not along blood-vessels or lymphatics, but along the axis cylinders of motor nerves, and the shorter the path and the more powerful the toxin, the sooner does it reach the cells in the spinal cord. From this situation it has been proved to spread both along the cord to the basal centres, and through it to the cells which influence reflex action and tonic contraction of the voluntary muscles.

Now the toxin of the tetanus bacillus has a specific selective action upon nerve tissue, and its union with it results in the formation of a relatively stable compound which it is difficult to analyze.

In these circumstances the antitoxin is almost powerless to cut short the effects which will necessarily be produced by the dose of toxin already received by the nervous system, and the series of events which result from this accident must run their course. On the other hand, antitoxin can neutralize any toxin that may be free in the nerve substance, sheath, or lymph spaces, and by such injections, clearly prophylactic, further affinity between nerve-cell and toxin may be prevented. With this knowledge before us, it becomes imperative to inject the antitoxin in those situations where the toxin will be most readily encountered; that is to say, along the motor nerves of the limb or into the arachnoid sheath of the spinal cord, and as the poison has to pass along this path before it can reach the general circulation, the administration of the antitoxin subcutaneously cannot be supported.

It has been suggested that a large dose of antitoxin injected subcutaneously or into the cerebral substance can, by exerting a "mass effect," succeed in disintegrating the product of the toxin and nerve cell; but so far there is little experimental proof of this assertion.

Many forms of antitoxin are supplied, the best being made by the Pasteur Institute in Paris, the amount of the injection made along the nerves or into the spinal theca varying from 10 to 100 c.c., according to the age of the patient, the severity of the disease, and the subsequent reaction.

On the whole, small doses, 10 c.c., repeated, are likely to be more satisfactory than a large single injection. All precautions must be taken to avoid sepsis.

Although, with standardized and carefully prepared serum, serious ill-results are unlikely to follow this treatment, certain complications occasionally attendant on the administration of the antitoxin must be mentioned; of these, rashes, urticaria, and painful effusion into the joints are sometimes encountered. Beyond simple symptomatic treatment they do not require further attention. Doses of 3 to 6 c.c. of a 25 per cent solution of sulphate of magnesia have been injected into the subarachnoid space by lumbar puncture: the drug appears to possess considerable antispasmodic power. It must, however, be used early. The injections may be given every other day.

Bacelli's treatment of tetanus by the injection of carbolic acid (10 to 15 min. of a 2 per cent solution) is said to be very successful in Italy; from a limited experience the writer recommends the method. W. H. Clayton-Greene.

TETANY IN CHILDHOOD. (See also CRAMP.)—Tetany, with its carpopedal contractions and irritability of peripheral nerves, is commonly seen in conjunction with laryngismus, convulsions, and rickets (*q.v.*).

It is practically always due to gastro-intestinal affections, and is cured by treatment similar to that for other rachitic neuroses. Fatal cases are rare, but tetany arising in marasmic weakly infants is often fatal. The stomach or the colon is usually dilated in such cases, and regular lavage, together with carefully selected diet, affords the only chance of recovery. Food should consist of peptonized milk and barley-water, or albumin-water and whey. Citrate of soda, in doses of 1 to 2 gr. to the ounce of milk, may render it more capable of absorption. Rectal alimentation is often necessary.

Chronic tetany occurring in children upwards of two years of age is usually associated with dilatation of the colon, and is fatal as a rule, in spite of treatment by lavage, careful dieting, and intestinal antiseptics. The question of operative interference (cæcostomy or appendicostomy) should therefore be entertained.

A more tractable form of tetany is sometimes seen in young girls at the time of puberty. It usually yields to treatment by purgation, tonics, and attention to general health.

Rickets is present in the majority of infants who suffer from tetany, convulsions, and laryngismus, and needs appropriate treatment. Potted milk and patent foods should be discontinued, and pure cow's milk, unsterilized and unpasteurized, should be given if procurable. Suitable clothing should be worn night and day, but the child should not be over-clothed. Fresh air is essential. Coddling in close rooms should be discouraged.

Leonard G. Guthrie.

THERMOTHERAPY.—The applications of heat for therapeutic purposes are practically innumerable, ranging from the linseed or oatmeal poultice of old times to the more elegant electrical thermophores or radiant-heat applicators of the present day. We must differentiate between the forms of heat as follows: (I) *Moist heat*; (II) *Dry heat*; (III) *Luminous radiant heat*; and (IV) *Diathermy*.

I.—MOIST HEAT.

The oldest and most widely known form in which moist heat is applied is that of the fomentation or poultice. The material best suited to the purpose is naturally that which retains its heat longest. Linseed and flax meal, although generally used by the laity, and often by the medical profession, cannot be said to excel in this way, but they possess advantages in being readily attainable and cheap. They are, however, messy, and cool easily. The split baked potato, formerly much in vogue in the treatment of tonsillitis, is a clean and effective way of applying heat to a small area.

When obtainable, one of the volcanic muds or clays, such as fango di Battaglia (there are many fangi to be had in Italy), is most efficacious, for this possesses the faculty of retaining heat for a remarkably long time, and is an application which affords much relief in painful conditions.

The use of kaolin and of diatomaceous earths for this purpose has emanated from America, and marks an improvement in technique.

One of the best known preparations of this sort is *antiphlogistine*. It is a proprietary preparation and somewhat expensive, but is very effective in many simple inflammatory conditions, especially when these are restricted in area. It is a compound of fuller's earth, several essential oils, and glycerin. The effect of the glycerin is that, being highly hygroscopic, it abstracts considerable moisture from the inflamed tissues. To be effective, this compound must

be applied as hot as the patient can bear it—generally 112° to 115° F.—in a layer about one-eighth to one-quarter of an inch thick. It is best heated by placing the tin container in a pot of boiling water, care being taken that the water does not boil over into the tin. The contents of the tin should be stirred occasionally while it is heating, to insure the temperature of the whole being uniform. Before making the application, the operator should test the temperature of the paste on the back of his hand. After being applied, the layer should be covered with cotton-wool, and removed in about twelve hours. A convenient spatula for spreading the paste is supplied with each tin. The use of anti-phlogistine is recommended in both pleurisy and pneumonia, and is certainly much to be preferred to the ordinary poultice, but it has the disadvantage that, to a large extent, it prevents the physician observing the progress of the disease by auscultatory examination.

Poultices are rarely used nowadays in lung conditions, particularly not in children, for they throw an extra burden on the already embarrassed respiratory muscles. For a poultice to be efficacious in general conditions, it must be applied very hot and in a thick layer, and after covering it up with some fabric, a useful accessory is a hot-water bottle of rubber, or an electric thermophore, to maintain the temperature.

Hot fomentations are usually made of several thicknesses of flannel or spongiopiline wrung out of boiling water.

A simple form of wringer is made by fixing a piece of strong huckaback towelling to two short pieces of stick—a piece of a broom handle does well. The dripping fomentation is placed in this and the towelling closed over it and twisted until all superfluous water is removed. When properly done, this avoids all scalding of the operator's hands. As fomentations cool rapidly, they should not be removed from the towelling until they are actually applied to the patient, when they should be overlaid with a piece of waterproofed fabric, and changed frequently. The proper temperature may be estimated by pressing the back of the hand against the fomentation; merely brushing against it is of no use.

Vapour Baths.—While dealing with moist heat, the *Russian bath* must be mentioned, although it is not greatly in vogue at the present day. This is due to the fact that the patients are subjected to an intense heat in a very moist atmosphere, which renders it very oppressive to most of them, little or no relief being afforded by natural evaporation from the surface of the body. The patients inhale air highly impregnated with steam, and high temperatures become impossible.

Certain subjects, however, who possess a very dry skin, prefer such a bath to a dry atmosphere like that of the Turkish bath. Psoriasis and certain forms of eczema obtain marked benefit from the use of the Russian bath.

The Steam Box, or Berthollet Bath, is employed for the application of steam to any given part of the body—elbow, knee, foot, or hand. Berthollet's apparatus consists of a central cylindrical chamber, from which steam is supplied, fitted with cylindrical projections for the various limbs. These projections are adapted closely to the parts by means of leather or rubber cuffs. The affected limb is adjusted within its respective cylinder, and having been securely packed, is exposed to as high a temperature of moist heat as can be borne—about 120° to 125° F. The period of application is from twenty minutes to half an hour, or more in some cases. At the conclusion, the limb is carefully sponged over, and massage applied. It is a valuable method in the treatment of any chronic joint affection of a gouty or rheumatic nature. Perhaps the most relief is afforded in rheumatoid disease. The absorption of effusions in traumatic cases is much promoted.

II.—DRY HEAT.

The Turkish Bath.—Therapeutically, this ancient bath has somewhat waned in popularity, with the medical profession at any rate. The tendency in certain subjects to headache after a bath, the risk to apoplectic subjects, and the tendency to faintness and exhaustion in weakly people, have induced some caution in prescribing it, and in every way the electric-light bath, in which the head of the patient is in the cool atmosphere of the room, is much to be preferred. A Turkish bath also takes up much space and is of a very elaborate nature.

The Lamp Bath, such as the "Century cabinet" and the like, while in a measure effective, is extremely risky. The lamp is easily overturned, and the material of which the baths are constructed is in no small degree inflammable.

The Electric-light Bath, in which we have phototherapy and thermotherapy combined, is a most valuable therapeutic agent which is being increasingly employed in this country. It is immeasurably superior to the unsafe and defective lamp baths so much advertised by certain firms, is very easily controlled, need not be expensive, and, owing to the increasing application of electric light as an illuminant, can be used in most modern houses. Many a severe chill has been checked and threatened pneumonia staved off by the timely use of one of these baths after undue exposure.

The bath is made in two types, the vertical and the horizontal, the latter being much the more comfortable. It is fitted with twenty to thirty incandescent lamps and a metal reflector. The patient sits or lies in the bath, stripped to the skin, the time of exposure varying according to the effect desired.

Duration.—Ten to twelve minutes will produce a tonic effect; for diaphoretic purposes an exposure of twenty-five to thirty-five minutes is necessary. The vertical form necessitates the patient sitting in a somewhat constrained upright position, which in certain subjects tends to faintness and sickness. The feet of the patient should be kept warm, and for this purpose most baths are fitted with an electrically heated footstool; failing this, the patient's feet should be in hot water.

The temperature of the bath varies from 65° to 150° C. The heat is largely radiant in character, and the temperature of the air in the bath is of very little moment. High temperatures are not bearable unless the air is absolutely dry. It is well, therefore, where exposure to a high range is wished for, to turn the lights on for fifteen to twenty minutes before the patient enters the bath.

Perspiration is more readily induced by this bath than by any other procedure. The body temperature rises rapidly—four to five degrees in twenty minutes. The increased elimination of CO₂ is very marked. The blood-pressure, after the primary rise, is lowered, and the number of red blood-cells increases about 15 per cent. By means of the prolonged dilatation of the skin capillaries, much blood is diverted to the surface of the body—to the relief of any internal congestion; while the absorption of morbid exudates from pleural or other cavities is greatly promoted.

THERAPEUTIC INDICATIONS.—Patients who have become "seedy" and run down from overwork and absence of adequate exercise, who are suffering from a lethargic condition due to mal-assimilation of food, and whose muscles are loaded with fatigue products, experience a maximum benefit from this application two or three times weekly. Headaches, and the condition known in former days as "uric acid diathesis," are markedly relieved and benefited. Fatty glycosurias benefit, and the tendency to acid intoxication so common in glycosuria is greatly lessened.

In obese patients, a frequent and thorough application of this procedure is

most beneficial, due care being taken to observe the effect on the circulation, as over-fat patients often experience faintness if the bath be prolonged or over-hot.

In renal disease, few applications or drugs afford such genuine relief as this bath, owing to the lessening of the kidney engorgement by the diversion of so much blood to the skin. Care is needed in prescribing it in cases of granular kidney, owing to the usually associated arteriosclerotic condition and tendency to apoplexy.

III.—LUMINOUS RADIANT HEAT.

The Dowsing Radiant-heat Apparatus is one of great value, and forms a distinct advance on the earlier forms of hot-air appliances. The heat can be thrown on any special part of the body, or the whole body be treated at once, according to requirements. By means of a rheostat contrivance, perfect control of the apparatus is insured, and the temperature can be regulated with the utmost nicety up to 400° or 450° F. The apparatus requires no time to heat up, but immediately the current is turned on the rays of heat constituting the treatment are produced at any desired temperature. The difference from the ordinary dry heat of a fire is demonstrated by the fact that a plate-glass screen will cut off the latter, while it makes no difference to the radiant heat. The heating cylinders are suitably mounted on movable standards, with reflectors easily adjusted to any position. For general treatment an ordinary narrow bedstead is employed, with four standards and reflectors, the rheostat being fixed at the back of the bed. The air is of necessity dry, otherwise such high temperatures would be impossible for the patient. To prevent the sheets scorching or catching fire, they are soaked in tungstate of soda, and the cushions are as a rule covered with asbestos sheeting.

Duration.—The bath usually lasts from twenty to forty minutes, and it is wonderful how comfortably the high temperatures are borne by the average patient. Even when the part affected is merely a joint, or in a case of sciatica, the best results are obtained by exposing the whole of the patient's body, for the general sudorific effect is obtained as well as the local benefit of the rays.

Free perspiration usually occurs, and both pulse and respiration are quickened. Painful affections are for the most part relieved very soon after the application of the rays, even though the relief be at first merely temporary. It is not usual to douche down the patient after this treatment, but merely to give him a dry rub with a towel. The effect of the bath is often enhanced, however, by the after-application of massage. Some patients insist on a spray before dressing.

Care is needful in prescribing this bath for very feeble, debilitated patients, as they often perspire profusely from the first, and get into a state bordering on collapse.

Tyrnauer's Apparatus for Hot-air Treatment.—It is claimed for this apparatus that the air within the enclosure is even in temperature, which is often not the case in hot-air machines. In some of such apparatus there may be a difference of 100° between the parts, depending on their distance from the source of heating. In Tyrnauer's machine the air is heated by means of electrical resistance wires lying in a trough beneath the apparatus. A temperature of 170° to 200° F. can be attained in five or six minutes, and in ten minutes this can be raised to 300° F. The temperature may be varied with the greatest ease at the operator's will.

The apparatus is made of oak or mahogany and metal, with a lining of white asbestos. There are three separate sources of heat, any one of which can be turned off or on, and the regulation of the temperature is further facilitated by the use of a perforated asbestos screen which may be raised or lowered to lessen the degree of radiation from the source of heat. The resistance wires rest

on an eternite (asbestos slate) tile or plate, and are regulated by switches connected with the electric supply by means of insulated cables. The risk of short circuit is carefully guarded against, as in the Dowsing apparatus, by means of double fuses. Each apparatus is supplied with a thermometer fixed in a prominent position, so that both the patient and bathman can read it. The amount of current consumed varies in the different apparatus from 5 to 18 ampères. An ordinary treatment costs twopence, on the average, in electric current supplied. The apparatus are both general and local, one for the whole body, one for the shoulder, or for the elbow, knee, arm, and so on. They are all well finished, durable, and very comfortably fitted to the patient, so that no fatigue is involved. In the apparatus for the knee, for instance, the whole joint is exposed to the hot air from both the anterior and posterior aspects, and not only from the anterior and lateral aspects, as in most apparatus of this nature.

One drawback to these mechanisms is their expense, a complete set costing over £300. They are patented in all countries, and are made by Schwarz, of Wiesbaden.

The Greville Non-luminous Hot-air Bath.—This resembles the Dowsing in that the heat is obtained by the passage of the electric current through wire filaments, but its wires are composed of non-oxidizable metals or compounds of metals, and are naked. These wires, arranged somewhat like the strings of a harp, are wound upon porcelain insulators attached to the back of the generator, while the front or inner side is a perforated sheet of aluminium. A temperature of 200° to 250° F. is easily obtainable, and the raising or lowering of it is under absolute control. The current may be derived from the main or, if used where no electricity is laid on, from accumulators. The rays convected from the naked wires have heat-giving properties only, and, like the Dowsing, are devoid of violet or ultra-violet rays. There are separate apparatus for each limb and one for the whole trunk.

Radiant-heat baths are specially recommended in subacute and chronic rheumatic affections, in the various forms of arthritis, infective and otherwise, and also in gouty neuritis and sciatica. Relief is often afforded to toxæmic headaches. The counter-indications are aortic disease of the heart and myocardial degeneration.

The usefulness of massage and movements to stiff joints is often enhanced by a preliminary exposure to the radiant heat, which seems to soften the adhesions and make them more yielding.

The Dowsing and Greville apparatus are let on hire, and not sold. Lists of depots throughout the country where the treatment is available, and particulars as to terms, may be obtained from the Dowsing Co., 24, Budge Row, E.C., and the Greville Co., 37, Upper Berkeley Place, W., respectively.

The Fan Hot-air Douche.—This is a very clever and useful little device placed on the market by the Sanitas Electrical Co. Constructed largely of aluminium, it weighs only about 3 lb. It requires a very light current, and can easily be worked off a wall plug. It consists primarily of a small fan, which, when in motion, creates a strong draught over a coil of fine nickel wire brought to a white heat by the same electricity which works the fan. The air is blown through a focus tube on to the part to be treated, and in a few minutes attains a very high temperature, so that the nozzle of the focus tube has to be kept at a distance of 12 to 15 inches from the body, to avoid burning the patient's skin: in any case a marked erythema is produced. It is valuable in the treatment of minor rheumatic affections such as myalgia, in neuralgia, and in neuritis in the arm, hand, or foot.

Being inexpensive and very portable, it is especially deserving of the attention of practitioners, since the only requirement for its use is the presence of an

electric current in the house. It can be carried in a small midwifery bag. The cost is about £3.

IV.—DIATHERMY.

Diathermy is a form of thermotherapy in which the thermal effects are produced in the depths of the tissues by means of electric energy. It is a thermotherapeutic procedure which differs entirely in several respects from any previously employed.

It is necessary to understand clearly that all the older methods of heat treatment, local or general, such as the poultice, hot-air douche, and electric-light bath, are *exogenous* methods of heat production; the subcutaneous tissues are heated by thermal conduction only after the skin has itself been warmed. Increased activity of the skin-circulation involving dilatation of the capillaries takes place, and heat is continuously carried off by the blood-current, with the result that all the circumstances combine to prevent the penetration of the heat to the deeper parts. On the other hand, in diathermy, the source of the contributory heat is *endogenous*. That is to say, the increase of heat is produced locally in the deeper tissues, and the actual amount depends on the ohmic resistance involved and the square of the current-intensity used.

The principle underlying the method is the translation of electric energy into heat by the opposition of resistance (the Joule effect). The current, to be effective and at the same time harmless, must be of the alternating type, as a constant current of sufficient strength to produce heat to any extent would cauterize the tissues; further, ordinary alternating currents would produce tetanic spasm of the parts treated; so that those we use have to be of a special type—similar to what we use in high-frequency treatment. The voltage, however, is not nearly so high as in that method, and the ampèrage is higher. While with high-frequency treatment the voltage commonly runs to 100,000, or even 1,000,000, and the ampèrage is infinitesimal— $\frac{1}{2}$ to 1 milliampère—in diathermy we use only 20,000 to 40,000 volts, but an ampèrage of 2 to 3 ampères.

The best apparatus introduced for this purpose is that of Dr. Nagelschmidt, of Berlin. It is rather an expensive one, and considerable care and attention to detail is required in using it. Unless the electrodes—which may be of metal guarded with flannel or wash-leather, or better, some form of clay—are very carefully laid against the patient's skin, sparking will occur, leading to a burn. Although the heat is developed, as has been mentioned, in the deeper layers of tissue, the patient only feels it in the skin. The sensation may continue for two hours or more after the application has ceased. A temperature of over 100° F. can be tolerated for only a short time—it becomes painful after that—but up to this, any temperature may be borne. Marked hyperæmia is induced, as with a Bier's bandage.

Duration and Dosage.—As regards these particulars in the treatment of different cases, judgement is of course needed on the part of the physician responsible, but Dr. Nagelschmidt has produced a special table which is of great help to beginners in this respect.

Indications.—Diathermy is extremely useful in treating gouty and rheumatic joint affections of a chronic nature, as well as sciatica and various forms of neuritis. Blood-pressure may also be reduced by means of it, and glandular activity stimulated.

The treatment is also applied for certain surgical conditions, in removing small malignant growths on the skin or mucous membrane. So used, it is a thermic method of inducing local coagulation necrosis, strictly limited, and directed and controlled by the operator. Where there is no secondary infection, some success has been attained.

T. D. Luke.

THORACENTESIS.—(See PLEURISY.)

THREAD WORMS.—(See WORMS, INTESTINAL.)

THROMBOSIS, CEREBRAL.—(See APOPLEXY.)

THRUSH.—Care should be taken to ensure cleanliness of the teat and “comforter.” The bowels should be opened with a dose of castor oil, and any indigestion corrected by a mixture of rhubarb and soda.

R Tincturæ Rhei	℥iij	Glycerini	℥iij
Sodii Bicarbonatis	gr ij	Aquæ Menthæ Piperitæ	q.s. ad 3j

For a child of one year or less, given thrice daily.

Locally, one of the following should be thoroughly applied with a soft camel’s-hair brush several times a day :—

1. Glycerin of boracic acid (B.P.) or borax and honey.
2. A solution of salicylic acid (1–250).
3. A solution of sulphite of soda (1 dr. to 1 oz.).
4. Solution of sulphurous acid (B.P.) 1–6 of water.
5. Borax and chlorate of potash (10 gr. of each) in 1 oz. of water sweetened with a little glycerin.
6. Permanganate of potash (1–1000).

Robert Hutchison.

THYROIDITIS, ACUTE.—Acute inflammation of the thyroid gland is a rare condition, and as a rule occurs only as a complication of some general infective disease, such as influenza. Acute strumitis, i.e., inflammation of a goitrous thyroid gland, is less uncommon, especially in districts where goitre is endemic.

During an acute thyroiditis the patient must be kept at rest in bed, and if there is much pain on movement of the head, it may be fixed by pillows. The diet should consist chiefly of milk as long as the temperature is raised, light solid diet being given as soon as the temperature becomes normal and the patient is free from pain on swallowing. During the acute stage, cold should be applied to the front of the neck by means of an ice-bag, an ice-poultice, or Leiter’s tubes. If these measures fail to check the progress of the inflammation, and if there is much pain, belladonna fomentations should be applied instead, and may be renewed at intervals of three or four hours until relief is obtained. At the onset of the attack, it is advisable to give 5 gr. of calomel or blue pill at night, followed by a saline aperient in the morning. During the febrile stage, sodium salicylate in 10 to 15-gr. doses may be given every three or four hours, and in some cases 3 to 4 gr. of potassium iodide may be added to the mixture with advantage. If pain is excessive, small doses of opium or of Dover’s powder may be given for its relief. If suppuration occurs, it is important to incise and drain the abscess as early as possible.

George R. Murray.

TIC DOULOUREUX.—(See NERVES, PERIPHERAL; NEURALGIA.)

TICS.—It is desirable to preface an account of the treatment of tic with some explanation of the term, as the word is still employed loosely for conditions which differ widely enough.

Every one is more or less familiar with so-called “nervous movements,” “movements of the nerves,” which are supposed to be perfectly harmless and scarcely worth therapeutical consideration. Not all these nervous movements are tics; many are no more than tricks or mannerisms, and, however distressing and persistent they may be, do not come within the scope of this article. We may best understand what is meant by a tic by taking Meige’s definition in full :—

“A tic is a co-ordinated purposive act, provoked in the first instance by some external cause or by an idea: repetition leads to its becoming habitual, and finally to its

involuntary reproduction without cause and for no purpose, at the same time as its form, intensity, and frequency are exaggerated: it thus assumes the characters of a convulsive movement, inopportune and excessive: its execution is often preceded by an irresistible impulse, its suppression associated with malaise. The effect of distraction or of volitional effort is to diminish its activity: in sleep it disappears. It occurs in predisposed individuals, who usually show other indications of mental instability."

With the aid of this definition we learn that tic is not synonymous with convulsion, although the fact that a tic is a normal movement *exaggerated* must not be lost sight of; nor is it a spasm, a term which is to be reserved for motor phenomena the result of irritation in a reflex area, e.g., the spasmodic contraction of the orbicularis oculi when a speck of dust gets into the eye; nor again is it a stereotyped act, by which is meant a *normal* movement repeated involuntarily only at certain times; e.g., some people put out the tip of the tongue when they are writing. The important points to appreciate are that tic is of psychomotor origin; that in every true tic there is a mental defect and a motor defect, the former consisting in impairment of volition; that the movement is, so to speak, the disfigurement of a normal movement, repeated in season and out of season, but in it co-ordination and purpose can practically always be detected; that tic is often preceded by a desire for its execution and succeeded by a feeling of satisfaction; and that it is painless, and disappears in sleep.

Any part of the body may be affected. We may have tics of the eyes, nose, lips, tongue, neck, arms, hands, etc. We may have sniffing, sucking, licking, biting, blowing, whistling, coughing, grunting, nodding tics, etc. Tic may occur by itself: some people never develop more than one solitary tic; or it may be multiple: one tic may coexist with or follow on another. Gilles de la Tourette's disease is a disease of multiple convulsive tics, associated with echolalia and coprolalia, and is peculiarly rebellious to treatment. Tic often occurs along with some other disease. Tics are frequently seen in epileptics, in idiots, in individuals suffering from psychasthenia and obsessional insanity; they are less commonly found in hysteria. On the other hand, the intellectual superiority of the *tiqueur* may be as prominent as his mental instability. Many figures celebrated in history had their tic.

The PROGNOSIS in a case of tic depends solely on the mental state of the patient. The intensity and tenacity of any tic are determined by the degree of volitional imperfection to which its subject has sunk. He who can will, can effect a cure, but left to himself the victim to tic cannot always escape from it.

TREATMENT.—*Medicinal*.—Most of the ordinary medicinal agents in vogue in nervous and mental diseases have at one time or other been applied to the cure of tic; most have proved equally inefficacious. Sedatives and hypnotics—among which the bromides, chloral, and the preparations of opium may in particular be specified—sometimes effect a transient improvement, but they cannot permanently modify the mental weakness which is at the root of the mischief. A combination of the bromides and valerian often seems to have some beneficial action. The inconstancy of the therapeutic results hitherto obtained must not be allowed to discourage us, for it is important to remember that success achieved by medicinal means may not always be attributable merely to suggestion.

General.—It is very desirable to pay particular attention to the patient's general health. Often some trivial exciting cause may be the origin of a series of tics, and its removal may effect a speedy cure. This is especially the case in children. Their clothing ought to be attended to; it must be easy and comfortable. As so many of the tics of children concern the head, face, or throat, the orifices ought to be examined, and the ears, eyes, nostrils, teeth, palate, pharynx, etc., scrutinized. Girls may develop head-nodding tics because the hats which their parents choose for them are conspicuous for their size and awkwardness. Imitation, more particularly at school, may cause the development of tics; hence the question of the patient's environment should be considered.

Once a tic has established itself, we may expect little help from the use of any form of instrument or apparatus to correct muscular insufficiency or hyperexcitability. Devices of this nature are to be deprecated. As Meigs and Feindel truly say, "The patient is relieved of his infirmity only to become the slave of his instrument."

Treatment by Re-education.—Systematized mental discipline has shown itself to be the method *par excellence* for the treatment of tic, because it is a recognition of the relations between the motor phenomenon and the patient's mental state. The method is a combination of "immobilization of movements with movements of immobilization." The patient is directed to perform various exercises, some of which are intended to teach him how to preserve immobility, while the object of others is to replace an incorrect movement by a normal one. To begin with, he is required to remain absolutely motionless, as for a photograph, for one, two, three seconds—in fact, as long as he can without fatigue. This period is gradually increased on successive days, the patient being encouraged by being assured that he can and will remain immobile. Place him at the outset in the position in which his tic manifests itself least often, e.g., sitting, then subsequently modify his position, and in every case explain to him the objects of the treatment and elicit his intelligent co-operation. The performances should be gone through regularly several times a day, and always at the same hours. Though the method is simple, it must be taken seriously. It is an excellent plan to take the exercises in front of a looking-glass, whereby the patient is informed of the degree of immobility attained. Indifference on either the doctor's or the patient's part makes the treatment futile.

In addition, the patient is taught the discipline of movements, the idea being to make him perform slow, regular, and accurate movements to order, addressing himself to the muscles of the area in which the tic is localized. They must be very simple at first, and the exercises must be very short. To begin with they should take place under the personal direction of the physician. As a specimen of treatment for a facial tic, we may quote the subjoined programme from Meige and Feindel: "Every day, and three times a day, at the same hours—nine, one, and six—the patient is to look at himself for two minutes in a mirror, preserving absolute immobility the while; to read aloud for two minutes; to speak in front of the glass for two minutes; to walk backwards and forwards in front of the mirror for two minutes. During these exercises he will endeavour to keep his facial musculature under control. If the tic assert itself in the course of one of the exercises, he will recommence the latter, if necessary twice; the third time he will leave it till the next séance." In tics of the limbs, shoulders, hands, feet, innumerable movements will suggest themselves for practice.

The unanimity of opinion on the value of respiratory gymnastics in the treatment of stammering has led to their adoption in the treatment of tics in general. It is undoubtedly the bestowal of the attention on the allotted task that has such a salutary effect. Thus, by way of discipline of movement, the patient stands supported against a wall, with shoulders braced back, and is instructed to take slow and deep inspirations, raising his arms the while, and letting them fall with expiration. The performance is repeated three times a day, for ten minutes at a time. Cruchet has found the following method of service: The patient lies on his back with his arms by his side and counts the numerals up to, say, sixty, taking deep breaths at regular intervals, and endeavouring to maintain absolute immobility. Then he proceeds to make similar long inspirations and expirations, elevating his arms synchronously with the former, and depressing them with the latter. The exercises may advantageously be repeated every three hours to begin with, then their duration may be increased and the intervals lengthened. Or he may stand with heels together and back against a wall, and recite aloud for three minutes. Respiratory drill often succeeds admirably.

As muscular exercise is a striking way of disciplining volition, mention must be made of a re-educational procedure of much practical value, viz., mirror drill. It is a matter of common observation that if anyone be asked to write synchronously with the two hands, the left hand will tend spontaneously to adopt the

mirror form of writing, in which the letters run from right to left. Mirror writing is the natural writing of the left hand. What is true of writing is no less true of other forms of motor activity. The simultaneous use of symmetrical muscles is easy, of asymmetrical muscles difficult. It is especially in motor disorders of functional origin that mirror movements prove useful, and the frequent unilaterality of these disorders readily allows of the institution of a re-educative mirror drill. Thus it is a good plan to set daily exercises in writing, drawing, painting, tracing, etc., and to insist on the patient's devoting both hands simultaneously to his task. It will be found advantageous to devise symmetrical movements for the fingers, then for the hands, the forearms, and so on, and to instruct him in each successively. In this way the simultaneous execution of a normal movement with right and left hand is facilitated, and the sound limb imposes regularity on the other. Whatever be the localization of the tic or tics, this is the technique to adopt. The patient's interest is stimulated, while his attention is riveted on his involuntary actions : so is his will disciplined.

The re-educational methods of respiratory and other exercises and of mirror drill are of great and proved value in the treatment of certain forms of *Torticollis*. In this term are included various conditions which differ widely in their pathogeny, and the methods we have mentioned are not applicable to all. We may have *torticollis* of neuralgic origin, the sequel to occipital neuralgia, and strictly comparable to the *tic douloureux* of facial neuralgia. With the disappearance of the pain the spasm vanishes. *Torticollis* may be an occupation neurosis, and should be treated accordingly. It may be paralytic in origin, analogous to the secondary spasm of facial palsy. It may be a true spasm, the result of peripheral irritation, and not at all likely to be benefited by the procedures we have mentioned. In a case of *torticollis* it is eminently desirable to ascertain its nature in order that the appropriate treatment may be adopted. There remains the condition known as mental *torticollis*, a true tic, which will be found on investigation to present the features of tic as they have been defined. It is in cases of mental *torticollis* that we most frequently meet with the efficacious antagonistic gesture. The patient is able by a mere touch, often on the wrong side of the neck, to inhibit a violent "spasm" over which he pleads he has otherwise no control. In such cases treatment by re-education is often of great service. Thus : Stand or sit in front of a mirror, and endeavour to maintain an absolutely correct position of trunk and shoulders. Lift the arms vertically and turn the head, say, to the right, then depress the arms while the head remains as it is. Bend the body forward, and stretch the arms out till they touch the ground, the head meantime being rotated to the right. Then rise up again with the head in the same attitude. After two or three efforts it will be found that the head can be kept straight for a few seconds. Many other modifications of the method will suggest themselves in particular cases. (See also WRY NECK, and TORTICOLLIS.)

S. A. Kinnier Wilson.

TINNITUS.—(See EAR, AFFECTIONS OF.)

TOE-NAIL, INGROWING.—This may be treated in the following manner :—

1. In mild cases a small pledget of cotton-wool should be introduced beneath the nail so as to raise it from its bed, the end of the nail being cut square. The ingrowth results from the nail curling round and growing in on the delicate and sensitive papillæ. If this simple treatment be undertaken with care and patience, the condition can be rectified. If there is much pain and tenderness, the nail may be softened by painting it with 20 per cent solution of caustic soda, the whole toe being then wrapped up in a moist, antiseptic dressing.

2. In more severe cases recourse may be had to a small metal lever introduced beneath the side of the nail, so as to gradually raise it up over the fleshy tissue of the toe. This method is rarely satisfactory.

3. If the patient is willing to undergo an operation, the method advised by Watson Cheyne should be adopted. It is infinitely superior to avulsion of the nail. Under anæsthesia, an incision is made along the nail fold right down to the matrix; in this way a flap is formed of the soft parts that lie alongside the ingrowing nail. Rather less than half the nail is then cut away, care being taken to see that the cut extends well down to the matrix, and that the nail-bed is thoroughly destroyed. If these precautions are not taken, the operation will be a failure. The flap is now readjusted so that the nail lies on a higher level than the soft parts, and it is secured with one or two sutures. This is a radical and very satisfactory method, and one which will completely cure the trouble.

TONGUE, EPITHELIOMA OF.—(See MOUTH AND PHARYNX, MALIGNANT DISEASE OF.)

TONSIL, MALIGNANT DISEASE OF.—(See MOUTH AND PHARYNX, MALIGNANT DISEASE OF.)

TONSILLITIS.—This term is generally confined to inflammation of the faucial tonsils. It is either acute or chronic.

I.—ACUTE TONSILLITIS.

This may be grouped under the following heads :—

(1) Follicular Tonsillitis; (2) Parenchymatous Tonsillitis and Peritonsillitis (Quinsy); (3) Ulcerative Tonsillitis: (a) septic, (b) chancre, (c) tuberculous; (4) Tonsillitis as a complication occurring in the course of an acute specific fever: (a) scarlet fever, (b) rheumatism, (c) syphilis (2nd stage), (d) diphtheria.

1. Acute Follicular Tonsillitis.—In the treatment of this affection it is most important at once to isolate the patient, especially if a child, and before applying any local application, to take a swab and have a bacteriological examination made. If the Klebs-Löffler bacillus be present, the case should be treated as one of diphtheria and be injected with antitoxin. The possibility of scarlet or rheumatic fever should also be remembered. General malaise and pain in the throat are the two most prominent symptoms, and very often a high temperature, running up to 103.5° or 104° F.

TREATMENT.—The first indication is a mercurial purgative, either a blue pill and the conventional black draught, or a large dose of calomel. Many patients cannot take calomel, owing to the intense griping it occasions. In such cases, a pill containing euonymin, scammony, and aloin may be substituted. Where the temperature is high, it is most readily reduced by drop doses of tincture of aconite continued every hour until it falls to 100° F. It may be combined with liquor ammonii acetatis, from ʒj to ʒj, given in a tumbler of hot water every four hours. Salicylate of soda in 10-gr. doses to begin with, and then continued in 5-gr. doses every hour until either buzzing in the ears occurs or the temperature falls to 100°, is sometimes very efficacious. Salicylate of quinine may be substituted for it, but it must be given in smaller doses. In the case of adults who do not object to the intensely bitter taste, the writer has often obtained striking results by giving a combination of 10 gr. quinine and 10 gr. powdered guaiacum. This should be taken into the mouth and allowed to dissolve slowly in contact with the inflamed tonsils. It seems to have both a local and a general effect, and may be repeated every three hours. Of the synthetic drugs, acetyl-salicylic acid or salipyrin may be substituted for the salicylate of soda.

Local treatment does not seem to have much effect, but the following may be tried. The tonsils may be swabbed every hour with a solution of peroxide of hydrogen (20 vols. strength). This sometimes has the effect of clearing out the follicles. To help to relieve the intense pain give an inhalation of Friar's Balsam (compound tincture of benzoin) ʒj to the pint. After using this for ten minutes give ice to suck for an equal length of time. This manoeuvre should be repeated about four times every two hours. Painting the tonsils with a strong solution of carbolic acid (1-20) sometimes gives great relief, the carbolic acid acting as a local anæsthetic. In the case of children, this should be done only by a medical attendant or a trained nurse, and the child should be directed not to swallow the saliva, as children are very susceptible to carbolic acid poisoning.

The writer has lately been treating a number of cases by means of an elastic bandage after Bier's method. The bandage is about two inches wide and is made for him by Messrs. Mayer & Meltzer, Great Portland Street, W. A Martin's pure rubber bandage will do as well, but is much more expensive. The bandage should be applied twice round the neck below the larynx, sufficiently tightly to make the face red, and the patient should *feel* it swollen (just as it feels when covered with a measles or scarlet fever rash). Sometimes a great deal of time has to be taken in adjusting the bandage so that it is not too tight, nor too loose, but just tight enough. There is only one criterion of whether it is correctly applied or not, and that is *the cessation of pain*. Where it has been applied properly, it should be left on for twenty hours and off for four.

2. Parenchymatous Tonsillitis and Peritonsillitis.—This may lead to formation of abscess in the tonsil itself, but more usually in the tissues above and around it.

The general treatment has been already indicated, but the following prescription should be given every four hours :—

R Tincturæ Ferri Chloridi	gtt. xx-xxx	Liquoris Strychninæ (1 %)	gtt. iv
Potassii Chloratis	gr x	Aquæ Chloroformi	q.s. ad ʒss
Glycerini	gtt. xxx		

When an abscess has formed, it should be evacuated as soon as possible. (See ABSCESS.)

3. Ulcerative Tonsillitis.—

a. Septic.—This generally occurs in those who are run down and exposed to microbic infection. Nurses and house surgeons are especially subject to it. Treatment should be on the lines already indicated, combined with change of air and tonics.

b. Chancre.—This is not so common in this country as it is on the Continent. Antisyphilitic remedies should at once be applied, and the chancre may be painted with weak tincture of iodine (B.P.).

c. Tuberculous.—The patient should be sent to a sanatorium, and the ulcer destroyed with the electro-cautery.

4. As a Complication.—

a. In Scarlet Fever.—The throat should be sprayed every two hours with a mixture containing equal parts of "hazeline" and peroxide of hydrogen, 20 vols., and the nose be washed out with an alkaline spray.

b. In Rheumatism.—Mandl's solution, containing 10 to 25 gr. potassium iodide, 5 to 10 gr. iodine, 2 drops oil of peppermint, and glycerin to one ounce, should be painted on the throat every three hours.

c. In Syphilis (2nd stage).—The ulcerated surface should be painted with a weak solution of cocaine, and then be carefully swabbed with weak tincture of iodine (B.P.), care being taken that none of it gets into the larynx.

d. In Diphtheria.—In addition to antitoxin treatment, the tonsils should be

carefully swabbed with a solution of 1-40 carbolic acid every four hours. (See DIPHThERIA.)

II.—CHRONIC TONSILLITIS.

After an attack or repeated attacks of acute follicular or parenchymatous tonsillitis, the tonsils may become permanently enlarged, and should either be reduced in size or be removed. They can be reduced in size by means of : (1) The Guillotine (Tonsillotomy); (2) The Snare; (3) "Morcellement"; (4) The Galvano-cautery; or (5) They may be entirely removed by the guillotine (Tonsillectomy or Enucleation).

1. *Tonsillotomy with the Guillotine.*—The best instrument to use is the Mackenzie, as it is the simplest. A general anæsthetic is not necessary unless there are adenoid growths present as well. In that case the tonsils should be removed after the adenoids, as they bleed more, and the patient being then less under the influence of the anæsthetic, the laryngeal reflex is more perfectly established. In the case of older children or adults, nitrous oxide gas, alone or combined with oxygen, may be used if the patient be very nervous, but as a rule it will suffice to paint the tonsils twice or thrice with a 10 per cent solution of cocaine.

The patient should be placed in a chair with an assistant behind to hold the head and also to push in the tonsil from the outside. As most surgeons are right-handed, it is best to take the right tonsil first, as the tonsillotome is then held in the left hand, and as a rule children do not begin to struggle until the first tonsil has been removed. The great mistake that beginners in the operation make is trying to use too big an instrument. The operator should have at least three sizes ready to hand, and use as small a one as possible. He should also remember that the tonsil will be smaller after the application of cocaine than when he first examined it.

The patient should be in front of the operator, and be asked to hold tightly to the arms of the chair or give his hands to an assistant or nurse to hold. It is most important that he should not have them free to catch hold of the instrument. Also he should be seated on a level with the operator, so that the latter can throw a good light into the mouth. In the case of the right tonsil, the operator depresses the tongue with the right forefinger, and taking the guillotine in his left hand passes it into the mouth edgewise. The process of getting the tonsil into the lumen of the guillotine consists of four movements :—

(a) The back of the guillotine is pressed against the tongue, and its edge slipped under the dependent part of the tonsil and hooked up under it, and the guillotine is turned more flatly against the tonsil. (b) The hand is then carried across the mouth, and the top of the guillotine is made to slip in behind the back of the tonsil, between it and the posterior pillar of the fauces. (c) The guillotine is then turned quite flat against the tonsil and manœuvred until the top of the tonsil also is brought into the lumen. (d) The hand is then brought back to the right side of the mouth and strongly pressed, so that the anterior pillar of the fauces is kept out of the way. The blade is then pushed home, either by means of the left thumb alone or by the thumb of the right hand.

In the case of children, the instrument should not be withdrawn from the mouth, as they may object to open the mouth again. It should be shifted to the right hand, and the left tonsil should be removed in the same way. Where the tonsils are of markedly different sizes, so that it is necessary to use different instruments, the second one should be introduced into the mouth before the first one is withdrawn.

The only danger after tonsillotomy is that of hæmorrhage. It is always well to enquire beforehand if the patient belongs to a family of "bleeders,"

and if so the tonsil should be removed by means of the cold snare, or, preferably, left alone. In ordinary cases the hæmorrhage generally stops after a few minutes, but if it does not do so, the throat should be well illuminated to see if a tag has been left, which sometimes happens. The hæmorrhage will generally stop with its removal; but if the patient is restless and faint from loss of blood, and cannot, or refuses to, show the throat properly, it is imperative to give a general anæsthetic, so that the exact source of bleeding may be discovered. If a small artery can be seen spouting, it should be caught with a long pair of forceps, and be either twisted or tied. Free capillary oozing generally stops when the patient becomes faint, but before that untoward condition is reached an emetic will lower the blood-pressure and so stop the hæmorrhage. Local styptosis is obtained by means of a sponge or swab dipped in pure adrenalin or hazeline, and held against the tonsil with one hand, while the other applies pressure to the outside. Ice applied to the back of the neck, and also sucked, will be found very useful. A very good styptic is made by taking a teaspoonful of tannic acid and gallic acid and making them into a thick paste with a little water. A medium-sized swab of cotton-wool, held by a sponge-holder or pair of adenoid forceps, should be dipped into this mass and then applied to the bleeding spot and held there for five minutes, with counter-pressure on the outside. Sometimes a concentrated solution of antipyrin applied in the same way rapidly causes the bleeding to cease. In some few severe cases it may be necessary to stitch the pillars of the fauces together.

The patient should remain quiet for two or three days, and take only cold milk or soft food. The bowels should be kept freely open by means of a saline purge. Where possible the writer always gives children full doses of bromide of potassium combined with arsenic for three or four days before and after the operation. It helps to soothe the patient's nerves, and certainly lessens the pain and sensibility of the pharynx.

For local after-treatment, Condy's fluid, diluted to a pale pink colour, or carbolic lotion (1-80), or hazeline, or Pond's extract diluted to a half, may be used in the form of a spray or gargle several times a day, especially after taking food. If the pain be very great, which is generally due to the anterior pillars of the fauces having been cut, orthoform or anæsthesine will often be found very efficacious. Where the throat remains in a sloughing condition for a long time, the process of healing can be hastened by swabbing with solution of peroxide of hydrogen (20 vols.).

2. *The Snare*.—This may be used either hot or cold where the tonsils are very big and fibrous and likely to prove very hæmorrhagic. As its virtue consists in slowly tightening the wire, it is an extremely painful process. It should therefore always be done under a general anæsthetic.

3. "*Morcellement*" is extremely useful where the tonsils are long and flat, and cannot be removed by the guillotine. The operation can easily be performed by means of special punch forceps.

4. *Galvano-cautery*.—This is used in the case of adults, and may be applied under cocaine, but as the cocaine reaches the surface only, it is best to inject a few drops of a solution containing $\frac{1}{2}$ per cent of novocain in a solution of 1-4000 epinephrin. It is a painful process if the cautery point gets beyond the region that has been anæsthetized. For that reason it involves a good many sittings.

5. *Tonsillectomy or Enucleation* is the best proceeding when the tonsils are subject to very frequent attacks of inflammation, or when the crypts are so deep that they are never completely empty, or when there has been a rapid recurrence after tonsillotomy. The operation may be done in an adult under local anæsthesia; a few drops of a solution containing $\frac{1}{2}$ per cent of cocaine and 1-4000 epinephrin should be injected into the tonsil through the top and bottom

of the anterior pillar, also into the supratonsillar space and into the posterior pillar. But it is much better to do it under general anæsthesia.

The operation can be done in the majority of cases by the guillotine alone. The first three steps are the same as those marked (a), (b), (c) for tonsillotomy. In the fourth step the hand, instead of being brought back to the same side of the mouth, is carried still further across the mouth so as to force the whole tonsil into the lumen, and if necessary it can be pressed in by pushing on the anterior pillar of the fauces. The tonsil can thus be enucleated with its capsule complete. If it be difficult to get the guillotine round the tonsil, either on account of the pillars being adherent to it, or from the surface being concave instead of convex, and the substance of the tonsil being quite friable, it is better to have an assistant; the writer has seen some dire results after so-called enucleation, imperfectly performed, such as the uvula and a large part of the soft palate being sliced off, large perforations left in the pillars of the fauces, and adhesions between the soft palate and posterior wall of the pharynx. One pair of small pointed forceps should be attached to the anterior pillar and another pair to the posterior, and these should be given to the assistant to hold, and if necessary the anæsthetist can do any sponging that is required to keep the field of operation visible. The surgeon then takes a pair of vulsellum forceps, preferably a pair over which a guillotine can be slipped, and seizes the centre of the tonsil, without gripping the pillars, and pulls the tonsil out of its bed. If the assistant now puts tension on the anterior pillar, it is possible to see the edge of the capsule. The next step is to take a curved pair of sharp-pointed scissors, specially made for the purpose, or a sharp tonsil scalpel (an ordinary thin long scalpel with the blade covered by adhesive plaster to within half an inch of the point will serve very well). With the instrument chosen the tonsil is first dissected from the anterior pillar, and then from the supratonsillar fossa. When this has been accomplished, the forefinger can be slipped in behind it and thus bring it away enclosed in its capsule. It should then be dissected from the posterior pillar; the operation can now be completed by slipping a guillotine over the forceps and so removing the tonsil; or if there be a great deal of oozing, a snare can be used, and be tightened up and left *in situ* while the other tonsil is dealt with. As it is essential that the site of operation should be well illuminated, a light fixed on the operator's forehead is better for the purpose than a reflecting mirror. Should hæmorrhage occur, it can be dealt with as before.

George C. Cathcart.

TOOTHACHE.—(See **TEETH, CARIES OF.**)

TORTICOLLIS.—(See **WRY NECK.**)

TORTICOLLIS, CONGENITAL.—By congenital wry neck we mean the condition due to shortening of the sternomastoid muscle present either at birth or soon after.

In considering the rational treatment of this condition, we must first consider briefly: (1) *The cause*; and (2) *The morbid anatomy*.

1. **Cause.**—*a.* Ischæmic contraction of the lower two-thirds of the muscle (*Fig. 81*). The so-called hæmatoma in the newly-born child which is followed by torticollis is a post-obstructive œdema, and the condition of the muscle is comparable to the condition of the forearm muscles in Volkmann's contracture.

b. Malposition in utero.

c. Syphilitic infiltration or definite gumma in the sternomastoid—very rarely.

2. **Morbid Anatomy.**—It is more common in girls than boys. Right and left sides are affected in about equal numbers. The sternal head is affected more than the clavicular, and so, as a rule, rotation is more marked than

flexion. As the child gets older, secondary deformities appear—i.e., other muscles and their fasciæ become shortened, the face on the affected side lags behind in development (although this asymmetry may only become obvious to the parents after the head has been put straight), and the base of the skull and the upper dorsal spine become twisted or scoliotic from the scoliosis in the cervical region. (Fig. 82.)

TREATMENT.—Treatment must be begun as soon as the condition is diagnosed, in order to prevent the asymmetry and the high dorsal scoliosis, this latter being exceedingly difficult to remedy. If the shortening of the muscle be remedied before puberty, the asymmetry of the face will disappear, but this cannot be expected after that age. In addition to the

administration of mercury, there are three forms of treatment: (1) *Mechanical*; (2) *Manipulative*; (3) *Operative*.

1. **Mechanical.**—Treatment by an artificial sternomastoid on the opposite side is useless, no instrument being equal to the surgeon's hand.

2. **Manipulative.**—

This will bring about a cure up to the age of six months. It may be tried in mild cases up to the age of three years.

Supposing the left sternomastoid be contracted: while an assistant holds down the left shoulder, the surgeon stands behind the child's head, his left hand holding the chin with the palm, the fingers passing up the left side of the face. His right forearm rests against the right side of the child's head; the palm of the hand rests on the top of the head, the fingers are on the left side of the

Fig. 81.—The so-called "hematoma" of the sternomastoid. There was no bruising, and no history of difficult labour.

Fig. 82.—Congenital torticollis in child, age 8. Note contraction of sternal head on right side; lateral curvature and rotation in cervical region: displacement of head bodily toward the left: right side of face smaller than the left side.

vertex. With this secure grip the head is rotated so as to stretch the shortened muscle. This manoeuvre is carried out by the doctor for three or four

minutes at a time every two days, when the deformity is well over-corrected as a rule. The child's mother or nurse is then taught to repeat it every morning to prevent recontraction. The manœuvre has been performed under an anæsthetic in older children, but is then certainly not free from risk. Besides the above manipulation, care should be taken that when the child is in its cradle or being carried on the nurse's arm, any tendency for the head to fall to one side by gravity should be in such a direction as to stretch the shortened muscle.

3. Operative.—Excision of the lower two-thirds of the muscle has been advocated; it is an unnecessary and mutilating operation. Lengthening of the muscle by a plastic operation has also been practised, a treatment unnecessarily complicated. Operative treatment consists in section of the muscle, either subcutaneously or by the open method. The subcutaneous operation has been given up. It might be done if only the sternal portion were affected, the clavicular fibres not having become secondarily contracted; or it might be done by some surgeons if the parents refused consent for an open operation.

Division of the sternomastoid by open operation, therefore, is the operative treatment. It may be divided at the upper end, so that the scar is hidden by the hair; it has been done in the middle of the muscle, but the scar is obvious, and the spinal accessory nerve and the vessels of the neck are in danger. The muscle ought to be divided at the lower end. If both heads are contracted, make an incision parallel to the clavicle; the resulting scar will be hidden by a necklace in later life. If the contraction is more marked in the sternal head, make an oblique incision, and the scar of this will, as the head is restored to the normal, be stretched longitudinally and be really invisible. There is no need for any apparatus after the operation. For the first ten days the child's head is kept rotated to the same side as the operation, between sandbags in bed. Following this, passive and active movements prevent re-contraction quite effectually.

TRACHEA, FOREIGN BODIES IN.—(See FOREIGN BODIES IN THE AIR-PASSAGES AND (ESOPHAGUS.)

TRACHEOTOMY.—(See LARYNGEAL OBSTRUCTION.)

TRACHOMA.—(See CONJUNCTIVA, DISEASES OF.)

TRIGGER FINGER.—This is a condition not infrequently seen, in which the patient, on attempting to extend the fingers actively, finds that one finger remains partially flexed. On extending it passively with the other hand, the obstruction is overcome with a distinct snap. I have seen it in the thumb and the ring finger. It is an annoying rather than a crippling trouble.

An attempt must be made to localize the obstruction. The commonest site is opposite the metacarpo-phalangeal joint. If it cannot be localized, fixation on a splint, and massage, with the administration of iodide, has sometimes been successful in relieving the condition. If this treatment be unsuccessful, the tendon must be exposed if the patient wishes it or if the site of the obstruction can be localized, operative treatment then being the method of cure. We may find: (1) A localized thickening of the tendon, which must be pared down. (2) Perhaps a cyst in the tendon, analogous to ganglion, which may be removed. (3) An adhesive band over the tendon. (4) A thickening of the tendon sheath, leading to narrowing of its lumen. Or there may be various other pathological conditions, which must be dealt with in an appropriate manner.

Robert Milne.

TRYPANOSOMIASIS.—The treatment of this disease during the early stages of pyrexia has sometimes succeeded. In the advanced stage, when cerebral symptoms have supervened, no treatment is effective.

Arsenic is the drug that has been most efficacious, but large doses are required. Liquor potassii arsenitis causes symptoms of arsenical poisoning, even when the dose is very gradually increased. Few persons can acquire tolerance for the large doses required, and its use has to be discontinued in the majority of cases, as symptoms of poisoning supervene.

Hypodermic injections of various preparations, usually in combination with aniline, enable larger doses of arsenic to be administered with less risk of poisoning. The preparations now used are those that have been successfully employed in infections of lower animals with the *Trypanosoma gambiense*. The doses given to men with promising effects are those mentioned.

Trypanoth 0·9-gr. doses, chrysoidin $\frac{1}{10}$ to $\frac{1}{2}$ gr., parafuchsin 5 to 20 gr. in cachet by the mouth, have been used with some benefit, but now the use of these drugs has been discontinued, as atoxyl has a much greater effect. They are sometimes given alternately with atoxyl.

Atoxyl, a compound of arsenic, has given good results in the lower animals. Todd proposes the administration of large doses intravenously. Intramuscular injections in man appear to control the course of the disease, but even with doses of 30 min. of a 10 per cent solution, symptoms of poisoning have occurred. It is well to begin with small doses, such as 10 min., and gradually increase the dose, stopping the treatment for a day or two if any symptoms of poisoning occur. Marked improvement is usually manifest when the dose is 20 to 25 min.

In cases of apparent cure the treatment must be continued for a long period, at least two years, as recrudescences occur, even in cases where no parasites have been found for several months.

This method of small or moderate doses continued for a long period has so far given satisfactory results. In the tropics, with natives, much larger doses are given and repeated in two or three weeks. With this method, though the immediate results are satisfactory, relapses nearly always occur. A number of the patients have developed amblyopia, optic atrophy, peripheral neuritis, and gastro-intestinal trouble. Antimony preparations have been highly successful in lower animals, and in man have a more rapid effect than atoxyl, but the local effects are severe, and tissue necrosis is induced. In Lambkin's medium, with specially prepared metallic antimony, better results are obtained, but in one case, both as 5 per cent and $2\frac{1}{2}$ per cent solutions, it led to the formation of large painful abscesses. The sodio-tartrate of antimony in $\frac{1}{2}$ -gr. to 2-gr. doses in 4 ounces of normal saline ($\frac{1}{2}$ to 1 per cent solutions) has been given as an intravenous injection. There are a sharp reaction, severe rigor, much salivation, and some cough, but the results as regards the trypanocidal action are most marked. In other cases no such severe reaction has occurred. The trypanosomes will reappear in a few days unless the injection be repeated. In atoxyl-resistant cases, such as most of those from Rhodesia, antimony is the only hope. Metallic antimony very finely divided has also been used in these cases as an intravenous injection in doses of $\frac{1}{4}$ to $\frac{1}{2}$ gr. The rigor is delayed, but on the whole the reaction is more severe than with the larger doses of tartar emetic, though the effect is more persistent. It is best given as intravenous injections, but these must be repeated at intervals of three days or so for a prolonged period. Salvarsan and copper salvarsan have only temporary good effects. Tartar emetic by mouth or rectum has some effect, but is not to be relied on alone in bad cases. Perchloride of mercury ($\frac{1}{2}$ per cent solution) in 15- to 30-min. doses is given by some alternately with the atoxyl: so that the atoxyl is discontinued for one or two weeks whilst the mercury is given,

and then the mercury discontinued and the use of atoxyl resumed. By this method it was believed that resting forms of the trypanosomes might be destroyed. The method has not been markedly successful in man. The effects of salvarsan are favourable for a time, but the results are not permanent.

Sleeping Sickness.—Negro-lethargy is one of the fatal terminations of chronic trypanosomiasis. When the symptoms are established, no treatment appears to have any effect. It is justifiable to try large intravenous doses of any of the drugs that exercise a beneficial effect in trypanosome disease, as the sleeping sickness is invariably fatal. Life may be prolonged by careful nursing and feeding.

TUBERCULOSIS.—(See BONE, TUBERCULOUS DISEASE OF; LARYNX, TUBERCULOSIS OF; PERITONITIS, TUBERCULOUS; EPIDIDYMITIS, TUBERCULOUS; PULMONARY TUBERCULOSIS; ETC.)

TUBERCULOUS GLANDS.—The infection of the various groups of cervical lymphatic glands by the tubercle bacillus is a very common affection, and one from which no age can claim immunity.

The pathological process represents the development of a tuberculous lesion in a singularly perfect manner, and, according to the mode of response which these tissues offer to the infecting agent, we are able to distinguish several grades of the disease.

It may be argued that the lymphatic glands, being peculiarly rich in low-formed cellular elements, are able to oppose a better resistance to the tubercle bacilli than is, for example, the kidney, with its more highly specialized epithelium; and it is undoubtedly true that the natural resistance of the patient in overcoming the tuberculous invasion is better exemplified in disease of the glands than of many other structures. At the same time it is more than doubtful if nature can ever effect a permanent cure; and there is every reason to believe that glands which have become caseous, and even calcified, retain within them a source of latent infection which in after years may be roused into activity. Possibly in the earlier stages, before caseation has been produced, the protective substances and phagocytic activity may destroy wholesale the pathogenic bacteria; but for the present it may be said that in the later stages the disease, though apparently inactive, must be dealt with surgically, lest a focus for future trouble be left untreated.

In this connection, the value of tuberculin in the treatment of the condition should be considered, for the effect of the vaccine inoculation, which is discussed later in this article, is simply to aid the natural process of repair.

When a focus of tuberculous infection has passed into the stage of caseation and calcification, although an apparent shrinkage may be noted, the exact pathological condition is a mass of necrotic cells surrounded by a fibrous or calcareous envelope. The bacilli remain embedded in this caseous cemetery, but the impervious surroundings which prevent their emigration prevent also the permeation of the protective substances from the blood-stream, and act as barriers to the passage of the leucocytes.

It will be clear then that while we may temporize with the early stages, and expect and receive valuable assistance from the "tuberculin" vaccine, the later stages, when caseation and softening have supervened, are more insidious and dangerous than is recognized, and more cut of the range of successful therapeutic inoculation.

Clinically, three main grades may be recognized, but these are simply stages of the same pathological process, and though in one form a single gland only appears to suffer, while in another a group of glands is attacked and a very

large amount of periglandular inflammation occurs, both forms will require, as a rule, the same plan of treatment. The three grades, which will be considered as affording examples of the stages of the disease encountered clinically, are as follows :—

1. *The Single Gland.*—This gland, frequently situated opposite the angle of the jaw, becomes enlarged and swollen, and on casual examination appears to be the only one affected. A more careful investigation will often reveal a local source of irritation in the mouth, and in some instances a number of smaller but definitely palpable glands in the vicinity of the primary swelling. This grade of glandular enlargement tends to caseation and softening, and by spread of the infection may rapidly pass into the second stage.

2. *The General Enlargement of the various Groups of Lymphatic Glands.* (a) The submaxillary; (b) The tonsillar; (c) The concatenate chain; (d) The para- and subtrapezial glands of the posterior triangle. Any or all of these groups may be attacked, and this particular stage is the one most commonly met with.

3. *A stage where Fibrosis has occurred around the Caseous Centres*, when there is a great amount of peri-adenitis, matting the glands together and to surrounding structures. This stage is found in adults and old people when the resistance to the tubercular invasion is well marked. Single glands rarely show this phase : it is commoner when larger groups have been affected, and a mass of great firmness and density is formed, which closely simulates a secondary carcinoma.

But while it is possible to classify cases under these main divisions, there are many other phases, especially of the second group. The appearance of these phases will depend upon many factors. (1) Upon the activity and virulence of the tubercle bacilli. (2) Upon the general health and resistance of the patient. (3) Upon the presence of a source of continual irritation. (4) Upon the occurrence of a "mixed infection."

In very young children, especially in those who are ill-nourished, there is an early tendency to fusion and breaking down of the glands. In some adults, on the other hand, the process may be characterized by such chronicity in development, by such absence of peri-adenitis and fixation, that the cases appear clinically like those of benign lymphadenoma. (It may not be out of place to point out that the exact status of benign lymphadenoma has not been clearly settled, and many cases which have been diagnosed as such have turned out later to be tuberculous.) (See LYMPHADENOMA.)

The subject of local irritation in respect to the development of tuberculous glands is an exceedingly important one, whether the region under discussion be the neck, thorax, abdomen, or thigh; and it has been proved satisfactorily that in the vast majority of cases the incidence of a tuberculous process in a glandular group has been preceded by injurious irritation in some part of the region drained by those lymphatics.

In the region of the neck there are so many sources of possible irritation that the most thorough investigation must be undertaken in all cases before any radical treatment of the actual glandular affection is contemplated. The scalp must be examined for patches of seborrhæic eczema, for other lesions, and for pediculi. The mouth must be examined for carious teeth, the ear for any evidence of chronic suppuration, and the nasopharynx and throat for adenoids and chronic tonsillitis.

The relative importance of these various sources of irritation differs according to the age of the patient. In children it is rare to find a carious tooth at the bottom of the trouble, but in them we find a fertile soil for the cultivation and dissemination of micro-organisms in the lymphoid masses and the enlarged tonsils which are so common at this age. Adults are rarely affected in this

respect, but a carious molar, hitherto unrecognized as the source of the mischief, can often be found on careful examination.

While considerable attention has been directed to these accessory or predisposing causes of tuberculosis, very little has been said about the many adventitious microbes which find their way from these local lesions to the lymphatic glands; and it would not be incorrect to state that, in the vast majority of cases of tuberculous glands, not only has a local irritative cause been responsible for the early enlargement of the glands, but organisms other than tubercle bacilli have entered the lymphatic circulation, so that the resulting infection is essentially "mixed." It is doubtful if this point has been sufficiently emphasized, and as it is extremely important, both in prophylaxis and treatment, more attention should be directed to it. It should be clearly understood that the local lesion is "irritative" not merely in a mechanical sense, but bacteriologically, and forms a source of bacterial infection, not by the tubercle bacillus alone, but by many other micro-organisms.

It has been possible, in a few cases, to isolate and distinguish these additional agents, but the great difficulty that attends their thorough recognition lies in the fact that many of them, especially some of the streptothrix group (an organism nearly always present in the mouth), cannot be cultivated.

It is now clear that the first essential in all cases of glandular enlargement is a thorough search for, and adequate treatment of, any local condition which may be considered a source of infection, and with this end in view enlarged tonsils and adenoids must be removed. Carious teeth must be extracted or filled. Eczematous conditions of the scalp must have special attention, and discharges from the ear must be carefully treated. Until all further infection has been prevented as far as possible, by the recognition and treatment of these various sources, no radical operation upon tuberculous glands is to be considered.

The treatment of tuberculous glands must be considered under :—

1. General and Prophylactic Treatment.—This will resolve itself into a careful consideration of the details mentioned in the previous paragraph, and the administration of cod-liver oil, iron, and malt—remedies which are of undoubted value in this as in other tuberculous conditions. The influence of fresh, and especially of seaside, air, as an adjunct to this treatment, must be duly appreciated.

2. Operative and Immunizing Treatment.—The particular operation to be performed in cases of glandular enlargement involves the consideration of the three groups of cases previously mentioned.

When a single gland is involved, or where at least the chief infection appears confined to that gland, this should be removed as soon as thorough treatment of any predisposing cause, such as a carious tooth, has failed to bring about a marked diminution in the glandular swelling. After the local lesion has been treated, iodine ointment should be applied to the skin over the swollen gland, and the patient should be watched. If this fails, the gland should be excised, for by this means the whole process may be arrested and the further involvement of adjacent groups prevented.

Should the gland soften and break down, a small incision should be made over it, the contents removed with a scoop, and the cavity swabbed out with pure carbolic acid; a drainage tube should be inserted, and the wound be allowed to close gradually. There must be some difference of opinion as to when excision should be attempted and when scraping only should be tried; but, in general, when the skin over the swelling is red and when the mass is adherent, it will be wiser to deal with the abscess by scraping and drainage, since, if an attempt be made to remove the whole of the affected gland, there is great risk

of wound infection. The small scar can be dissected out later when healing has taken place.

The treatment of the second variety will depend upon the condition of the glands. If, in the enlarged groups, there are several points where the glands are breaking down and are adherent to the skin, it is wiser to deal with them as advised above. Since in these cases there is nearly always a "mixed infection," there is considerable risk in making an extensive dissection of the triangles of the neck. If the various abscesses be opened and drained, and general measures be taken to improve the resistance of the patient, a radical operation may become unnecessary, or at least be rendered much safer.

Where, however, large groups of glands are affected, or where contiguous chains have been attacked, no marked softening or suppuration having taken place, it may be advisable to undertake the radical operation. This is an operation of major surgery, and requires as much care and skill as any that the surgeon may be called upon to undertake; further, it is distinctly a dangerous one, since, apart from the risk of injuring important structures, the mixed infection which is present may give rise to serious, even fatal, complications, a virulent form of septicæmia sometimes supervening.

The actual extent to which the dissection is carried will depend upon the needs of the case, but the same general principles should be observed in dealing with the localized groups of enlarged glands as in the more extensive cases which alone will be described.

Incision.—Either a curved incision following the lines of natural cleavage of the skin, as recommended by Kocher, passing from the mastoid region to the middle line in front below the jaw, may be made, or an oblique incision in front of or behind the sternomastoid. There is little doubt that the "collar" incision of Kocher, which can be employed in the lower as well as the upper part of the neck, leaves a less conspicuous scar than the commonly employed oblique incision. At the same time, the latter gives a better exposure of the parts, and if care be taken to suture the investing layer of cervical fascia and platysma as well as the skin, the scar will not stretch to any great extent.

The incision should always be a free one, and it is much better to err on the side of a long, than of a short, incision in this dangerous region. When the incision has been made, the dissection should be begun from below, the surgeon gradually working upwards until the uppermost gland, usually the tonsillar or jugulodigastric, is reached. This gland lies deeply, in relation to the posterior belly of the digastric, the jugular vein, the spinal accessory nerve, and the transverse process of the atlas. It drains the tonsil, is usually the first gland to be infected, and some difficulty attends its removal. The dissection must be systematic, all the lymphatic glands, fat, and intervening cellular tissue being removed until the anterior and posterior triangles are completely bared. Much stress must be laid on this detail, for it is usually futile simply to remove those glands which are obviously enlarged, leaving countless small infected masses lurking behind in the fatty cellular tissue. A recurrence of the trouble after an extensive operation is a disappointment to all concerned, and it is best prevented by a thorough dissection.

From the moment the incision has been deepened through the fascia colli, four structures claim the greatest attention from the surgeon, according to the position of the mass of glands that has to be removed: (1) The spinal accessory nerve; (2) The internal jugular vein; (3) The facial nerve; (4) The thoracic and right lymphatic ducts. Many other important structures are exposed, but are less likely to be injured.

1. *The Spinal Accessory Nerve* is met with in both triangles. In the posterior it crosses from the middle of the posterior border of the sternomastoid obliquely

to the lower third of the anterior border of the trapezius. In the anterior triangle it will be found passing round the prominent transverse process of the atlas and entering the deep surface of the sternomastoid, in an adult, $1\frac{1}{2}$ inches below the tip of the mastoid process. If, in a patient of any age, a line be drawn between the angle of the jaw and the tip of the mastoid, and another line at right angles to the centre of this, passing obliquely across the sternomastoid and cutting the middle of the posterior border of the muscle, and if this line be prolonged across the region of the posterior triangle to the trapezius, a very fair idea will be gained of the course the nerve pursues, and it is advisable for the surgeon to keep this in mind during his dissection. Unfortunately the nerve is intimately connected with the affected glands, and in some cases is displaced from its normal line, but it may be remembered that when the chief mass of glands lies below the middle of the posterior triangle, the nerve will be displaced upwards; conversely, when the mass is in the upper part, it will be displaced downwards. When the region of the nerve is reached, blunt dissection must be employed, and every band must be tested for motor nerve fibres. Fortunately, the slightest stimulus from the director or blunt dissector will cause a contraction of the trapezius, and in this way the nerve may be isolated. In spite of the fact that the nerve appears to be embedded in the glandular mass, it is nearly always possible to free it completely without damage. The same rules apply to the nerve in the anterior triangle, but its greater depth renders the dissection more difficult. Should the nerve be accidentally divided, the ends must be sutured.

2. *The Internal Jugular Vein* is in evidence in most operations on enlarged cervical glands. In the majority of cases it is easy to clear away the glands of the concatenate chain which lies along it, for the vein, though naturally very thin, becomes thickened by the pressure of the glandular mass. During the dissection the vein may be wounded, or small branches torn from their point of attachment to the vein wall. Neither accident is serious if properly treated. The opening must be picked up accurately with artery forceps, and a ligature must be applied very tightly, so that the opening is satisfactorily closed. The vein wall is very elastic, and several points may be tied in this manner without the smallest ill effect.

Serious injury to the vein is best avoided by clearly exposing it in the early stages of the dissection. In cases where the vein is so matted to the mass of glands that it cannot be removed without serious damage to its walls, a double ligature must be placed on the vein below the mass, and the vessel must be divided in this position. The lower end is allowed to drop back into the wound, but the upper end, together with the mass of glands, is dissected up until the mastoid process is reached. Another ligature is now placed on the extreme upper part of the vein, and the vein and glands removed *en masse* below this ligature. Although no serious consequences arise from ligature or removal of the vein, it must be preserved if possible.

Wounds in the upper part of the vein require further mention. Lying deeply beneath the mastoid process and in relation to the tonsillar gland, an injury to it is of more serious consequence here than lower down. The sudden flooding of the wound with a quantity of blood is sufficiently alarming, and added to this there is the difficulty that will be experienced in applying forceps or a ligature. Should this accident occur, the wounded vein must be immediately plugged with the finger or with gauze packing, and all excess of blood must be mopped up; then a pair of large artery forceps must be passed along the controlling finger and an attempt must be made to grasp the opening. Sometimes this results in an increase in the rent, and if this be the case, or if it be found impossible to apply a ligature, gauze plugging must be carefully packed on to

the vein, in an upward direction, so as to control the supply of blood coming from the cranial cavity.

Although bleeding furiously and alarmingly when injured, the internal jugular is a cowardly vein, and bleeding can at once be arrested by judicious plugging. The plugging should be changed in forty-eight hours, a smaller strip being inserted; but if the removal causes fresh bleeding, a strip similar in size to the original must be used.

Another accident which may result from injury to the internal jugular is the entry of air into the veins. Fortunately this is of very rare occurrence, and can be prevented by prompt treatment of the wounded vessel.

3. *Injury to the Facial Nerve* or its main trunks is most unlikely to occur, since the nerve lies so deeply in the parotid; one branch, however, may be damaged: this is the "ramus anastomoticus," the lowest branch of the cervico-facial division, which runs below the body of the lower jaw to innervate the platysma and the risorius, and to communicate with the transverse cervical nerve in the neck. If the curved incision be made too near the mandibular margin, this nerve is divided, and some weakness of the angle of the mouth will result. The skin incision should lie at least one inch from the lower border of the jaw.

4. *The Position of the large Lymphatic Trunks* in the lower part of the neck must be remembered. They are most likely to be injured when the dissection is being carried out over the lower part of the scalenus anticus muscle. The thoracic duct looks like a vein, so great care must be taken of all deep veins in this region. Should it be injured, an attempt may be made to suture it.

After the dissection has been completed, and all vessels have been secured, the wound is closed. It is advisable to employ separate sutures of catgut to bring the edges of the incision in the deep fascia together. A drainage tube should be employed for twenty-four to forty-eight hours.

After-treatment consists in keeping the patient absolutely still in bed until primary union has occurred (for ten to twelve days). Sand-bags should be placed on either side of the head, or better still, a poroplastic splint should be fitted on over the dressings.

The treatment of cases which fall under the third group is conducted on the same main lines. In most instances, owing to the firm matting of the glands to the surrounding tissues by the peri-adenitis, it will be inadvisable to attempt more than the extirpation of the central caseous areas, after the manner previously described. Occasionally some radical operation may be indicated, but this must be left to the discretion of the surgeon.

The keloid form of scar which often develops at the site of a tuberculous sinus, or in the line of an incision for the removal of these glands, will be found to yield rapidly to the influence of tuberculin.

Vaccine Treatment.—No account of the treatment of a tuberculous lesion would be complete without reference to the tuberculin treatment introduced by Sir A. E. Wright. Undoubtedly it is of benefit, and in many cases produces marked amelioration, even subsidence, of the glandular swellings, but whether it is destined to remove these cases from the hands of the surgeon entirely is a matter of doubt, at least for the surgeon. Owing to the fact that in most cases the infection is mixed, the tuberculin treatment will fail to bring about complete resolution, and although it is possible to vaccinate successfully against many other organisms, the infecting agent in these cases cannot always be cultivated, as has already been pointed out. Again, it is generally conceded that when softening and suppuration have occurred, the vaccine treatment will be unsuccessful.

On the whole, the position at present with regard to the vaccine treatment

is this: as a preliminary to surgical treatment it should, when possible, be employed. If the case fails to benefit from it, or if caseation and softening of the glands occur, one of the operations described above is to be recommended.

TUMOURS, INTRACRANIAL.—(See INTRACRANIAL TUMOURS.)

TUMOURS OF THE JAWS.—(See JAWS, TUMOURS OF.)

TUMOURS, SPINAL.—(See SPINAL TUMOURS.)

TURBINATES, HYPERTROPHY OF.—(See RHINITIS.)

TYPHLITIS.—(See APPENDICITIS.)

TYPHOID FEVER.—(See also SPECIFIC THERAPY.) In most cases of typhoid, the diet and treatment of pyrexia will be the same as those given under FEVERS, ACUTE INFECTIOUS. But in consequence of the ulceration of the bowel which doubtless occurs in most cases, and may be slow to heal, it is advisable to be cautious during the early convalescence as well as during the acute stage of the disease. Still, caution should not be carried to the extreme of confining the patient to a purely milk diet (see the article on FEVERS, p. 358). There can be but little doubt that in the past the intestinal ulceration has, in respect of the diet, been held in too great dread. Following Coleman the writer is now in the habit of feeding typhoid patients liberally. When the patient comes under treatment, he is placed on milk (three pints) for twenty-four hours. Then, beginning with cream and lactose, various articles are added to the diet till by the end of seven to ten days the following daily menu is reached: milk, 2 pints; cream, 1 pint; lactose, 3½ oz.; coffee, 1 oz.; tea, ½ oz.; bread, 3 oz.; butter, 1 oz.; eggs, 3 (raw, or lightly boiled); custard, 4 oz.; rice, 3 oz.; mashed potatoes, ½ oz.; apple sauce, 1 oz. On this diet he is kept until the temperature begins to stay near normal and he feels hungry; then a little boiled fish is substituted for some of the cream; and gradually the patient is got back on to his normal diet.

The patient's condition must be carefully watched, and it may be necessary to alter or reduce the diet considerably in certain cases and under certain conditions (diarrhœa, vomiting, etc.).

Purges should be avoided, except during the first three or four days of the illness, when a moderate dose of calomel or castor oil may be given. At a later date it is dangerous to set up anything like vigorous peristaltic action of the bowel. If there is constipation during the febrile stage, and especially if, as is frequently the case during convalescence, the stools are hard, an ounce of the following mixture three or four times a day will be found very useful;* it serves to keep the motions soft, and so prevent straining:—

℞ Olei Olivæ	℥x	Sodii Bicarbonatis	gr v
Liquoris Potassii	℥j	Aquæ Destillatæ	q.s. ad ℥xij
Saccharini	gr ij		

An occasional soap and water enema may be necessary in addition. Unless a very experienced nurse is in attendance, the physician should inspect the patient's stools daily, otherwise some of the conditions to be mentioned may be overlooked. If there is diarrhœa, that is, if there are more than five or six stools in twenty-four hours, the ordinary milk and water should be replaced by whey or peptonized milk.† The same diet should be adopted if, with only two or three loose stools daily, the milk is not being digested. If the diarrhœa is very frequent or offensive, some antiseptic should be given, such as perchloride of mercury ⅓ to ⅒ gr., resorcin 3 to 10 gr., or carbolic acid 1 to 3 min., or quinine and

* A daily enema obviates the necessity of using laxatives.—AMERICAN EDITOR.

† Altering the proportions of fat and carbohydrate is often all that is required to control diarrhœa.—AMERICAN EDITOR.

chlorine mixture.* Turpentine is useful when the diarrhoea is accompanied by tympanites. If there is abdominal pain, 6 to 10 min. of laudanum every three or four hours, with hot fomentations to the abdomen, will usually give relief.† Troublesome vomiting is occasionally met with. This is best treated by omitting everything by mouth, except a little water, for twelve hours, and then letting the patient have whey or peptonized milk.

All the antipyretic measures mentioned in the general article, FEVERS, ACUTE INFECTIOUS, may be employed in typhoid fever; but children and old people do not bear cold packs or baths well, and baths are contra-indicated when there is peritonitis or hæmorrhage. Baths, cold or warm, may safely be given during menstruation.

Tympanites.—Ice, or a Leiter's coil with iced water, should be applied to the abdomen. Turpentine may be given internally in 5 to 10-min. doses every four hours; or 2½ to 5 min. of the essential oil of cinnamon of the best quality, every two hours. But both these drugs may cause unpleasant symptoms if pushed.

Hæmorrhage.—The writer has tried various drugs, including acetate of lead, turpentine, and epinephrin; but after considerable experience he believes that subcutaneous injections of morphia and ergotine, with ice, or a Leiter's coil with iced water, to the abdomen, and iced-water injections into the rectum,‡ are the best remedies.

Should much collapse follow severe hæmorrhage, subcutaneous injections of two pints or more of sterilized salt solution (1 dr. of sodium chloride to a pint) should be given. The patient's extremities should be wrapped in wool.

Perforation.—The symptoms of perforation are: (1) Sudden abdominal pain, very often, but not always, severe. The pain may be referred to a particular region, especially the right iliac, but not infrequently the patient declares that it is "all over the stomach"; (2) Pain, in many cases exquisite, on palpating, even gently, one or another region of the abdomen; in most cases it is the right iliac region. In a few cases pain can be elicited only by rectal palpation; (3) Rigidity of the abdominal muscles, especially over the affected viscus, and therefore mostly those of the right iliac region. This is usually accompanied by (4) Immobility of abdominal muscles in respiration.

The presence of these four symptoms justifies the diagnosis of perforation, but not one of them may be marked, even though perforation has occurred. Therefore other symptoms are of importance. They are: (5) A rigor, at the time or soon after the occurrence of sudden pain; (6) Alteration in the condition of the abdomen, usually in the direction of distention, though sometimes it becomes retracted. It is most important that the physician should inspect the abdomen daily, in order that he may be able to detect slight sudden changes in its appearance; (7) Increase in the pulse-rate; (8) A rise, much less frequently a fall, of temperature; (9) Vomiting, not usually frequent; (10) An anxious appearance of countenance; (11) Collapse.

It should be remembered that the symptoms of perforation may occur and persist for an hour or two, then completely pass off; so that it may be thought that after all the accident has not taken place. In such cases the symptoms are not as a rule severe. Later, the signs of peritonitis set in; abdominal pain, distention, rigidity, repeated vomiting, a frequent thready pulse, an anxious and pinched face. The obliteration of the liver dulness may mean the presence of free gas in the peritoneal cavity; a condition which is not usually

* Forty minims of strong hydrochloric acid are poured on 30 gr. of powdered chloride of potassium in a 12-oz. bottle, which is filled up gradually with water, the mixture being frequently shaken while the water is being added, so as to absorb the gas as it is evolved. To the solution when made, 21 gr. sulphate of quinine are added. An ounce should be given every 3 or 4 hours.

† Care must be taken not to mask symptoms of perforation. —AMERICAN EDITOR.

‡ Iced water injections, it is believed, will cause undesirable peristalsis. —AMERICAN EDITOR.

found till some hours after perforation has occurred. Directly the diagnosis of perforation is made, laparotomy should be performed, unless the patient is in too collapsed a condition to stand the operation, which must in that case be put off till he rallies. The writer has operated on several cases, and believes the following remarks may be useful to other practitioners :

As time is of great importance, everything should be ready. This can easily be ensured in a hospital. In private practice Dr. Hector Mackenzie's suggestion is a good one, that the medical attendant shall have made an arrangement whereby he can secure the attendance of a surgeon ready to operate at the shortest notice.

Generally the most useful incision is one in the right iliac region (through the linea s. milunaris if it can be hit off readily) ; but if there is any reason to suspect that the perforation is not in the lower portion of the small intestine, then the incision should be in the middle line below the umbilicus.

If the perforation is not seen at once upon opening the peritoneal cavity, find the ileo-cæcal valve and examine the small intestine from the valve upwards. If no perforation is found, examine the cæcum and vermiform appendix, and then the sigmoid flexure and the rest of the large intestine. Remember, too, that the symptoms of intestinal perforation may be caused by perforation of the gall-bladder, and by the rupture of a suppurating mesenteric gland, or splenic infarct ; though these last three lesions are, fortunately, very rare. In some cases, too, where perforation has been diagnosed, peritonitis only has been found on operation, and even, in a few unusual cases, nothing abnormal within the abdomen. Having found the perforation, clear away any faecal exudation, and invaginate the perforation with five or six Lembert's sutures of the finest silk, using an ordinary sewing-needle. The row of sutures should be placed longitudinally. Having inserted the sutures, make certain that none of the contents of the bowel can escape. It is well, before putting in the sutures, to pack round the coil of bowel concerned with sterilized gauze, so that if, during the insertion of the sutures, any faecal matter is accidentally evacuated, it will not escape into the peritoneal cavity. An assistant must hold the portion of bowel that is being dealt with.

Unless the whole, or nearly the whole, of the peritoneum has become inflamed, and the inflammation is purulent or offensive, the writer believes that it is best not to flush out the peritoneal cavity. It should be swabbed as clean and dry as possible with pledgets of sterilized gauze. Except in cases where the peritonitis is quite localized, one or two cigarette drains should be put in the pelvis, and a small cigarette drain or a strip of gauze to the sutured ulcer.

In the few cases where the perforation is too large, or the ulcer too extensive or thickened, to permit invagination, the affected piece of bowel should be brought to the abdominal wound, and secured there in the hope of dealing with it later.

As it is necessary to get through the operation as quickly as possible, the abdominal wall should be sewn up with gut sutures passed through all the layers.

Immediately after the operation the patient should be put to bed in as upright a position as possible, and in this position he should remain for at least four days. Meanwhile continuous rectal injection of warm normal saline solution should be carried out, 2 to 6 litres (70 to 210 ounces) a day by means of an apparatus for the purpose, used in connection with a "Thermos" flask. Strong black coffee (14 ounces to 21 of salt solution) should be given per rectum, if stimulation be required, for ten or twelve hours continuously. At first the patient should be allowed only small quantities of fluid by the mouth, but the amount may be quickly increased to the full liquid diet.

In cases of suspected perforation, opium or morphia should not be given

until it is definitely decided whether an operation is to be performed or not. As a rule, while doubt still exists, the pain is not severe and may be relieved by hot fomentations. Opium masks the symptoms and renders diagnosis more difficult; but when a decision is arrived at, whether for or against, a subcutaneous injection of morphia should be given.

Cystitis.—For this the best treatment is hexamethylenamine, 10 gr. three times a day. In any case of typhoid fever where the catheter has to be used, it is advisable to give hexamethylenamine to prevent cystitis. Hexamethylenamine acts best when the cystitis is due to the *Bacillus typhosus*. In the ordinary form of cystitis, with ammoniacal urine, the usual treatment should be adopted.

Thrombosis, usually of the veins of the lower extremities, especially of the left, must be treated by keeping the limb raised and bandaged (from the foot upwards). If the thrombosed vessel is painful, glycerin and belladonna, equal parts, should be smeared over the affected region. Citrate of sodium should be given in 10-gr. doses three times a day.

Serum and Vaccine Treatment.—During the last few years a few cases have been treated with the serum of horses immunized against the typhoid bacillus, apparently with some success. The amount given has been from 20 to 200 c.c., spread over several days. The vaccine used for prophylactic inoculation has also been employed therapeutically in persons suffering from typhoid fever. But neither the serum nor the vaccine has in the hands of English observers led to the remarkable results claimed by Chantemesse, of Paris, for the serum prepared by himself; this, unfortunately, is not to be obtained in this country.

Quarantine period: three weeks, but it is seldom necessary to enforce it.

E. W. Goodall.

TYPHUS FEVER.—It is most essential that abundance of fresh air should be allowed to circulate freely round the patient. If this condition be fulfilled, not only will the disease progress more favourably than if there is a want of ventilation, but those in attendance upon the patient will be less likely to catch the infection.

For the most part the general directions as to treatment given in the article **FEVERS, ACUTE INFECTIOUS**, and **TYPHOID FEVER**, will apply to typhus. But it is not necessary to be quite so careful about the diet in typhus as in typhoid fever.

Hypostatic pneumonia is common during the second week; to avoid it, the patient should not be allowed to be too long in one position.

During the end of the first and the beginning of the second week of the disease, the delirious patient requires constant watching; he may be noisy and even maniacal, and will have to be prevented from getting out of bed. A patient may have strong delusions, on which he may act, without being delirious.

Stimulation is frequently called for towards the end of the second week.

In severe attacks, the patient should not be allowed to sit up, even in bed, too soon after the crisis, for muscular and cardiac weakness are usually pronounced. Moreover, complications, especially affecting the lungs, may arise during the early days of convalescence.

The patient may be considered to be free from infection four weeks from the beginning of the illness.

Quarantine period: three weeks.

E. W. Goodall.

ULCERS.

GENERAL TREATMENT.—Ulcers are wounds which are slow in healing, as the result of either constitutional disorders—diabetes, albuminuria, anæmia, etc.—or of imperfect local treatment. The first essential in the treatment is to deal

with the constitutional disease as far as possible, so that the tissues may the better respond to local surgical measures. When grave constitutional disturbance is present, no active operative treatment should be undertaken.

Local Treatment will consist in encouraging a healthy reaction, so that fresh, active granulations may form which can be covered either by the natural growth of the epithelium at the periphery, or by skin grafts transplanted on to the surface. When once an ulcer has become healthy, and shows signs of active healing, all that is necessary is to protect the part from undue pressure or irritation, and to facilitate the growth of epithelium. For this purpose nothing is better than strips of green protective, perforated to allow the discharge from the granulating surface to escape, the whole area being subsequently covered by an antiseptic gauze dressing. The gentle pressure of the protective keeps the granulations flat and allows the epithelium to grow unchecked and uninjured over the surface of the ulcer. The limb should, when possible, be kept at rest until healing has taken place. In any case of ulcer, the venous return from the parts should be assisted as much as possible, either by the position of the limb, or by firmly bandaging from its extremity to a point well above the situation of the lesions. Certain kinds of ulcers, however, will require special treatment.

The Inflamed Ulcer is one in which an active infective process is at work, causing increasing destruction of the tissue, and acute inflammatory phenomena. It arises in old neglected ulcers which have been contaminated by dirty dressings. The patient should go to bed, and the leg should be elevated and dressed with moist antiseptic gauze or carbolic acid fomentations. If the surface is not a large one, it should be painted with a solution of strong carbolic acid. A careful watch must be kept for a spreading cellulitis.

The Callous Ulcer is one the edges of which are everted and indurated, and the base covered with small unhealthy granulations. There is usually a considerable amount of matting together of the surrounding tissues, and sometimes in long-standing cases the ulcer is adherent to the bone. In order to procure healing, it will be necessary to stimulate the callous surface, either by applying blisters to the edges and margins of the ulcer, or by scraping away the everted, indurated margin. In addition, it is often advisable to incise the tissues deeply, about one inch from the margin of the sore, so that contraction may take place. If such ulcers are thoroughly scraped, and carefully dressed, or if the limb be kept at rest and elevated, they will soon become healthy. Skin-grafting may be required in the later stages. Calcium iodide in 3-gr. doses thrice daily has been stated to give marvellous results in cases of chronic ulcer. It may be used in conjunction with any of the above methods of treatment.

The Anæmic Ulcer is a weak, avascular condition which occurs in anæmic women. There is no thickening as in the callous variety, but there is no attempt at healing. The administration of iron by the mouth, and the application of stimulating dressings—*lotio rubra*, Unna's plaster, or Friar's balsam—will give satisfactory results.

The Irritable Ulcer is a painful condition due to the exposure of an inflamed nerve filament in the base of the ulcer. The point of tenderness should be accurately localized, and the nerve fibres divided a little distance above the ulcer or the tender point. Subsequently the ordinary treatment should be undertaken.

The Varicose Ulcer is the common variety seen in the out-patient department. It is very difficult to treat unless the patient will consent to remain in bed. If the so-called ambulatory treatment be adopted, a certain number will heal slowly. This consists in "strapping" the ulcer with Unna's gelatin

bandage, which supports the limb and prevents it swelling. The objection to this treatment is that the dressing has to be frequently renewed when the discharge is copious. Another method is to encourage a healthy reaction by stimulating lotions or ointments—the cyanide of mercury ointment is an excellent application—and to bandage the limb from below upwards with a crêpe Velpeau bandage: this should be put on first thing in the morning before the foot begins to swell, and the patient should walk or stand as little as possible. In some cases benefit will result from excision of the dilated veins.

Varicose ulcers are liable to bleed when the destructive process has attacked one of the dilated veins. Properly treated this is not a serious matter, but neglect or carelessness may lead to fatal results. A firm, antiseptic dressing should be applied over the bleeding ulcer, and the limb should be carefully bandaged from below upwards. The patient should be confined to bed until the ulcer shows signs of healing, and the limb should be elevated above the level of the trunk.

The Perforating Ulcer is a destructive condition of the tissues arising from suppurating in a bursa beneath a callosity or corn. The suppurating tracks into the joints and may burrow for a considerable distance into the sole of the foot. It is usually associated with tabes dorsalis, but occurs in other conditions. The ulcer should first be cleaned by moist, antiseptic dressings, fomentations, or baths, and all the thickened epidermis should be cut away. If the sinus is unhealthy it should be scraped. The cavity should be plugged with gauze soaked in lotio rubra or Friar's balsam, and the track should be allowed to close from the bottom. During treatment the patient should not walk on the affected foot.

The Phagedænic Ulcer is an acute destructive process, occurring in alcoholics or diabetic patients. It may or may not be associated with syphilis. In appearance the ulcer resembles the inflamed variety, but the process is more acute, the tissue destruction and sloughing are more extensive, and the constitutional symptoms are more severe. The ulcer should be cleaned with peroxide of hydrogen, all sloughs should be cut away, and the surface may be swabbed over with strong carbolic acid. After this preliminary treatment the limb should be placed in a bath, or constant irrigation should be employed. Stimulants and tonics will be required, and the general treatment should be as in cellulitis (see ERYSIPELAS). In the later stages of healing, care must be taken that undue contraction does not interfere with the function of the limb (see also BURNS). Exuberant granulations should be touched with silver nitrate.

Among recent applications for chronic ulcers should be mentioned scarlet red ointment, decoction of comfrey, and horse serum. The first two are cell-proliferants, stimulating epithelial growth, and are certainly of value; the third method is still on trial.

The method of exposing ulcers to a current of oxygen has given very satisfactory results, and is to be recommended. The gas is allowed to play on the surface of the ulcer for periods varying from ten to twenty minutes, after which a dressing is applied in the ordinary way. W. H. Clayton-Greene.

UNDULANT FEVER.—In the majority of cases the disease is acquired from drinking goats' milk, as many goats are infected with the *M. melitensis*. For prophylaxis, in any place where undulant fever occurs, all milk used must be well boiled, or—and better—tinned milk only should be used. Treatment here is essentially symptomatic. Quinine, salicylates, and antipyretics are often used, but have no action beyond temporary relief of the symptoms in some instances, and as the disease runs a most protracted course, the use of

such drugs cannot be persisted in. Vaccine treatment has given varied results, but in some (mild) cases has been beneficial.

Diet must be light and nutritious; solid food often appears to cause or precipitate a relapse. Constipation has a similar effect.

The temperature is best reduced by local applications, sponging, etc., and, if hyperpyrexia threaten, by the use of cold baths. The joint affections may be relieved by local applications. The occasional use of hypnotics may be necessary.

C. W. Daniels.

URÆMIA, RENAL TOXÆMIA (Acute and Chronic).—(See also COMA; and NEPHRITIS, CHRONIC.) Uræmia is commonly described as occurring in two forms. In the one the symptoms are of acute onset, of great severity, and of grave prognostic significance. In the other they are of gradual onset, of less apparent severity, and of very indefinite character. They are often called, respectively, acute and chronic uræmia. The two groups stand in such strong clinical contrast to each other that it would be well if different names were employed to designate them. For the acute cases, "acute uræmia" might be retained; for the chronic, "chronic renal toxæmia" might be a better term.

By **Chronic Uræmia**, or **Chronic Renal Toxæmia**, is meant that gradual failure of health and nutrition, with the various and often indefinite symptoms, which is met with especially in the later stages of granular kidney, but in some degree also in the later stages of chronic parenchymatous nephritis. The condition has already been dealt with and its treatment discussed in the article on NEPHRITIS, CHRONIC.

Acute Uræmia.—From both the above conditions acute uræmia is clinically distinct. The great characteristic is the suddenness with which the symptoms arise. Without any warning the patient is seized with twitchings, which rapidly develop into violent epileptiform convulsions. The patient becomes unconscious, and dies within a few hours unless the fits cease.

If acute uræmia threaten, still more if it have already developed, active measures are imperative.

The patient should be put into a *hot bath*, or, if too ill for this, should have a *rapour* or *hot-air bath*, or be *packed*. At the same time *diaphoretic remedies* should be given; but if the symptoms are very urgent, *nitrate of pilocarpine* should be administered by subcutaneous injection; $\frac{1}{6}$ -gr. dose is sufficient at a time, repeated as required at intervals of an hour. Some brandy or gin and citrated caffeine may be given to obviate any depression which might be produced by the drug, though these doses are, as a rule, borne without detriment.

The bowels should be relieved by some rapidly acting purge, of which *elaterium* is the best, in the form of the pulv. elaterini co. (B.P. 1898), 1 to 4 gr., aided, if necessary, by an enema.

If the tension be high, *nitroglycerin* or the *nitrites* might be given, but this is best reduced by the other measures employed. If the fits are very severe, a whiff or two of *chloroform* has been advocated, but it should not be used unless it cannot be avoided. The *bromides* and *chloral* are too slow in their action, and are fitted rather for restlessness and sleeplessness, for which *morphine* also may be given, and without the risks formerly attributed to it.

Should the fits persist, the question of *bleeding* will arise, with the object of removing the poison. To do any good the bleeding must be free, and many ounces of blood removed. This is in many cases followed by immediate improvement; but the loss of so much blood necessarily leaves the patient very feeble, and where asthenia has been a prominent feature of the case, it is obviously to be used only as a last resource.

With the two objects of diluting the poison and promoting its elimination,

hypodermoclysis has been employed, that is, considerable quantities of water or weak saline solution have been injected sub cutem. This is a measure which is impossible with acute or chronic parenchymatous nephritis, where the patients are œdematous, but is not irrational in cases of granular kidney, where there is little or no œdema.

Another method recently advocated is *lumbar puncture*, or *lumbar drainage*. Improvement has been said to follow this operation in certain cases.

The continuous *inhalation of oxygen* for some hours seems on the whole, in these urgent cases, to yield the best results. Under its influence the intolerable restlessness often subsides, and the patient falls asleep; and even the fits seem to be reduced in severity. Its administration must be persisted in continuously or almost continuously for some hours. To give it for ten or fifteen minutes only every hour or so is practically useless. The inhalation of oxygen has this further advantage, that it can be combined with any of the other methods of treatment.

Whatever form acute uræmia may take, the prognosis is grave. If any one of the forms has a less serious significance than another, it is, strange as it may seem, that in which epileptiform convulsions occur.

Samuel West.

URETHRA, RUPTURE OF.—Rupture of the urethra may occur with laceration of other viscera in severe injuries of the pelvis, or it may be the solitary lesion produced by violence applied to the perineum. Only the latter class need be considered here. Laceration of the urethra may be produced by the unskilful passage of instruments (see URETHRAL STRICTURE), or by injury from without, such as falls astride a beam, or kicks or blows on the perineum.

The history of an injury to the perineum should always be the signal for a careful examination of the urethra, whether signs of laceration to this tube be present or not. The signs of rupture of the urethra are the appearance of blood at the meatus apart from micturition, and the presence of a tender swelling at the injured area. Retention of urine frequently accompanies these signs.

A patient seen after such an accident before he has attempted micturition, should be prevented from passing urine, and an immediate attempt made by catheter to ascertain the extent of the injury to the urethra. With the utmost gentleness a large-sized metal catheter is passed down to the point of injury, and it should be guided along the roof of the canal, for this is the portion of the urethral wall that is most likely to escape injury. If on gentle manipulation the catheter passes onwards smoothly, and the position of the instrument, the freedom of its beak, and the flow of urine show that it has entered the bladder, the laceration has affected only part of the wall of the urethra.

If the rupture is situated in the penile urethra, a silk-wove or rubber catheter should be fixed in position and retained for three or four days, the urethra being washed alongside it daily. The passage of metal instruments should be commenced in a fortnight, and continued regularly to prevent the development of a stricture.

If the rupture is in the bulbous urethra, or behind this, an operation should be performed as soon as possible. If the catheter has been successfully passed, it is retained until the operation can be carried out. If the catheter cannot be passed, the urethra is probably completely severed, and no prolonged attempt to enter the bladder should be made. If the bladder is distended, and immediate operation is impracticable, the urine should be withdrawn by suprapubic puncture, rather than allow it to be passed into the perineal tissues by attempts at micturition.

At the operation the patient is placed in the lithotomy position and the perineal hæmatoma incised. If the rupture lies in the bulbous urethra, a median incision should be made, but if the rupture is situated deeply in the membranous urethra, a curved transverse prerectal incision will give the best exposure. The clots are turned out and a stream of hot lotion from an irrigator is directed into the wound to stop oozing. If the urethra has not been completely severed there is no difficulty in finding the torn edges, and a catheter is passed along the penile urethra and guided into the bladder. The edges of the ruptured urethra are trimmed and united as accurately as possible with catgut sutures. The bladder is now distended with fluid through the catheter, and the patient placed in the horizontal position. The bladder is opened above the pubes, and a large rubber drain introduced. The catheter is now removed and the perineal wound closed round a rubber drain.

If the urethra has been completely severed, a search is made for the vesical end, which may be found as a loose shred of tissue, or may resemble the twisted end of a large blood-vessel, or may be identified by the persistent bleeding of a small vessel in its wall; suprapubic pressure may cause some urine to trickle from the urethral stump. If the search is successful, the ends are united with catgut sutures over a gum-elastic catheter and the perineum sutured in layers. Suprapubic drainage is then established.

Should the search for the vesical end of the urethra prove fruitless, suprapubic cystotomy should be performed and a bougie passed along the urethra. The vesical end is identified, and the operation completed as before.

Should the patient have already attempted micturition, and catheterization have failed, the position is less favourable for the discovery and union of the separated ends of the urethra. In such a case the search may prove unavailing, and the practitioner will have to content himself with free incision of the swollen tissues, and the insertion of large drainage tubes.

The patient should be supported by stimulants, such as alcohol by the mouth, and strychnine subcutaneously. Urinary antiseptics, such as hexamethylenamine (10 gr.) and boracic acid (15 gr.) should be given after the operation.

Suppression of urine occurs in some cases, and is treated in the same manner as when due to other causes (see URINE, SUPPRESSION OF).

The patient should be warned of the stricture which will inevitably follow the lesion, and the passage of instruments should be commenced a few weeks after the rupture.

J. W. Thomson Walker.

URETHRAL CARUNCLE.—If the treatment of a urethral caruncle is not thorough, the condition is almost certain to recur. Cauterization without an anæsthetic is useless, as it cannot be done efficiently. Removal of only the growth itself, by either knife or cautery, is insufficient treatment. A small portion of the posterior wall of the urethra, to which the base of the caruncle is attached, must be removed as well, otherwise the caruncle will probably recur. The growth should be dealt with by a wedge-shaped incision which removes the whole of its base, the resulting wound being closed by the insertion of two or three catgut sutures. If there is free bleeding, the sutures may be inserted on one side of the incision before the cut is made on the other side; then the suture can be completed after removal of the growth without the fear of landmarks being obscured. While the sutures are being inserted and tied, it is well to place a catheter in position, lest the urethral orifice should be too much narrowed. If the cautery is used, instead of scalpel and sutures, care must be taken that none of the tissue round the meatus is burnt; otherwise the patient may complain of pain for several days. After suture there is usually very little, if any, pain.

H. Russell Andrews.

URETHRAL STRICTURE.—(1) A diagnosis of stricture having been made, the treatment consists in dilatation by means of instruments. (2) Certain complications may arise during this treatment which require special consideration. (3) Some cases of stricture are not suitable for dilatation, and a cutting operation is required.

1. Treatment of Stricture by Dilatation.—Metal bougies or flexible bougies of silk or cotton web coated with certain preparations are used.

Metal instruments may have a conical or, better, a bulbous end. The graduation varies slightly with the individual instrument-maker, and the instruments bear two numbers, which show the size at the tip and at the thickest portion of the shaft. Metal instruments have the following advantages: they withstand boiling, and last for many years; they have a smooth, highly-polished surface, that is easily kept surgically clean. They are specially useful in certain tortuous strictures, in cartilaginous strictures, and in strictures that have been dilated up to a large size and still require the occasional passage of an instrument. In the lower sizes they readily injure the urethral mucous membrane, and should be handled with the greatest caution. When not in use they should be smeared with vaseline before being laid aside. They should be re-plated on the first sign of cracking or scaling of the nickel.

Gum-elastic instruments or bougies should be pliable and resilient. A good bougie tapers gradually to a bulbous or olivary tip, and presents no abrupt shoulder. The shaft should be stiff, but the half of the instrument next the tip should bend readily to the touch. Whalebone bougies are dangerous instruments and should not be used. Bougies are graduated according to French scale, which indicates the circumference in millimeters, or to an English scale similar to that used for metal instruments.

The French bougies possess the advantage of an exact and constant measure, and they ascend by finer gradations of size (roughly 3F. to 2E.). The finer woven instruments made in England are as well-shaped and durable as the French, but the less expensive bougies are much inferior.

Pliable bougies are not so likely to damage the urethral mucous membrane as metal instruments. They are especially useful in the smaller sizes, and are preferable for the dilatation of most strictures up to 21 or 22F. size. Beyond this size they are stiff and unwieldy, and are better replaced by steel instruments.

The most useful sizes of bougie are from 10 to 16F., but one or two filiform bougies are a necessary part of the surgeon's outfit. The following numbers will be found useful when selecting bougies: two filiform bougies, and numbers 6, 10, 12, 14, 16, 18 and 20 of the French scale.

There are three essentials to the satisfactory passage of an instrument in a case of stricture of the urethra: the instrument must be aseptic, must be well lubricated, and must be used with a gentle hand.

Metal instruments are prepared by boiling for ten or fifteen minutes in a supersaturated solution of ammonium sulphate. Elastic bougies may be plunged into boiling water and then placed in cold carbolic solution, care being taken to remove the carbolic before using the instrument. After use these instruments should be washed in running water, the oil being entirely removed, then be swabbed with a solution of perchloride of mercury or carbolic, and carefully dried. They are kept in a glass tube or an enamelled metal box with a little lycopodium powder.

The efficient oiling of the instrument is of the utmost importance. Olive oil, liquid paraffin (paroleine), liquid vaseline, or one of the following formulæ may be used as a lubricant for urethral instruments:—

R Phenolis	1 part	Olei Amygdalæ	8 parts
Olei Ricini	7 parts		
R Cocainæ Hydrochloridi	gr v	Olei Ricini	
Olei Eucalypti	℥x	Olei Olivæ	āā ʒss
R Hydrargyri Oxyeyanidi	gr iiiss	Tragacanthæ	gr xlvj
Glycerini	ʒvss	Aquæ Dest. Sterilizatæ	q.s. ad ʒiij

A ready method of use is nearly to fill a tall narrow beaker with 5 per cent carbolic solution and pour into it several teaspoonfuls of boiled olive oil or paroleine, which will float to the top. The instrument is placed in the jar while the patient is being prepared, and is lubricated by the floating oil as it is withdrawn.

The third essential is a delicate touch. The want of this accounts for most of the accidents which result from the passage of urethral instruments.

The method of passing instruments is as follows: The surgeon stands upon the left side of the recumbent patient, and handles the instrument with his right hand while he manipulates the penis with his left. In the introduction of a steel instrument, the penis is grasped behind the glans by the thumb and forefinger of the left hand, and the tip of the instrument inserted into the meatus, while the shaft of the instrument lies transversely across the left Scarpa's triangle. The handle of the instrument is now carried gently towards the patient's abdomen and onwards to the middle line, and gradually raised meanwhile, so that the point drops downwards and backwards. During this manœuvre the left forefinger and thumb draw the penis upon the instrument. The handle is lightly held between the right forefinger and thumb, and the slightest hitch receives instant attention. If the instrument is stopped at the stricture, a smaller is tried, until one is found that will pass. As the point passes down to the bulbous urethra, the left hand leaves the penis, and the fingers are used to support the perineum. The point of the instrument passes into the membranous urethra as the handle becomes vertical and swings downwards, and the left forefinger and thumb replace the right, while the handle is gently depressed between the thighs and pushed onwards.

In passing elastic bougies, it must be remembered that the operator has little power for changing the direction of the point of the instrument, and the passage of the bougie into the membranous urethra depends upon its pliability. The penis is grasped behind the glans by the thumb and forefinger of the left hand, and the penis kept on the stretch to render the urethra straight and obliterate the folds in its walls. The bougie is introduced and lightly held by the corresponding digits of the right hand. If the instrument engages in the stricture, it is pushed gently onwards. If the point is arrested, it is withdrawn a little and again pushed on. If the attempt fails, a smaller instrument should be selected, and so on until the size that will pass is reached. If, on the other hand, the bougie first passed lies loose in the stricture, a larger instrument is passed, until the size is reached which is lightly gripped by the stricture. This "fitting" a stricture with an instrument must be distinguished from dilatation of the stricture.

In attempting to pass an instrument through a small stricture, filiform bougies are employed. They should not be resorted to until the operator is satisfied that he is really dealing with a small stricture, for the point of a filiform bougie readily catches in any fold of mucous membrane, and for this reason may fail to pass where a stricture of comparatively wide calibre is present, or where the obstruction is spasmodic in character. If the filiform bougie fails to pass, it is withdrawn and gently advanced again. On further failure, the tip of the instrument is bent to an angle and the bougie again introduced. The face of the stricture is now searched by turning the bougie round and testing the different parts of the circumference. If this manœuvre fail,

it should be repeated with another filiform bougie. A syringeful of oil may be injected into the urethra and the meatus gripped with finger and thumb to retain the oil, while at the same time the searching of the face of the stricture with the filiform bougie is continued. If this is unsuccessful, a number of filiform bougies should be passed into the urethra, and they will engage in any pockets or false passages. By trying each bougie separately, one of them may pass on through the narrow opening.

It is sometimes of assistance to pass a large bougie down to the face of a stricture, and after withdrawing it to pass a filiform. In this way the opening of the stricture may be centred, and obstructing folds of mucous membrane pushed aside. If these attempts fail, and no retention is present, the patient should be replaced in bed and a brisk purge administered. A further trial should be made next day, and will usually be successful. An instrument sometimes passes readily when the patient is under an anæsthetic, when all other methods have failed.

When several strictures are present, a bougie smaller than will fit the anterior strictures will be required to negotiate the second narrowing, for if the instrument accurately fits the first stricture, it can only be pushed straight onwards without in the least altering the direction of the point. A stricture which lies immediately in front of the membranous opening of the urethra will give rise to difficulty in the passage of instruments, for the membranous opening is on the roof of the bulbous urethra, and the bougie impinges upon the floor of the canal, which rises up towards this opening. In these cases it is often necessary to resort to a rigid metal instrument, the point of which is more easily guided into the membranous opening.

Routine Treatment of Stricture.—The majority of strictures of the urethra are amenable to dilatation by instruments. Dilatation is carried out in three ways: (a) As intermittent dilatation; (b) As rapid dilatation; (c) As continuous dilatation.

Intermittent dilatation is the best method of treatment of the majority of strictures, and is carried out in the following manner. The diagnosis of stricture by the passage of a bougie of large size (say No. 20F.) down to the stricture having been made, the next step is to "fit" the stricture with its proper size of bougie. A much smaller instrument is at once tried (say No. 10F.), and if this fails to pass, successively smaller numbers are used, resorting at length, perhaps, to a filiform.

When a bougie that passes is found, it may lie loosely in the stricture, and if so a larger size is passed until the proper size is reached, which passes but can be felt to fit the stricture. This size is noted, no attempt being made to dilate the stricture by passing larger instruments. An interval of four to six days is now allowed, and the size which fitted the stricture is again passed, followed by the next larger size in the scale, and this is repeated after a similar interval. The scale is thus gradually ascended until the size of the stricture has reached 21 or 22F. Above this size the gum-elastic bougies become too rigid and difficult to guide, and steel instruments should be employed.

During the ascent of the scale, the interval between the instrumentation should be extended gradually. At 14F. a week may intervene, at 18F. a fortnight, at 20F. three weeks, and with the larger steel bougies (12-14, 13-15, 14-16) a month should elapse. If all goes well this will be extended to two months, three months, and finally the patient will call once in six months or once a year to have an instrument passed.

No absolute rule can be laid down as to the largest size to which the urethra should be dilated. The natural size of the canal varies in different individuals. If necessary, the meatus should be incised in order to let large-sized bougies

pass. In most individuals the urethra should admit a bougie of 22F. calibre, and it is advisable to dilate a stricture beyond this if possible.

The urethra should be syringed before and after the passage of the bougie with a weak solution of permanganate of zinc (1-5000) or of silver nitrate (1-10,000).

During the dilatation, and especially during the earlier part of the treatment, urinary antiseptics should be administered. Hexamethylenamine (5 gr. thrice daily), hetralin (7 gr.), helmitol (7 gr.), and boric acid (10 gr.), are among the best of these. The following prescription may be found useful:—

R Hexamethylenamine	gr v	Syrupi Aurantii	℥xx
Acidi Borici		Infusi Buchu	q.s. ad ʒj
Ammonii Benzoatis	āā gr x		

To be taken thrice daily.

When the intervals between the passage of instruments is prolonged to a month, the patient may take these medicines for two days before and two days after the operation. A slight gleet often accompanies stricture, and should be treated by the patient using an injection night and morning with a hand syringe. Permanganate of zinc, $\frac{1}{2}$ gr. to the ounce, or sulphocarbolate of zinc in the strength of 1 per cent, is a suitable injection. The dilatation of the stricture will remove the principal cause of the discharge. The time taken for the treatment varies according to the behaviour of the stricture. At the end of three months the patient may be in a position such that a large steel is passed once in two months. It is seldom that a case can be dismissed before the end of six months or a year. Some patients, especially those belonging to the hospital class, are careless and irregular in their attendance, and after a time the stricture gets into a callous condition which is beyond the hope of complete cure.

Strictures which have not become tough and leathery from long duration, irregular treatment, and prolonged irritation from chronic inflammation, will be cured by this means. A few of these relapse after a year or two, and require an instrument at long intervals; hard, tough, leathery strictures of long standing will not be cured by this treatment.

In cases where the patient gives a history of dribbling, where the clothes are saturated and the prepuce sodden with the leakage, the surgeon should at once resort to filiform bougies, for the stricture is of very small calibre. Where a filiform bougie is the largest instrument that will pass, we have to deal with either a very narrow stricture, or a moderate-sized stricture in which congestion or spasm is superadded. After a brisk saline purge and confinement to bed for two days, spasm or congestion will have subsided, and a bougie of moderate size (10 to 12F.) will pass, and intermittent dilatation may be commenced. On the other hand, the stricture may still grasp a filiform bougie, and a choice of the following methods is open: rapid dilatation, continuous dilatation, a further attempt at intermittent dilatation, or a cutting operation. Rapid dilatation is to be condemned: it means rupture of the stricture and a more dense scar at a later date. Continuous dilatation is useful in these cases. The patient is kept in bed, and the filiform bougie which was passed after so much difficulty is fastened in by tying a silk ligature round it and fixing the ends to the sides of the penis by means of strapping. The urine trickles alongside the bougie. After twelve hours a slightly larger instrument can be substituted, and after twenty-four hours a 6 or 7F. can be passed. The continuous dilatation is now abandoned and intermittent dilatation commenced.

It is not always possible to have the patient in bed for the passage of urethral instruments, but it is essential during the earlier operations until the surgeon is familiar with the "temper" of the stricture with which he has to deal.

2. Complications of Dilatation.—When blood appears at the meatus, the mucous lining of the urethra is torn, and a peculiar sensation of fine grating is felt if the point of the instrument tears up the urethral wall and forms a false passage. On the occurrence of such an accident the further passage of instruments must be suspended. The urethra should be washed with a warm boracic or permanganate of zinc solution, to which a little hazeline or the tincture of hamamelis (B.P.) may be added if the oozing is pronounced. Copious bleeding rarely occurs. An ice-bag should be applied to the perineum.

A fortnight should elapse before further attempts are made to pass instruments (see URINE, RETENTION OF). Additional gentleness should be exercised in the first passage of instruments after this accident, and the urethroscope is invaluable in demonstrating the position of the urethral opening and of the false passage. Where a false passage of old standing is known to be present, it may be avoided by passing a fine bougie gently into it and then introducing a second into the urethra alongside the first bougie.

The appearance of a urethral discharge, and of signs of urethro-cystitis, such as frequent and urgent micturition and murky urine, are the result of imperfect asepsis. They are prevented by the sterilization of instruments, of lubricant, and of the hands, and the washing of the penis and urethra before the passage of instruments. Urinary antiseptics (*vide supra*) are also valuable in preventing the occurrence of the infection and in its treatment. An injection with a hand syringe of a solution of permanganate of zinc ($\frac{1}{2}$ gr. to the ounce), or of sulphocarbolate of zinc ($\frac{1}{2}$ per cent), or a copious daily urethral lavage by means of a douche-can and urethral nozzle with permanganate of zinc (1-5000), will quickly cure the urethritis.

A sense of faintness, or actual syncope, may occur during the passage of instruments. For this reason the patient should invariably be in the recumbent position for the operation. The usual remedies for syncope are adopted, and the instrumentation is suspended. On succeeding instrumentations a solution of eucaine (8 per cent) should be injected into the urethra as a precaution against this accident. Cocaine should not be used as a routine measure, for besides the danger of absorption of the drug the surgeon loses a very important guide and check to his manipulation when he abolishes the urethral sensation.

Rigors and catheter fever result from rough handling of instruments, from attempts at rapid dilatation, and from want of asepsis. The measures of precaution against this have been stated above. Some patients are specially sensitive in this respect, and a cutting operation may become necessary.

On the occurrence of a rigor, the patient is put to bed surrounded by hot bottles, and hot drinks, such as tea or hot gin and water, and the following draught, should be administered :—

R. Quininae Sulphatis	gr v	Spiritus Ætheris Nitrosi	℥ x
Hexamethylenamine	gr x	Infusi Buchu	q.s. ad ʒj

A brisk saline purge should be given.

3. Cutting Operations in Stricture.—The patient may desire operation on account of the time taken by dilatation, or the impossibility of carrying out this treatment owing to his residing at a distance from a doctor.

Urethrotomy becomes necessary in strictures where dilatation has failed for the following reasons : (1) The stricture is readily dilated but quickly returns to its previous size (resilient stricture); (2) The stricture is dilated up to a certain size (10 or 12F.), but no further progress can be made (tough, cartilaginous strictures); (3) A rigor, and perhaps partial suppression of urine, follows the most gentle attempts at instrumentation (irritable stricture); (4) Hæmorrhage: a very few strictures bleed at the slightest touch, and are

better cut on this account ; (5) The stricture is very narrow, and a filiform bougie is only passed after much difficulty ; (6) Failure to pass any instrument (impassable stricture).

Strictures complicated in the following manner also require urethrotomy : (7) Complication by some bladder condition which requires investigation or treatment, such as tuberculous disease, stone, chronic cystitis, etc. ; (8) Peri-urethral abscess ; (9) Extravasation of urine ; (10) Fistulæ ; (11) Urethral stone.

Spasmodic Stricture.—The spasm affects the constrictor urethræ, and the obstruction is in the membranous urethra. The obstruction is intermittent ; in an organic stricture it is continuous and increasing if untreated.

In spasmodic stricture a large instrument, if gently handled, will pass on after a slight delay. The use of cocaine (10 or 15 min. of a 2 or 5 per cent solution) is permissible and advantageous if the diagnosis has been clearly established.*

The cause of the urethral spasm must be diligently sought for, as upon it depends the treatment. Causes of reflex irritation, such as anal fissure, inflamed piles, etc., should be treated, when present. Most frequently the spasm results from some urethral irritation, such as subacute inflammation in the prostatic urethra, or a small stone caught in this portion of the urethra in its outward passage. The latter accident will be treated by passing a large steel bougie and pushing the calculus back into the bladder, when it will be dealt with as a bladder stone. Posterior urethritis is treated by the passage of a large metal instrument and the instillation of a few drops of nitrate of silver solution (5 gr. to the ounce) into the prostatic urethra by means of a Guyon's syringe. Two or three instillations at intervals of a week will usually suffice. Retention of urine as a complication of this condition should be treated by a hot sitz-bath and an opiate, and failing these by the passage of a catheter.

Meatal Stricture.—This is best treated by meatotomy. A few drops of solution of novocain (4 per cent) and epinephrin are instilled into the urethra just behind the meatus, and are expressed again after five minutes. A blunt-probed bistoury is introduced into the narrowed meatus with the cutting edge downwards, and the lower lip of the meatus freely incised in the middle line. Free oozing may result, and is controlled by the application of a pledget containing epinephrin solution, and a little pressure. Sounds must be passed after the first three days, as the lips rapidly unite and the outlet may return to its original size.

J. W. Thomson Walker.

URIC ACID GRAVEL.—The guiding principles in the treatment of patients who pass crystals of uric acid or urates in the urine are : (1) To diminish the excretion of uric acid by the kidneys ; and (2) To increase its solubility in the urine.

Diet is of the first importance. The usual advice—to lessen the consumption of red meat—is not really sound. It is often much more important to restrict the intake of sugars, starches, and fats. Especially is this the case in stout patients (see OBESITY). In less well-nourished individuals the diet-plan should be constructed on the same lines as that suitable for gout (q.v.). Alcohol is best avoided altogether if possible, but plenty of pure water should be drunk.

General metabolism should be promoted by regular exercise in the fresh air. In order to maintain the activity of the liver and bowels, small doses of mercury are useful—e.g., $\frac{1}{2}$ to $\frac{1}{15}$ gr. calomel, or $\frac{1}{8}$ gr. blue pill, daily. The natural sulphate waters—e.g., Hunyadi—are very valuable, and a sufficient dose of one of them to produce a free action of the bowels may be taken in a tumblerful of hot water each morning, and continued for weeks if necessary.

The acidity of the urine may be lessened by the use of Vichy or Contrexéville

* Death has followed the use of cocaine in the urethra.—AMERICAN EDITOR.

water, or by the administration of citrate of potash. Care should be taken, however, not to render the urine actually alkaline by these means, as that might lead to a deposition of phosphates.

In many cases great benefit is obtained from a course of treatment at Contrexéville, Wildungen, Vichy, Evian, or Carlsbad, especially if the patient be of the plethoric, free-living type. (See also CALCULUS.) *Robert Hutchison.*

URINE, RETENTION OF.—This results either from a loss of expulsive force of the bladder muscle, or from obstruction at some part of the urethra. The diagnosis must be accurately made before treatment can be undertaken. The surgeon must distinguish between anuria and retention, and between retention due to atony and that due to obstruction.

A patient with anuria refers to previous attacks of renal colic, hæmaturia, or other signs pointing to progressive renal disease, and the cessation of periodic micturition may have immediately followed such an attack. Symptoms of bladder trouble are absent, and have been absent or insignificant during the course of the disease. The patient is in no pain, there is no distention of the bladder, and an instrument passes readily along the urethra into the bladder, but draws no urine.

In retention of urine there is usually a history of gradually increasing difficulty in micturition, the stream has become progressively smaller and more feeble, and there may be some involuntary dribbling of the urine. The bladder is distended, and usually appears as a smooth rounded swelling above the pubes, firm on pressure and dull on percussion. In retention from atony of the bladder muscle, there is no pain and no desire to empty the distended viscus. In obstructive retention, recurrent spasmodic attempts of the bladder to overcome the obstruction usually double the patient up with cramp-like pain. Sometimes a few drops of urine may be squeezed out in one of these attacks. In some patients, however, pain is remarkably absent, and this is especially the case in old men where the obstruction results from enlargement of the prostate. Diagnosis is made by the passage of a large-sized instrument, which enters the bladder easily if the retention be due to atony, but is arrested or retarded if a stricture or other obstruction be present. The absence of obstruction and the discovery of signs of spinal disease clinch the diagnosis.

The following are the chief types of cases that will be met with in practice :—

1. *In Acute Inflammation of the Urethra (Gonorrhœa, etc.)*, every means should be adopted to relieve the retention without passing a catheter. The patient should be placed in a hot bath or made to sit in a hot sitz-bath, and directed to pass his water in it, and a large hot-water injection should be introduced into the rectum. If this fail, a suppository containing extract of belladonna ($\frac{1}{2}$ gr.) and aqueous extract of opium ($\frac{1}{2}$ gr.) should be given. The following have also been recommended; a minim dose of ferric chloride every five minutes, and 15 minims of spirits of nitrous ether in half a glass of water every fifteen minutes. If relief is not obtained in half to three-quarters of an hour, a catheter must be passed and the urine withdrawn. An anæsthetic will usually be necessary, for the urethra is intensely sensitive. The canal must be thoroughly washed with a solution of permanganate of potash (1-5000) or protargol (1-10,000) from a douche-can, allowing the fluid to flow in and out of the canal. A glass nozzle and a bell shield are used, and prevent splashing. To this 10 or 15 min. of novocain solution (4 per cent) may be added, which may suffice to numb the inflamed urethra for the passage of an instrument. A soft rubber catheter, or failing this a metal catheter, is passed very gently and the urine withdrawn. It is advisable to wash out the bladder with the weak permanganate or protargol solution before the catheter is withdrawn. If a morphia and belladonna

suppository has not already been given, one should now be inserted into the rectum, and the patient returned to bed.

If acute prostatitis and a prostatic abscess be present, operation is indicated as soon as possible.

2. *Blocking of the Urethra by Stone, Foreign Bodies, Pedunculated Bladder Growths, Blood-Clot, etc.*—The diagnosis is made by the history, and relief by catheterization should be given without delay.

The filling of the bladder with blood-clot from a sudden copious hæmorrhage in a case of bladder growth will cause retention of urine. The condition is serious on account of the grave danger of septic infection of the clot. Very little time should be spent in attempts to break up the clot with metal catheters and washing, or by means of lithotrite. Suprapubic cystotomy, with washing out of the clot masses and drainage of the bladder with a large rubber drain, is necessary, and should be done by an experienced surgeon.

3. *The Distended Atonic Bladder of Spinal Disease* should be relieved by catheter with the same precautions as are adopted in enlarged prostate. After a few weeks the condition of the bladder improves, so that it regains some of its power, a varying quantity of residual urine persisting, which must be drawn off at regular intervals. Fluid extract of ergot (15 min. thrice daily) is a useful bladder tonic in these cases.

4. *Retention from Reflex Spasm in Diseases of, or after Operation on, the Rectum, Anus, Testicles, etc., and Hysterical Retention.*—In operation cases the catheter is passed without delay, in order to avoid distress. In other cases hot baths and other means (*vide supra*) should be tried before resorting to the catheter. A metal catheter is the best form of instrument in such cases. After relief of the retention, the cause of the spasm should be treated, to prevent recurrence of the symptom.

5. *Retention with Enlarged Prostate.*—The diagnosis is made by the history of the case, the age at which the symptoms commenced, and rectal examination. The preliminary measures detailed above may be tried, but recourse to the catheter will nearly always be necessary. Three points must be insisted upon : (a) The most rigid asepsis ; (b) The delicate handling of instruments ; and (c) All the urine of an over-distended bladder must not be withdrawn at once, or at least must be drawn off very slowly.

a. The catheters, whether gum-elastic or metal, must be boiled, the hands carefully cleansed, the penis washed with antiseptic, and the urethra washed with permanganate solution.

b. The instrument selected should be either gum-elastic or metal. Coudé and bicoudé catheters are useful, and may pass very easily. Where a difficulty is encountered, it may be due to the distorted shape of the prostatic urethra, and the greatest gentleness should be exercised in pushing the instrument onwards. Sometimes the urine does not flow because the catheter has not been pushed sufficiently deeply along the elongated urethra to reach the bladder.

If the coudé and bicoudé instruments fail, a metal instrument may be tried. Special prostatic metal catheters which possess a very long curve are a part of every set of metal catheters. A method that may be adopted where other means have failed is to bend an English gum-elastic catheter containing its stylet into a curve, which commences by dropping downward from the plane of the shaft of the instrument and then forms a complete curve. This may pass, and if not, it has been recommended to pull the stylet out with the catheter in the urethra, so that the beak of the instrument seeks still further forwards and enters the bladder. Failing these manœuvres, it may be necessary to puncture the bladder suprapubically with an aspirator needle (see URETHRAL STRICTURE).

c. Two dangers attend the rapid emptying of an over-distended bladder: hæmorrhage from the vessels of the bladder or kidney, and suppression of urine. The patient must be in bed and in a warm atmosphere. Only 10 or 15 oz. should be drawn off, and an interval of half an hour to an hour should elapse before a similar amount is again withdrawn, and so on until the bladder is empty, the catheter being kept in the urethra meanwhile.

Another method is to withdraw a pint of the urine and introduce in its place half a pint of warm boracic solution, and so on until only boracic solution is left. Or, again, a catheter of very small calibre may be introduced and the urine allowed to dribble slowly away. When the bladder is empty, a few syringefuls of silver nitrate solution (1-15,000) should be injected and allowed to flow away. Stimulants will usually be necessary in these cases. A mixture containing hexamethylenamine 5 gr., strychnine sulphate $\frac{1}{20}$ gr., and infusion of buchu 1 oz., every four hours, combines stimulation with antiseptics. Whisky may be given at regular intervals in feeble patients. The catheter should be tied in, and the patient confined to bed for several days. At the end of this time a decision will have to be made as to whether "catheter life" is to be commenced or an operation performed.

6. *Retention with Stricture.*—A hot sitz-bath and hot rectal injection, followed by a morphia ($\frac{1}{4}$) and belladonna ($\frac{1}{4}$) suppository may be tried, but recourse to instruments will in most cases be necessary. The passage of instruments into narrow strictures has been described elsewhere (see URETHRAL STRICTURE). In cases where a No. 7 or 8 French bougie can be passed, it should be withdrawn and a catheter of this size introduced. Where a filiform bougie only will pass, it should be tied in with a fine piece of silk, the ends of which are carried along the sides of the penis and fixed by means of strapping. The urine trickles past the filiform, and after a few hours the stricture will allow of a larger instrument being passed, and eventually a catheter is introduced.

A more rapid method is to use a special instrument, consisting of a metal catheter with conical end which screws on to a filiform bougie. The bougie acts as a guide, and the catheter is forced through the stricture. Harrison's whip bougies are sometimes useful in these cases. They consist of a long tapering gum-elastic bougie, the end of which is filiform, while the shaft rises to a calibre of 18 or 20F. These may be made with a groove along one side by which the urine trickles away. Catheters of this description may now be obtained, and are a useful means of drawing the urine in a difficult case. Another special instrument is a tunnelled catheter, which can be threaded upon the filiform bougie and pushed through the stricture.

There is less danger in completely emptying a distended bladder in a case of stricture than in enlarged prostate, for the age of the patient is less and the kidneys are usually less extensively diseased. At the same time precautions are necessary to guard against suppression of urine. If instrumentation fails, the bladder should be emptied with an aspirator needle. The most suitable point for the puncture is an inch above the upper margin of the pubic symphysis in the middle line. The percussion note should be dull. The skin is first incised with a sharp scalpel, and then the aspirator needle introduced. The urine will flow from the cannula without a negative pressure being produced.

The dangers connected with suprapubic aspiration of the bladder are puncture of the peritoneum with subsequent peritonitis, leaking of the wound in the bladder, and the formation of prevesical abscess. The peritoneum should not be injured where the bladder is distended and the percussion note dull. The aspirating needle should not be a large one, lest some leakage at the point of puncture take place. A prevesical abscess may result from a septic needle or from a leakage of septic urine.

Usually, after a single aspiration an instrument can be introduced through the stricture and tied in, but rarely the puncture must be repeated several times. In all these cases urinary antiseptics (hexamethylenamine 5 gr., boric acid 10 gr., ammon. benzoat. 10 gr., syr. aurant. $\frac{1}{2}$ oz., infus. buchu 1 oz.) should be administered. (For *Nervous Retention*, see ENURESIS.) *J. W. Thomson Walker.*

URINE, SUPPRESSION OF.—This may occur as an accidental complication of surgical disorders, and requires prompt and energetic treatment; or it may represent the last phase of a progressive incurable disease such as cancer of the bladder or uterus, and, as such, treatment is unavailing.

The surgical forms of anuria that call for treatment are calculous anuria, post-operative anuria, infective anuria, and hysterical anuria. The latter is included, as it may complicate surgical operations. Calculous anuria may be due to the blocking of one ureter with a stone where the other ureter is free. The suppression of the urinary flow during an attack of renal colic may continue for some hours and pass off with the subsidence of the pain. If it be continued for a longer time it is likely that the other kidney has already been destroyed by calculous disease, and surgical interference becomes urgently necessary. This form of suppression (obstructive) is at first unaccompanied by symptoms of uræmia. The operative measures consist in exploring the kidney and ureter of the side at which pain was most recently felt. The earlier such cases are submitted to a surgeon the better will be the prognosis. About 50 per cent may be saved by prompt operative interference.

Post-operative anuria may be met with in any form of surgical interference with the urethra, the bladder, or the kidney. The practitioner is most likely to meet with it after the use of instruments for dilatation of stricture of the urethra, or after the passage of a catheter in a case of enlarged prostate with retention of urine. Some hours after the passage of instruments, often after the first passage of urine, the patient has a rigor, the temperature rises to 102° or 103°, the urine rapidly diminishes, the secretion ceases, and the patient becomes restless, delirious, and finally dies comatose.

The prophylaxis of this very fatal complication has been described under URETHRAL STRICTURE. It is summed up in the following: avoidance of traumatism in passing instruments, asepsis, protection against chills, and administration of urinary antiseptics during the treatment of stricture.

When suppression sets in there are three objects to be aimed at: (1) To re-establish the flow of urine; (2) To remove toxic bodies from the circulation; (3) To maintain the strength of the patient.

Diuretic drugs should be given, e.g., citrate of potash 7 to 10 gr., spiritus ætheris nitrosi 10 to 20 min., infusion of buchu or infusion of scoparius (10 per cent) 1 to 2 oz., every four hours. The rectum should be washed out and a large saline enema introduced. Counter-irritation to the kidneys should be applied in the form of local poultices, mustard leaves, or turpentine stupes, or as dry cupping.

Should these means fail, infusion of glucose solution (2½ per cent) should be given into the median basilic vein. Two pints of the solution are introduced under strictest aseptic precautions. In the writer's experience this is the most powerful means at the command of the surgeon for producing diuresis.

The bowels should be freely opened. If the patient is not vomiting, an ounce or more of magnesium sulphate in a small quantity of warm water may be given by the mouth. A large, hot saline injection may be passed into the colon by means of a long rectal tube, or an enema of soap and water, or one containing turpentine 1 oz., or sulphate of magnesia 1 oz. and glycerin $\frac{1}{2}$ oz.

The skin should be made to act as freely as possible, but in producing diaphoresis it must be remembered that there is some tendency to collapse in these

cases. A hot pack, hot dry air, or vapour bath may be given. Pilocarpine should be used with caution. A hypodermic injection of $\frac{1}{60}$ gr. may bring about a copious and beneficial diaphoresis.

Stimulants should be freely given. Alcohol, ammonium carbonate, digitalis, and strophanthus may be administered by the mouth, and strychnine hypodermically in doses of $\frac{1}{30}$ gr. every four hours.

J. W. Thomson Walker.

URTICARIA.—The successful management of this troublesome and intractable malady consists in discovering the cause—if one can.

Amongst common causes the following should be borne in mind : (1) External parasites ; (2) Articles of diet, e.g., shell-fish, mushrooms, pickles, pork, eggs, cheese, oatmeal, strawberries or other fruits, and sour wines (but almost any article of diet may cause it in persons who have an idiosyncrasy : an intelligent patient, by keeping a watch on his diet and noting the incidence of attacks, may sometimes discover for himself the offending article) ; (3) Certain kinds of clothing, e.g., flannel, or the wearing of dyed materials next the skin ; (4) Uterine and ovarian irritation in women ; (5) A gouty constitution.

Enquiry should also be made as to the use of any possible external irritants, e.g., skin or hair lotions.

In *acute cases* it is well to begin treatment with a purge and, if there be any signs of gastric irritation, by the administration of an emetic. These may be followed by sod. phos. 1 dr. every four hours. Meanwhile the diet should consist of milk only. Locally, one of the applications mentioned below may be used to relieve itching.

In *chronic cases*—failing the discovery of any cause—the treatment is : (1) Local ; (2) General.

1. Itching may be relieved by warm baths containing either 2 oz. of potass. sulphurat. or 4 oz. of sod. bicarb. to 30 gal. of water ; or menthol or naphthol soap may be used with an ordinary warm bath. After remaining for ten to fifteen minutes in such a bath, the skin is lightly dried and one of the following applied :

a. LOTIONS :—

R Acidi Carbolici vel Mentholis $\frac{3j}{3ij}$
Glycerini $\frac{3ij}{3ij}$
Alcoholis $\frac{3ij}{3ij}$
Aquæ Camphoræ $\frac{3v}{3v}$

R Lotio Carbolici 1-40

R Acidi Hydrocyanici Diluti $\frac{3j}{3ij}$

R Vaselini Salicylici 2 per cent

R Unguenti Diachyli } partes æquales
Ung. Picis Liquidæ }

c. A dusting powder of oxide of zinc, talc, camphor, and starch.

Linen or silk should be worn next the skin both day and night, and the bed-clothes should not be too heavy.

In obstinate cases, a strictly lacto-vegetarian diet is always worth a trial.

2. Many *internal remedies* have been recommended, some of which succeed in one case, some in another. Amongst these are the following : salol (10 gr. thrice daily) ; ichthyol (5 min. in capsule thrice daily) ; calcium lactate (10 to 20 gr. thrice daily for three days) ; citric acid in effervescing mixture ; phenazone or phenacetin ; colchicum in gouty cases ; thyroid extract, gradually increased ; atropine (gr. $\frac{1}{120}$ to $\frac{1}{100}$ in pill at bedtime).

The use of the high-frequency current (fifteen minutes on the couch, current of 300 ma. and local effluve) is also said to have cured some obstinate cases.

In **Giant Urticaria** the above internal remedies may be tried, but those most likely to be useful are calcium lactate, colchicum, or the salicylates. In

acute cases a purge of pulv. rhei co. may cause the disappearance of the swelling. In order to prevent recurrence, the general health should be kept at as high a level as possible and tonics administered if necessary. Dyspepsia and intestinal putrefaction should be specially avoided. For the latter, acetyl-salicylic acid, menthol, and camphor are to be recommended. A mild course of thyroid treatment is sometimes helpful.

Lichen Urticatus is the form of urticaria most commonly met with in children, and must be treated on the above lines. Worms must always be remembered as a possible cause in such cases. The diet must be simple, and should contain no fish or raw fruit. Locally, the writer has found tar applications (e.g., one teaspoonful of liq. carb. deterg. to half a pint of water) relieve the itching best, with or without the aid of the baths mentioned above. These should be given in the morning, and not at bedtime. Internally, small doses of rhubarb, soda, and grey powder are sometimes helpful, or 5-min. doses of ichthyol with an equal quantity of glycerin. Quinine ($1\frac{1}{2}$ gr., in a sugar-coated tablet, for each year of the child's age) may be given at bedtime.

UTERINE HÆMORRHAGE.—(See HÆMORRHAGE, UTERINE.)

UTERUS, CARCINOMA OF.—(See MENORRHAGIA.)

UTERUS, DISPLACEMENTS OF.—These do not occupy their former high place in gynæcology, but require treatment if they cause pain or discomfort.

1. **Anteflexion and Anteversion.**—The virgin uterus is generally markedly anteflexed and anteverted, and unless the uterus is bent forward by the contraction of inflammatory adhesions—a very rare condition—anteflexion and anteversion require no treatment. The fact that the cervix can be felt “bulging into the rectum” does not prove the presence of any abnormal condition. The presence of marked anteflexion in a case of spasmodic dysmenorrhœa does not prove that the anteflexion is responsible for the dysmenorrhœa.

2. **Retroflexion and Retroversion.**—These conditions, which may be considered together for our present purpose, are very common, and are often of no importance, causing no symptoms and needing no treatment.

If the retroversion is due to a slight degree of prolapse, this should be treated, usually by a ring pessary. If there is no prolapse, and the patient complains of backache, increased in severity just before the periods, pain on defæcation, and dyspareunia, and it is found that pressure on the body of the uterus or ovaries through the posterior fornix causes pain, we may conclude that the retroversion is responsible for some or all of the symptoms. The treatment consists in pushing up the fundus, preferably by one or two fingers, and then anteflexing and anteverting the uterus by bimanual pressure. If the reposition is successful, a Hodge's pessary should be inserted to keep the uterus in the proper position. If attempts at digital or manual reposition fail, the sound may be used *secundum artem*, or reposition effected by pulling on the anterior lip of the cervix with volsellum forceps.

Insertion of a Hodge's pessary without previous correction of the faulty position is useless. After insertion of the pessary an examination should be made to ascertain whether the uterus is remaining in the proper position or not, as the presence of the pessary will only aggravate the symptoms if the retroflexion returns. Hodge's pessaries are often inserted upside down or hind-before, with, as might be expected, disappointing results.

If the fundus of the uterus is found to be fixed, probably by adhesions, no forcible attempt at reposition should be made. The choice of treatment in

such a case lies between attempts to secure absorption of the inflammatory adhesions by rest, hot douches, medicated tampons, etc., and abdominal section.

It is most unwise to tell the patient that her uterus is bent, or in the wrong position. To do so is to sow the seeds of neurasthenia and chronic invalidism.

3. Prolapse of the Uterus and Vaginal Walls.—The treatment of these conditions depends on the degree of prolapse. It can be considered most easily under the following five headings: (a) Cystocele; (b) Rectocele; (c) First degree of prolapse of the uterus, i.e., when the uterus is lower down than it should be, but is still entirely inside the vagina; (d) Second degree of prolapse, i.e., when the uterus is partly inside the vagina and partly outside; (e) Third degree of prolapse, i.e., when the uterus is entirely outside.

a. Cystocele.—If there is simple relaxation of the anterior vaginal wall, this may possibly be remedied by douches containing alum. If a pessary is needed, a ring is best when the vagina is roomy, and a small Graily Hewitt's pessary when the vagina is atrophied in elderly women.

b. Rectocele.—This condition is often found by itself, particularly in middle-aged and elderly women. No form of pessary, except perhaps Zwancke's butterfly pessary, or, in some cases, a cup-and-stem pessary, will do any good. The best treatment is posterior colporrhaphy, with advancement of the perineum.

c. d. If the vaginal orifice is not too large, a ring pessary should be used, except in cases where the rectum is tender. In such cases a Hodge's pessary often gives better results, its surface in contact with the rectum being "bevelled" as it were. If the vaginal orifice is too large for a ring to be retained, the choice lies between a cup-and-stem pessary attached to a waist-belt, or some operative procedure.

e. In cases of complete prolapse, the first thing to do is to push the uterus, bladder, and inverted vaginal walls upwards. This is done easily as a rule, but occasionally it is impossible until the patient has lain in bed for twenty-four hours or so, preferably with the pelvis raised. In rare cases an anæsthetic is necessary. To keep the uterus up, recourse must be had to a cup-and-stem pessary, or to operation.

The friction ulcers seen commonly on the exposed surface of the cervix and vaginal walls usually heal in a short time when the uterus is kept in its place. A douche of lead lotion is to be advised.

A patient who is wearing a pessary should douche herself with a solution of a drachm of common salt to a pint of water, or use an astringent douche, e.g., a solution of alum or tannic acid, and should be told that she must not go longer than three months without having the pessary changed. For most patients a daily douche is necessary. An intelligent patient may be taught to remove a ring pessary herself, clean it, and replace it. It is practically impossible for a patient to replace a Hodge's pessary herself. If she attempts to do so she will probably get the upper end in front of the cervix instead of behind it.

4. Chronic Inversion of the Uterus.—This should be treated by continuous pressure with Aveling's repositor. The vagina should be packed with gauze so that the repositor cannot slip, and the patient should be examined at short intervals while the instrument is *in situ*. If these precautions are not taken, the edge of the repositor, blunt though it is, may cause ulceration, or the instrument, having done its work, may become gripped by the cervix and retained in the cavity of the uterus.

H. Russell Andrews.

VACCINE THERAPY.—(See SPECIFIC THERAPY.)

VAGINISMUS.—In cases where sexual intercourse is impossible on account of spasmodic contraction of the sphincter vaginae, often accompanied by adduction of the thighs and sometimes by opisthotonos, a careful search should be made for any tender spot. If any such local cause can be found it must be treated (*vide* DYSpareunia and STERILITY). In some cases it is found that the hymen has never been satisfactorily stretched or torn, and stretching or removal under an anæsthetic may cure the vaginismus. In other cases nothing abnormal is found. If the patient has been married only a short time, dilatation under an anæsthetic is usually all that is necessary. One finger is inserted, then the tips of two fingers, until by a gradual process of stretching two or three fingers can be inserted. If this is done gradually, there is as a rule no deep tearing and no bleeding beyond a little oozing. Should the vaginal wall be torn, however, there may be troublesome bleeding, to check which the vagina must be packed with gauze, so care must be taken that the orifice only is stretched. It is well to have catgut sutures ready in case a tear of the hymen should bleed freely. Some operators always pack the vagina with gauze, the removal of which next day without an anæsthetic convinces the patient that there is no abnormal narrowness. If the hymen has been torn and the carunculæ hymenales are very sensitive, it may be wise to dissect them off. In cases where the sphincter vaginae is very strong, its spasmodic contraction narrowing the orifice unduly, stretching is not enough, and part of the sphincter must be cut through. This little operation, colpoplasty, is useful in cases where the husband is less virile than is normal. A fairly deep median incision is made through the lower part of the posterior vaginal wall into the tissues of the perineal body. The wound is sewn up so as to make a transverse scar, thus causing a permanent enlargement of the vaginal orifice.

After stretching or enlargement of the vaginal orifice by incision, glass vaginal dilators of graduated sizes should be inserted for a few days until the patient realizes that the passage of a foreign body into the vagina is possible and practically painless.

In many of these cases there is a neurotic element, which must be treated by improvement of the general health, etc.

H. Russell Andrews.

VARICELLA.—(See CHICKEN-POX.)

VARICOCELE.—The treatment required for this condition may be either palliative or radical. Palliative treatment is sufficient for the great majority of cases, but radical measures are sometimes indicated when the local trouble is great, and are inevitable when "Service requirements" call for their employment. When free to choose, the surgeon will operate but seldom. The slighter cases do not require such treatment, and the graver ones often suggest the co-existence of an underlying psychological abnormality which no operation can reach or benefit. There are, moreover, some special risks connected with the operation itself. The local trouble—entailing pain and distress as it does—may indeed act as a natural check to unwholesome outbreaks of excessive emotional excitement, and so even subserve on the whole the advantage of the patient. It is a fact that the melancholia which is sometimes associated with these cases may be increased by an operation which is quite successful in its local results. On the other hand, when the local trouble is serious, but at the same time unaccompanied by the graver symptoms of neurosis, excellent results may be expected. Even then, however, the operation is not one to be undertaken lightly.

It has been stated by eminent authorities that atrophy of the testicle never follows varicocele. It seldom does, though abnormal softness and flabbiness of

the organ are not infrequently noticeable; but that atrophy may occur I am certain, for I have watched its development. It must be admitted, however, that atrophy of the testicle following varicocele occurs most commonly as a direct result of hopeless anatomical injury inflicted during operation, which has sometimes included not only destruction of the small veins of the areolar tissue surrounding the vas—on which the parts below the seat of operation depend for venous return after the main trunks have been ligatured—but even ligature of the spermatic artery itself. These risks are to be avoided by careful operation. The areolar tissue surrounding the veins which are to be tied and removed must not be wounded or injured, except in so far as is necessary to expose the veins for dissection. The dissection must then be made close and clean off the veins, conserving most carefully the tissue in which they lie embedded. On no account are the veins to be separated by any crude incision through the connective tissue uniting them with the other constituents of the cord. It is also to be remembered that even in careful and experienced hands the maintenance of an adequate venous return is not absolutely assured. The risks are slight if due care be exercised, but the minute veins of the connective tissue have been known to prove unequal to the task imposed on them.

For the majority of cases treatment is simple. We are to enjoin obedience to well-known laws of health. Regular exercise, attention to the state of the bowels, avoidance of sexual excess, and sometimes the desirability of marriage, should be specially recommended, and for local measures the use of a suspensory bandage and frequent cold bathing. The indications for operation are: (1) A large varicocele with pain on standing or after exercise, and increased by hot weather or sexual excitement; (2) "Service demands." Many young men otherwise eligible are refused admission to the public services for a small varicocele. It is necessary for their admission that this should be removed, though there are no surgical indications for the operation.

THE OPERATION.—The veins are to be carefully dissected from other structures of the cord through an inch-long transverse incision over the external abdominal ring, and excised between ligatures, one above and the other below. The cord may be shortened at the same time by transfixing the stumps of the cut veins and tying their ends together. No drainage is required. The patient should be kept in bed or in a recumbent position until the wound has soundly healed and a strong cicatrix has formed. In from twelve to fourteen days he may get about with a suspensory bandage, but it will be from four to five weeks before the full beneficial effects of the operation will be experienced. Before undertaking the operation, any atrophy of the testicle present at the time should be noted.

Rutherford Morison.

VARICOSE VEINS.—Treatment as affecting the leg only will be considered. Varicocele and hæmorrhoids are separately dealt with elsewhere. Other varieties of varicose disorder are by comparison of minor surgical importance, and their treatment in the main is deducible from the general features of that applying to the leg. The treatment may be either palliative or radical.

In many cases no appreciable discomfort is experienced from even large varicose veins, and for these, beyond cold bathing and rubbing, nothing is needed.

In a large number of instances fatigue is felt after walking or prolonged standing, and there is a sense of fullness and heaviness in the limb. The indications will generally be to remove any hindrances to the return of venous blood from below, such as tight garters and corsets, fecal accumulations in the sigmoid flexure, abdominal tumours, etc., and to forbid prolonged standing.

Local treatment by an efficient support is of the greatest importance. A well-fitting elastic stocking is most easily applied and most serviceable. These

require, however, frequent renewal, as they soon become useless, and the yearly cost of their upkeep is considerable. An elastic bandage, or one possessed of elasticity, such as of flannel or crape, if carefully applied from the foot upwards, every morning before rising from bed, serves the same purpose as the elastic stocking, and without expense. Rubbing the limb, especially from below upwards, and cold bathing are valuable aids towards keeping the skin healthy and the veins free from engorgement. For the majority of patients I know of no exercise so suitable as cycling.

Cases for Operation.—In most instances the troublesome varicose changes occur in the internal saphenous vein and its tributaries. In these cases—and in these only—operation gives very satisfactory results.

The Indications for Operation are : (1) Nutritional disturbances of the skin of the leg, e.g., eczema and ulcer ; (2) Adhesion of the dilated veins to the thin, stretched, overlying skin, which makes rupture possible ; (3) Swelling, pain, and weakness in the leg which have resisted other treatment ; (4) In some instances, inflammation and thromboses of the diseased veins. Thus, operation may be specially called for when thrombosis is gradually extending upwards towards the saphenous opening, and threatening to invade the deep trunks, or when portions of the thrombus have been detached, and have caused symptoms of embolism. In these inflammatory conditions the upper end of the vein should be ligatured at the commencement of the operation in order to obviate *immediate* risks of embolism.

THE OPERATION.—Many operations are described, but only two require serious consideration. These are : (1) Excision of the upper part of the internal saphenous vein (Trendelenburg's operation) ; (2) Excision of the vein from the ankle to the saphenous opening. Our choice between these two operations can be settled by a test. The veins are to be emptied by elevation of the limb, the patient lying down. Then, if a finger be pressed over the upper part of the saphenous vein and the patient stands up, no rapid refilling of the veins may occur. If the finger pressure is relaxed the diseased vein may quickly distend, showing that its valves are incompetent, and suggesting that excision of the upper part of it (Trendelenburg's operation) may suffice, but it seldom does. If, in spite of finger pressure above, the diseased veins fill on the assumption of an erect posture, excision of the whole vein is indicated. The very long incision required for this has always, in my experience, healed without trouble, though it must be remembered that any operative interference with veins, apart from the risks of sepsis, which are avoidable, are attended by the danger of pulmonary embolism, from which several deaths have been recorded. The upper portion of the vein can be easily removed through a short transverse incision over it at the upper end, and a second or more below. After exposure of the vein above, it is divided, ligatured at its proximal end, and clamped below. It is again exposed by a short transverse incision about ten inches lower down, clamped below, and divided above the clamp. A long-eyed or acorn-pointed probe is then passed upwards into the open end of the vein till it reaches the upper exposed portion. A ligature round the acorn head of the probe and the vein, or a suture through the vein and the eye of the probe, fixes the two firmly together. By traction on the probe the vein is drawn out and removed, more readily by the eyed probe, which withdraws the vein turned inside out instead of crumpled up as with the other probe. This process may be repeated lower down till the whole vein has been extirpated ; but it is not as a rule satisfactory for the leg portion, where adhesions to the skin and surrounding parts are usually present, and excision there is a better method.

The incision should as far as possible avoid the most unhealthy portions of skin. Though it must cross the bends of a sinuous dilated vein occasionally,

it should on the whole take a marginal course, so as to run clear of the thin, stretched skin by which the vein is covered. When skin and vein are adherent, the skin must be excised with the vein. In addition to excision of the vein trunk, any specially dilated portions and saccules should be excised through small separate incisions.

Hæmorrhage from varicose leg veins is of infrequent occurrence, but I recall being called to see a middle-aged woman, and finding her held up on a chair by friends, her leg in a pail of mixed blood and cold water; brandy was there in abundance, and she was dead. The bleeding was due to spontaneous rupture of a sacculus of the internal saphenous vein, as it usually is. The horizontal posture, with removal of constriction above, elevation of the limb, and a pad with a moderate compression bandage, at once stops the bleeding in these cases. As soon as the skin wound has healed the diseased vein should be excised.

Rutherford Morison.

VARIOLA.—(See SMALL-POX.)

VERTIGO.—This condition is the result of many pathological states; the following include the more common of these:—

1. **Ocular Vertigo.**—Treatment consists in the correction of the ocular defect (paralyzed muscle, myopia, etc.). (See EYE, INJURIES OF.)

2. **Aural Vertigo** (Auditory vertigo, Ménière's disease).—It is first necessary to negative the existence of any removable exciting cause (cerumen, tympanic catarrh, active middle-ear disease). Gout and syphilis are held to act in some cases as a predisposing cause; any evidence of active manifestation of either will call for its appropriate treatment. (See EAR (Internal), GOUT, and SYPHILIS.)

In all cases, counter-irritation behind the ear is useful. Iodine should be applied every night until the skin is blistered: equal parts of strong and weak tincture of iodine (B.P.).

Internally, the bromides and iodides are of great value, especially if combined with belladonna.

R Potassii Bromidi	gr xv	Tincturæ Belladonnæ	℥ viii
Potassii Iodidi	gr x	Aquæ Destillatæ	q.s. ad ʒ ss
Liquoris Potassii Arsenitis	℥ iij		

Thrice daily in a little milk after food.*

In obstinate cases, quinine sulphate is worth a trial, 3 to 10 gr. thrice daily in milk.

Another remedy which has been strongly recommended is the administration of salicylate of sodium with gelsemium:—

R Sodii Salicylatis	gr xv	Tincturæ Gelsemii	℥ xx
Spiritus Ammonię Aromatici	℥ xv	Aquæ Destillatæ	q.s. ad ʒ ss

Three times daily.

Tincture of jaborandi (B.P. 1898) in doses of thirty minims, gradually increased to one teaspoonful, thrice daily, has been found useful in intractable cases.

In some of these cases the condition is associated with, perhaps dependent on, senile cardiovascular changes, and due attention to arrest of high blood-tension will give relief. In a considerable number, spontaneous cure may be looked for, usually with more or less complete deafness. Recently electricity has been employed, with encouraging results. The galvanic current should be used, with the negative electrode in the auditory passage, and the positive electrode upon the dorsal or lumbar regions. The ear electrode, with the help of a pledget of absorbent cotton, is extended as far as possible to the tympanum. The mean intensity of the current employed is from 15 to 20 milliampères; each applica-

The alkaloids will precipitate in this mixture. Shake well.—AMERICAN EDITOR.

tion lasts from twelve to fifteen minutes, and should be repeated three times per week.

Surgical intervention must be considered in cases which have failed to respond to prolonged general and local treatment, and where the vertigo renders the patient's life intolerable. (See also **EAR, AFFECTIONS OF.**)

3. Gastric Vertigo.—Recurring vertigo sometimes occurs in the subjects of various stomach ailments. Some authorities insist that in such the dizziness is always due to a coincident aural cause. In treatment, it is certainly important to make sure that no other origin for the vertigo is present. The stomach affection may be comparatively trivial, or grave. Relief can be given only by treatment appropriate to the gastric condition. (See **DYSPEPSIA, ATONIC, and STOMACH DILATATION.**)

4. Neurasthenic Vertigo.—The subjects of neurasthenia not infrequently complain of recurring dizziness, and this symptom may be a very prominent feature of their sufferings. Their disordered imaginations conceive it to indicate grave cerebral peril. To reassure the patient is an important part of the treatment, which otherwise consists in the general management of the neurasthenic state. (See **NEURASTHENIA.**)

5. Epileptic Vertigo.—Epileptics are prone to vertigo; the attacks may alternate with, or replace, the more typical fits. The treatment is that of epilepsy.

6. Migrainous Vertigo.—True migraine may manifest itself in dizzy fits. (See **MIGRAINE.**)

7. Vertigo from Organic Diseases of the Central Nervous System.—Attacks of vertigo are sometimes an early or late sign in grave disease of brain or cord. They may occur in acute brain conditions such as cerebral hæmorrhage, or in chronic states, as cerebral or cerebellar tumour. Tabes dorsalis and insular sclerosis are examples of spinal cord disease in which vertigo is common.

8. Cardiovascular Vertigo.—The subjects of arteriosclerosis are exceedingly prone to vertigo, which, with or without epileptiform seizures, is frequently a prominent feature. In association with bradycardia, it constitutes the Stokes-Adams' symptom-complex. The vertigo calls for no special treatment beyond that of the associated circulatory changes. (See **ARTERIOSCLEROSIS.**)

In addition to the above, a considerable number of diseased states may manifest themselves by vertiginous symptoms. In anæmia from any cause, and chronic uræmia, vertigo may be the prominent complaint. Constipation, and the presence of certain intestinal parasites, also may give rise to troublesome giddiness. Sea-sickness and cliff-sickness are examples of vertigo occurring in healthy people. For the treatment of all these, the reader must be referred to the appropriate sections of this work.

Lewis Smith.

VISCEROPTOSIS.—(See **GASTROPTOSIS.**)

VOLKMANN'S ISCHÆMIC PARALYSIS.—Ischæmic paralysis was described by Volkmann in 1875. The condition is generally attributed to tight bandaging in the treatment of fractures of the arm, the pathological condition being a chronic myositis. There should be no mistake about the diagnosis, for the position and appearance of the hand are characteristic. The fingers are flexed at the interphalangeal joints, and in severe cases consist of skin and bone with very little pulp, and have the dry appearance of a bird's foot; the metacarpophalangeal joints are extended, so that the hand and fingers have the curve of a dinner fork; the wrist is flexed.

The diagnosis is confirmed by the following simple test: when the wrist is passively dorsiflexed, the fingers contract and curl up into the palm of the hand;

and when the wrist is passively put into full flexion, the fingers extend without any effort on the part of the patient. This movement is so peculiar that if once recognized it can never be mistaken. The deformity is due to fibrous changes in, and partial contracture of, the muscles. To restore the balance of movement several ingenious procedures have been devised. One of these is to lengthen every tendon at the wrist. This involves an extensive dissection; the after-treatment of the wound must take precedence of the treatment of the deformity, and if any trouble occurs the position of the fingers may get out of control. Another method which has been recommended and practised is to remove a portion of both radius and ulna, so as to adapt the length of the forearm to the shortened muscles. This also has the obvious objection that difficulties may arise in the after-treatment, and like the former has the inherent fault that it promotes the formation of still more cicatricial tissue in a limb in which there has already been too much fibrous tissue formation. The writer invariably attacks these cases by endeavouring to stretch the contracted short parts.

The procedure is as follows: First, an assistant passively flexes the wrist; this causes the fingers to extend, and in this position small sheet-metal finger-splints are fixed to each digit with strapping. Over these, at the same sitting or a day or two later, a flat palmar splint is strapped to keep the phalanges and metacarpals in line. Next, at intervals of two or three days the wrist is gradually extended a few degrees at a time till the wrist and hand are in extreme dorsiflexion. The first sign of recovery is a restoration of pulp in the tips of the fingers, which are left exposed. Next the patient recovers a little power of voluntary dorsiflexion. From this stage, perseverance in the treatment by position, aided by massage of the muscles of the forearm, will lead to the desired result. In milder cases of recent origin, good results are almost certain; in severe cases of long standing, improvement is very slow and tedious, but it is always safe to predict a considerable degree of recovery. Robert Jones.

VOMITING, CYCLICAL ("Fitful," "Periodic," "Recurrent," "Lithæmic," or "Bilious Vomiting," "Vomiting with Acetonæmia," "Migrainous Gastric Neurosis," "Food Fever," "Acid Intoxication").—Recurrent attacks of vomiting, with or without pyrexia and headache, often associated with the odour of acetone in the breath, and its presence in the urine, together with diacetic and β -oxybutyric acids, are not uncommon in children aged between three and eight years. Such attacks have been described under each of the above titles, but probably all are not of similar nature, neither is their causation always the same. They are most common in neurotic, highly-strung, precocious children. A family history of gout, rheumatism, "bilious headaches," migraine, and various functional neuroses is often ascertained.

Predisposing causes, in some cases, seem to be an indoor life and want of exercise, chronic constipation, emotional excitement, mental or physical fatigue, or a diet excessive in fats or carbohydrates. In a few cases, eye-strain due to ametropia may predispose to periodic attacks of vomiting and headache. Sometimes a neurotic disposition and a tendency to vomit on slight provocation seem alone accountable, and the attacks resemble, and are in after-life replaced by, migraine.

DIAGNOSIS OF CYCLICAL VOMITING WITH ACIDOSIS.—A history of previous similar attacks is usually forthcoming. In primary attacks, the possibility of ptomaine poisoning, acute indigestion and gastritis from overfeeding, gastric influenza, appendicitis, intussusception, intestinal obstruction, renal colic, and meningitis should be borne in mind. Operations for non-existing appendicitis have been performed in some cases of cyclical vomiting; but sometimes, as Comby maintains, recurrent and subacute appendicitis may be the real cause.

Enquiry as to diet will perhaps lead to the diagnosis of "food fever," and observation of the patient's demeanour and surroundings may suggest a purely neurotic origin of periodic headache and vomiting. Eye-strain rarely, and migraine commonly, account for such attacks. The absence of acidosis distinguishes the neurotic variety from true cyclical vomiting.

TREATMENT OF CYCLICAL VOMITING :—

Prophylaxis.—When there is sufficient evidence of habitual excess in fats and carbohydrates in the diet, periodic attacks of vomiting, headache, and pyrexia may sometimes be prevented by prescribing a simple mixed diet without excess of the articles named. In some cases, however, the causes of the attacks cannot be thus explained; their origin seems to be in hepatic inadequacy, often associated with chronic constipation. The bowels should be regulated by rhubarb and soda, grey powder, or occasional doses of calomel followed by a saline draught. The success which some have claimed for prolonged treatment by alkalies has not been shared by the writer.

For cases of purely nervous or hysterical origin, a quiet and unemotional life led in the open air as much as possible, should be prescribed. Separation from relatives and a careful selection of associates and environment are often advisable.

Prodromal symptoms are often absent in cases of cyclical vomiting, but when they occur, calomel $\frac{1}{4}$ gr., with sodium bicarbonate 5 gr., should be given half-hourly until six doses have been taken, and be followed half an hour later by a saline laxative. During an attack, the incessant vomiting usually renders all medication by mouth useless. Sips of hot water may be given every quarter of an hour, or ice to suck, and hot fomentations should be applied to the epigastrium. A twenty-four hours' fast is usually obligatory, but when vomiting shows signs of abatement, small quantities of albumin-water, barley-water, whey, or peptonized milk may be supplied. The lower bowel should be unloaded at the onset by means of a water enema.

In prolonged cases rectal alimentation may be necessary and saline injections, to which bromides in $\frac{1}{2}$ - to 1-drachm doses may be added when there are much restlessness and mental distress. The prognosis is almost invariably favourable unless the symptoms follow anæsthesia. In the latter case, as mentioned elsewhere, the fatality is probably the result of toxæmia of intestinal origin, and the same may be said of fatal cases of spontaneous cyclical vomiting. In instances of this kind the value of salol and other intestinal disinfectants is problematical. By the time that their employment is considered necessary, the disease has already advanced beyond control.

Leonard G. Guthrie.

VOMITING IN CHILDHOOD.—In children, as in older persons, vomiting may be due to gastric derangement, or may be symptomatic of a general disturbance, such as an eruptive fever, or of the onset of a local disease outside the alimentary canal, such as nephritis, cerebral disease, etc.

Symptomatic vomiting need not be interfered with unless it becomes distressing. Should it be so a sedative may be given, such as $\frac{1}{20}$ gr. of cocaine in a teaspoonful of water (to an infant of six months old), or a hypodermic injection of $\frac{1}{40}$ gr. of morphia. Obstinate vomiting may result from a hernia or an invaginated bowel, and must be treated, of course, by appropriate measures for relieving those conditions. Vomiting arising towards the end of an attack of diphtheria is suggestive of heart failure, and the proper steps must be taken at once to meet this formidable complication.

When vomiting occurs in gastric derangement, it is the result of catarrh of the stomach set up either by a chill or by inappropriate or excessive feeding. It is common enough in infants, and is one of the chief causes of the high

mortality amongst the children of the poor. In a healthy child, mere regurgitation, immediately after a meal, of a portion of the food taken is not to be looked upon as a sign of gastric disturbance. The milk is returned without retching or any sign of effort, and its appearance merely shows that more food has been swallowed than the stomach can comfortably retain. Even sucking infants who are strictly confined to the breast are subject to catarrhs, during which the milk is vomited sour and curdled, with every sign of gastric distress. But it is a mistake on this account to wean the child. All that is necessary is to forbid suckling for twenty-four or forty-eight hours, feeding the child in the meantime with barley-water, flavoured, in alternate bottles, with a teaspoonful of extract of malt. The mother's milk can be drawn off with a breast pump, but it must not be given to the infant. For medicine we may order :—

R. Zinci Sulphatis gr $\frac{1}{12}$ Infusi Chiratae q.s, ad 3ss
Glycerini m $\frac{v}{v}$

To be given three times a day before food.

Or, 3 gr. of citrate of potash in the same bitter infusion.

In hand-fed babies, vomiting from gastric catarrh at once suggests a revision of the dietary, for, as in the case just referred to, a diet which is well suited to a healthy stomach often ceases to agree in the altered conditions. If the vomited matters are sour, special attention should be paid to the quantity of milk given in each meal, and it may be necessary to reduce this to a half, a quarter, or a sixth part of that originally allowed, or even to forbid it altogether. Its place can be taken by veal broth made weak and thickened with barley and strained ; fresh whey with cream and barley-water ; or whey and barley-water with Mellin's food. The size of the meal is also of importance. Vomiting of the food must be taken to show that too much has been swallowed, and therefore less must be allowed for the next meal. In bad cases, one teaspoonful at a time is often all that can be retained. If so, this must be given every quarter of an hour. If the child is very weak, cold white wine whey in teaspoonful doses may be given frequently.

It is, of course, essential that everything ordered should be perfectly fresh and in good condition. Whey, after four hours, cannot be given to the infant with safety, and barley-water must be considered stale after six hours. Attention, too, must be paid to the absolute cleanliness of the spoons and feeding-bottles. For medicine, the remedies used may be those above recommended. But we may order also small doses of arsenic or ipecacuanha with an alkali and bitter infusion, or a combination of the tinctures of rhubarb and nuxvomica. Thus, for a child of six months old :—

R. Liquoris Potassii Arsenitis	℥ss	Glycerini	℥x
(aut Vini Ipecacuanhæ)		Infusi Chiratzæ	℥ss
Potassii Citratis	gr iij		q.s. ad

To be given three times a day.

Or,

R	Tincturæ Nucis Vomiceæ	℥ ½	Glycerini	℥ x
	Tincturæ Rhei Compositæ (B.P.)	℥ ij	Aquæ Menthæ Piperitæ	q.s. ad ʒ ss

To be given three times a day.

In cases where the vomiting is obstinate, ingluvin in doses of $\frac{1}{2}$ gr. every three hours is often a successful remedy. Another equally valuable one is calomel; $\frac{1}{2}$ gr. to be laid upon the tongue every hour.

If the stomach contractions are violent, a poultice containing $\frac{1}{2}$ part of mustard should be applied for several hours to the epigastrium. If the vomiting has persisted for several days before the child comes under observation, and the gastric irritability is not quickly allayed, it is well to wash out the stomach.

In hand-fed babies, vomiting, if neglected, or unskilfully treated, is apt to become chronic. In such cases it will be noted that the feet and legs are habitually cold, and the first step in the treatment will consist in covering the lower limbs and feet with a thick layer of cotton-wool. This simple measure in itself is often successful, and the sickness ceases when the feet are warm. At the same time, measures must be taken to prevent a fresh chill, and it is well to revise the dietary upon the lines already laid down, and, for medicine, to prescribe one or other of the remedies recommended above.

An occasional form of vomiting which, if it continue, may reduce an infant to a state of extreme emaciation, and even prove fatal, is that which results from monotony of diet, the child being fed morning, noon, and night on the same thing. Each meal is vomited with little effort, quite unchanged, and the infant seems to keep almost nothing on his stomach. If a change be made to another food the vomiting ceases for a day or two, but returns as soon as the stomach has got used to the alteration. The simple remedy for this state of things is variety in the meals, and a mere difference of flavour is all that is needed. A teaspoonful of Mellin's food or extract of malt added to each alternate bottle during the day, with a third food for the night, usually makes a sufficient variety; but in exceptional cases the diet must be so arranged that no two meals in the twenty-four hours shall have quite the same taste.

In the case of older children, vomiting must be treated on exactly the same lines. A revision of the dietary is essential. Sweets and fruit must be forbidden, and milk and starch allowed only in very small quantities; indeed, in many, if not in most children, vomiting is apt to persist as long as milk continues to be taken. If the attack is acute, it is best to allow nothing but water, hot or cold according to the taste of the patient, and to apply a hot linseed-meal poultice containing $\frac{1}{5}$ part of mustard to the epigastrium for six or eight hours. The withholding of food is readily submitted to, as there is complete distaste for nourishment of every kind. It is judicious, however—more, perhaps, for the sake of the friends than for the benefit of the patient—to make use of a nutritive suppository several times in the day.

While the vomiting goes on, the washing bath must, of course, be discontinued, for so sensitive does the patient become to impressions of cold, that the smallest exposure tends to keep up the derangement. It is best to forbid washing of any kind except sponging of the face and hands, and to keep the child in bed with a hot bottle to his feet and a layer of cotton-wool over his abdomen and chest. For medicine he may take the sulphate of zinc mixture recommended above, increasing the dose of the sulphate to $\frac{1}{10}$ or $\frac{1}{8}$ gr.; or use, as alternatives, any of the other remedies which have been suggested.

When vomiting ceases, weak veal or chicken broth, with rusk or dry toast, can be given; afterwards, as the appetite improves, an ordinary diet can be returned to, but the change must be made cautiously and by gradual steps.

These attacks almost always occur in children who are suffering from an acute post-nasal catarrh, and are the consequence of the passage of septic mucus into the child's stomach in large quantities. If the fauces be inspected, the mucous membrane at the back of the pharynx will be found to be red and thickened, looking like red velvet, and glistening with moisture. Often gelatinous yellowish mucus can be seen adhering to the surface or creeping slowly downwards. It is important to treat this condition without delay. The throat should be painted twice a day with glycerin of boric acid (20 per cent), and a few drops of a solution of resorcin in normal saline solution should be instilled into each nostril three times a day and allowed to gravitate downwards into the throat. The attacks are accompanied by a rise of temperature, which may reach 103° F. or higher on the first day, and the liver is generally congested.

If it can be felt to be obviously enlarged, an aperient dose of calomel should be given as soon as the stomach can keep it down.

In cases where the attacks occur, as they may do, at regular intervals—every few weeks or months—they are often spoken of as periodic or cyclical vomiting. This and the form of vomiting which is dependent upon pyloric obstruction are treated in separate articles.

Eustace Smith.

VOMITING, NERVOUS OR HYSTERICAL, should be treated by isolation, and where the food is regurgitated from the œsophagus it may be necessary to feed with the stomach tube. As a rule the throat is sufficient. (See also **HYSTERIA**.)

Robert Saundby.

VOMITING OF PREGNANCY.—(See **PREGNANCY, DISORDERS OF**.)

VULVO-VAGINITIS, as it occurs in little girls, is a most obstinate disease, requiring careful and prolonged treatment. At the outset it is important to ascertain by bacteriological investigation whether it is the simple or the gonorrhœal form of the affection that one has to deal with.

In *simple* cases the parts should be thoroughly irrigated two or three times daily with an antiseptic solution (saturated boric acid or 1-5000 perchloride). The solution should be applied with a syringe or a swab, and gauze soaked in it may be left in contact with the mucous membrane. The surrounding skin should be protected by white precipitate ointment (5 gr. to the ounce). In the more severe cases silver solutions (1 to 5 per cent protargol or argyrol) may be used instead of the above lotions. Suppositories containing 1½ gr. of salol in cocoa-butter may be introduced into the vagina two or three times daily. General cleanliness should be strictly observed, and the use of a sulphur bath every other night is often helpful. The general health should be built up by tonics.

In the *gonorrhœal* cases treatment must be even more energetic. It must be remembered that this form of the disease is highly contagious, and the patient should therefore be strictly isolated and the utmost care taken to prevent the carrying of infection by napkins, washing utensils, sheets, etc. All such articles should be thoroughly disinfected before being washed. The local treatment is the same in principle as that employed in simple cases, but stronger antiseptics are required (e.g., perchloride 1-2000, protargol 5 to 10 per cent, argyrol 5 to 25 per cent). Perrin uses a 10 per cent solution of protargol in glycerin, applied to the vagina and cervical canal by means of cotton-wool; if the urethra is affected it should also be applied to the urethral canal by means of a urethroscope. A compress of 1 per cent protargol is applied to the vulva for a few minutes three or four times daily. A diaper or pad should be worn to prevent the child carrying infection to the eyes. Quarantine should be continued for some time after all organisms have disappeared from the discharge.

In the gonorrhœal cases treatment by a stock vaccine has lately been strongly recommended. An injection of 50 million may be given at any age over six months, and repeated every fifth day, increasing the dose by 10 millions each time. After five injections have been given the interval may be increased to ten days. If necessary the dose may be raised to one of 200 million.

Robert Hutchison.

WARTS.—These may be treated either by caustics or excision. Caustic treatment, which leaves little scarring, is sometimes satisfactory. The wart should be pared down so that the caustic can act on the deeper layers, and either nitric acid, or a mixture of salicylic acid 100 gr. to collodion 1 oz., recommended by Cheyne and Burghard, should be painted over the area. This treatment is repeated twice a day for about a fortnight, at the end of which time the warts will have disappeared.

If more radical treatment be desired, the whole wart should be excised. This must be done cleanly, since if any part is left recurrence will take place.

If an extensive crop of warts develop on the prepuce, the best treatment is to perform circumcision.

W. H. Clayton-Greene.

WEIR-MITCHELL TREATMENT.—(See NEURASTHENIA.)

WHITLOW.—The suppurative condition of the fingers known as whitlow or felon usually results from a punctured wound with a septic instrument, or is due to subsequent infection of a simple cut.

It is usual to speak of four different varieties of whitlow, which depend upon the depth of the infection; and as the particular variety met with in a given case may require special treatment, all four will be alluded to under their respective headings.

1. *Subcuticular.*—The pus collects beneath the epidermis; there is often an exudation of blood-stained serum with very little pus, and the epidermis may be stripped up for some distance from the underlying dermis.

2. *Subcutaneous.*—In this form the infection tracks into a deeper level, and the tough tissue of the finger pulp becomes attacked. It is excessively painful, owing to the tension produced, and if neglected may lead to the following varieties.

3. *Thecal.*—This is a suppurative tenosynovitis. The synovial membrane which accompanies the tendons along the flexor sheaths becomes infected, and the whole canal may in this way become filled with pus. In the case of the thumb and little finger, the results may be still more serious, owing to the communication which usually exists between the synovial membranes of the flexor sheaths and the great synovial membrane or palmar bursa which envelops the flexor tendons in the palm. Fortunately this accident is rare, but its occurrence is a very serious matter, often leading to destruction of the hand and permanent crippling.

The flexor sheath cannot be said to extend beyond the distal extremity of the second phalanx, so that whitlows which are confined to the region of the terminal phalanx and carefully treated should not give rise to this complication.

4. *Subperiosteal.*—In this form the infection gives rise to a periostitis, the periosteum of the terminal phalanx being attacked and necrosis of the bone a common result. The intimate connection of the skin and periosteum by the fibrous ligaments which traverse the superficial fascia favours this result.

GENERAL TREATMENT.—This consists in incising the tense and suppurating area as soon as possible, in providing rest for the affected finger by a suitable splint, and in the application of antiseptic dressings. But while these directions appear sufficiently simple, it will be necessary to elaborate them according to individual cases.

In the subcuticular variety, which is practically painless owing to the pus lying superficial to the sensitive papillæ, a free opening can be made without any anæsthetic, and all undermined skin can be snipped away with scissors without the least discomfort to the patient.

The subcutaneous form is more difficult to treat, and it may be said at once that the causes of failure are usually an insufficient incision and the absence of rest to the part. It often happens that an incision has to be made without an anæsthetic, and the timidity of both the operator and his patient results in an insufficient opening being made. Although with thorough cocaine anæsthesia the operation may be quite satisfactory, it is always advisable to give a general anæsthetic when possible.

In making the incisions into the swollen infected area, two precautions must

be taken : (1) To see that the opening is adequate, so that the pus can discharge freely. This is not so easily achieved. Owing to the dense fibrous tissue in the part, as soon as the greater part of the exudation has been let out, the edges of the wound tend to close, and there is retention of the pus. To obviate this it is recommended that two elliptical incisions be made and a portion of skin and subcutaneous tissue excised so that the pulp is freely opened up, and sloughs should be carefully removed with a spoon. (2) Care should be taken in making the incision that the flexor sheaths be not damaged. This precaution is very necessary, for it has often happened that an energetic operator, with the above rule in mind, has carried his incision right down to the synovial membrane of the sheath, and has caused an infection of it.

In the thecal form free incisions will be required opposite the centre of the second and first phalanges ; either central or lateral incisions may be made, but there appears to be no special advantage in the latter.

The subperiosteal form is treated in the same manner, but subsequently it will be necessary to remove the necrotic bone.

The After-treatment is of much importance. Fomentations and baths of weak antiseptics are of undoubted value, but they are often overdone. It is rarely that a whitlow requires fomentations for more than three or four days, and much harm results from allowing the tissues to become sodden and unhealthy from too much water treatment. In favourable cases a dry dressing may be applied in the first week ; and as soon as pain has disappeared, gentle passive movements of the fingers should be undertaken to break down the adhesions which have a tendency to form in the thecal variety. Bier's treatment by passive congestion or suction is of distinct value.

Unfortunately, the result is too often a stiff and useless finger, which may require amputation. But this must be looked upon as a last resort. It is true that where the process tends to spread, and where there is a risk of infection of the hand and arm, amputation must be seriously considered, and again, where after careful treatment a useless appendage remains ; but while it is impossible to lay down absolute rules for these cases, it should be clearly understood that amputation is only called for in the acute stages to avert a more serious condition ; and even where the finger appears totally and irretrievably destroyed, it is much better to wait until the suppurative process has subsided before venturing on the amputation. By such a course the free opening up of lymphatic spaces in the presence of acute infection is prevented, and the surgeon is often able to save some part of the finger in the form of a stump which will be of service to the patient. It is astonishing how often a bad suppurative condition of the fingers results in an almost complete cure.

The above remarks apply to the whitlows met with on the palmar aspect of the digits, but the allied condition on the dorsum—**Paronychia**—is to be treated on similar principles, plus the free removal of the nail.

W. H. Clayton-Greene.

WHOOPIING-COUGH.—The following contribution is based on the careful study of over 550 cases which have been under the writer's care in the whooping-cough ward at the Hospital for Sick Children, Great Ormond Street.

The treatment of whooping-cough constitutes one of the reproaches to the art of medicine. We have no method by which we can shorten the disease, nor can we do more than pilot the case to recovery, modifying symptoms, guarding against complications, and making our patient as comfortable as we can during an illness which has no rival in its discomforts. A specific for whooping-cough has yet to be found. To all those I have tried (and they are over thirty in number), the handwriting on the wall is literally applicable : " Tekel " (" Thou art weighed in the balances, and art found wanting "). Nevertheless, much

can be done to alleviate the sufferings of the patient, both by general management and by the use of suitable drugs.

Treatment can be best considered under the heads of (1) General hygienic management; (2) Special drug treatment; and (3) The treatment of complications.

1. General Hygienic Treatment.—As soon as the disease is recognized, the patient should be isolated, and two rooms should be set apart for occupation by the patient and his attendant. The rooms should communicate with one another, or at least be on the same floor, and should be freed from superfluous furniture and hangings. If gas is laid on, the presence of a ring burner will be found of great utility, both for the preparation of food and for the vaporization of medicaments. One room should be kept as the day, the other as the night room. Carpets are not desirable in the sick-room, and in the absence of a cork linoleum floor covering, a waxed drugget, properly lined, should cover the whole floor. Nothing, however, is so suitable as cork linoleum, which is warm to the feet, quiet to walk on, and can also be readily cleaned with antiseptic solutions.

In the case of infants and small children, the cot should have a side which can be let down next to the nurse's bed, up to which it must be drawn. The nurse is then able to attend to the child without having to get out of bed. Cots with fixed high sides must be discarded. A bed-board or bed-table will be found most useful, not only as a support against which a child can lean during paroxysms of coughing or vomiting, but also as a place where he can always find a vessel into which he can vomit or expectorate, and where he will find a handkerchief, or rather its equivalent.

Preparation in the way of draw-sheets must also be made, as the involuntary passage of urine and motions during the paroxysms of coughing or vomiting are very common. On this account, older children also may be pinned up with a napkin. Because of this liability to accidents, the use of combination sleeping-suits is to be condemned, and a flannel nightgown or pyjamas should be adopted. Nothing tight should be worn around the neck. When it is impossible to provide a special attendant for the patient, it is most desirable that those who come in contact with the infected children should, when in the sick-room, wear an overall garment of a washing material, preferably glazed holland.

Precautions against infection and reinfection should include the disinfection of all vessels, cups, dishes, and utensils used by the patient, before they leave the sick-room. All accidental contamination of floor or clothing by vomited material should be rectified by the use of antiseptic solutions (carbolic acid 1-40, izal, sanitas, formalin), and handkerchiefs should be replaced by small squares of linen which can be burnt after use, or by pledgets of absorbent cotton-wool. In older children, an enamelled basin (not an earthenware one) will be found most useful when vomiting is at all frequent. Its use not only makes for cleanliness, but affords a sense of security which is not unimportant in nervous children.

Ventilation.—Both rooms should be well ventilated and be capable of being thoroughly aired, but it is not advisable to adopt, in the early stages of the disease, what is now called the "open-air treatment." Ventilation is essential, but the reduction of the temperature of the room below 60° F. is not advisable, and tends to increase the liability to bronchial catarrh and bronchopneumonia. On the other hand, it must be borne in mind that the temperature of the room is apt to become unduly raised by the means employed for the production of vapours used therapeutically. In the earlier stages, and as long as there are signs of bronchitis, the patient should be kept to the two rooms; but in warm weather, if the attack be not a severe one, there is no need to keep the child

to the house, provided he does not associate with other unprotected children. In towns, the practical impossibility of isolation except within the house, makes it advisable to keep all cases of whooping-cough confined to the house during the first three or four weeks of the developed disease.

A recognition of the increased liability to pulmonary catarrh during and after whooping-cough, should make us insist on the careful clothing of children during convalescence. Both arms and legs should be kept covered. Prudence and not fashion must regulate the clothing.

Diet.—On account of the severe gastric disturbance, which is so marked a feature of many cases of whooping-cough, attention to the diet is essential. It must be light and nutritious. The meals must be small and frequent, and when vomiting is at all marked, considerable discretion as to the amount, character, and frequency of the feeds must be exercised.

In the early stages, the diet should consist of milk duly diluted with barley-water, water, or lime-water, of animal broths, milk puddings, jellies, custard, and eggs. When the febrile stage is subsiding, fish and minced or pounded meat may be given, but all rich foods are to be forbidden. If vomiting is severe, iced milk, malted milk, peptonized milk, milk and soda-water or albumen-water, may be tried; but when not retained, I have found nothing so useful as meat juice. This, in cases of extreme exhaustion, may be administered every quarter or half hour in 15- to 20-min. doses in a dessertspoonful of water.

2. Drug Treatment.—Perhaps for no disease have so many preparations been claimed to be curative as for whooping-cough. No one drug can claim in any sense of the word to be a specific. A serum prepared by Dr. Leurieux was tried by me in three cases, without producing the least beneficial result.

The treatment can be divided into (a) Local, and (b) General or internal.

a. Local.—Of these applications, undoubtedly the most useful are various inhalations. These are best administered by means of vaporizers, which cause the atmosphere of the room to become permeated with the medicament. Carbolic acid or cresolin I have found most useful. Cresolin has the advantage that it does not require such an aqueous vapour for its diffusion, and consequently the atmosphere is drier, while the risks of scalding or of accidental poisoning with carbolic acid are fewer. Cresolin is vaporized by means of a small lamp.

Creosote may be used either in a kettle, or sprinkled on a towel hung in the vicinity of the bed. The vapour is unpleasant and irritating. Creosote may be used in combination with other volatile disinfectants, as thymol, eucalyptol, carbolic acid, by sprinkling these on absorbent wool and then enveloping them with cotton-wool and gauze, so that the irritant material cannot come in contact with the skin. With some such preparation balls, dolls, and other toys may be stuffed. Ten drops of the following preparation may be employed in this manner :—

R Thymol	℥iiss	Olei Caryophylli	℥ij
Creosoti	℥iiss	Ætheris Acetici	℥iv
Acidi Carbolicæ Puri	℥ij		

Ten drops on cotton wool as an inhalation.

Turpentine, thymol, terebene, or eucalyptol may also be used as inhalations, in the strength of 1 dr. to 3 oz. of spirit and 7 oz. of water.

Many writers have advocated the employment of local applications to the mucous membrane of the throat, nose, and larynx by means of sprays, douches, or by direct application. I cannot speak at all favourably of any of these methods. Steam sprays are risky, and frighten children. The hand sprays are much less objectionable, but the results obtained from their use are quite

incommensurate with the trouble, upset, and frequent aggravation of coughing and vomiting which too often attend their use. Painting the throat is useful if we wish to excite vomiting, but, apart from this, even applications of perchloride of mercury, repeatedly used, with the object of exercising germicidal influence on the suspected organisms of whooping-cough, have proved utterly useless at my hands. Cocaine has been used for its anæsthetic effects on the respiratory mucous membrane, and it is said with good effect, but it is far too risky a drug to employ without the greatest circumspection, on account of the susceptibility of some children to cardiac syncope from quite small doses of cocaine. Removal of enlarged tonsils or of adenoids is frequently of the greatest benefit to the patient, especially in the later stages of the disease, and I have seen obstinate cases promptly subside after the operation. Many a case of whooping-cough is unduly protracted by the omission to attend to this requirement.

While local applications to the throat are of little service, applications to the chest are most useful. Liniments produce local hyperæmia, some of their constituents are absorbed, the volatile constituents are inhaled, and in addition, the rubbing of the child's chest improves its musculature. Turpentine liniment is the most useful; another not unpleasant one is the following:—

R. Olei Carui		Olei Eucalypti	2 parts
Olei Succini	āā 3 parts	Linimenti Camphoræ	24 parts

M. Ft. lin. To be rubbed on the chest night and morning.

The chief indication for the use of liniments is the existence of bronchial catarrh or of collapse of the lung.

If the child is very weak or drowsy, and has extensive bronchopneumonia, a turpentine stupe should be given after the chest has been rubbed with vaseline.

After the application of a liniment, the chest should be covered with a cotton-wool jacket, which should be worn during the day, to be exchanged for a similar one, put on after the evening rubbing and worn during the night.

Recently, applications of fluorine have been recommended, but I understand from those who have tried them that they are unable to substantiate the exaggerated claims made as to their utility.

b. Internal.—The treatment of whooping-cough by internal medication can be divided into that of the catarrhal and of the paroxysmal stages, and that of decline and of convalescence.

In the catarrhal stage, the drugs of most use are the expectorants: ipecacuanha; carbonate, chloride, and acetate of ammonia; iodide of potassium; spirits of nitrous ether; squills. In this stage, phenazonum (antipyrin) or citrophen is often of use. When the secretion in the bronchi is thick and tenacious, as evidenced by the sticky râles, iodide of potassium in 1- to 3-gr. doses is useful, but chloride of ammonium and apomorphia have both proved of little use in my experience.

In the paroxysmal stage, the drugs which are most likely to be useful are phenazonum, a combination of iodide of potash and chloral hydrate, glycerin of carbolic acid, and bromoform. In some cases diamorphine hydrochloride, belladonna, and bromides and cannabis indica have been useful, but for none of them can a specific action be claimed. As a routine treatment the following mixture may be given:—

R. Phenazoni	gr. iij	Vini Ipecacuanhæ	
Potassii Iodidi	gr. ij	Spiritus Chloroformi	āā ℥v
Ammonii Carbonatis	gr. j	Aquæ Menthæ Piperitæ	q.s. ad 3ij

For a child seven years old. Two teaspoonfuls to be taken every six hours.

Chloral hydrate has been much more useful when given in combination with iodide of potash than when given alone.

Should vomiting be a marked symptom, a combination of 1 to 3 min. of glycerin of carbolic acid with 5 gr. of carbonate of bismuth is most useful.

Belladonna, which is perhaps the drug most commonly used in the treatment of whooping-cough, has proved in the majority of cases of very little, if any, use; but here and there cases are met with in which full doses of belladonna do seem to control the severity of the attacks. *Cannabis indica* has yielded just as satisfactory and unsatisfactory results as belladonna.

Should the paroxysms be very severe, a whiff of chloroform vapour will be found to be the best method of relieving them. Among the drugs tried, but which did not give definitely satisfactory results, were bromides, quinine, aristochin, *drosera*, *grindelia*, *tinet. blattæ*, *salol*, *benzol*, antimony, alum, arsenic, perchloride of mercury, *pilocarpine*, and *apomorphine*.

Bromoform in doses of 5 min. is sometimes useful, but it must be remembered that on exposure to the light it decomposes and becomes inert, and, what is much more serious, is very apt to separate out of the mixture containing it, and settle at the bottom of the bottle; and the patient, in more than one case which has come under my notice, has received a toxic, though fortunately never a fatal, dose from the bottom of the bottle.

When pulmonary catarrh is persistent, creosote is often of great use, and in combination with bismuth acts most beneficially in cases of chronic intestinal catarrh.

During convalescence, nothing has proved so useful as cod-liver oil, given either with iron or with maltine. Quinine is much more useful during convalescence than during the acute period of the disease. Most of the iron preparations are useful during convalescence. When emaciation has been marked, the addition of plasmon or somatose to the food may be tried, or virol added to the diet.

Change of air is perhaps the best restorative, but the necessity for protection from exposure to cold must be impressed on parents and nurses.

3. Treatment of Complications.—Most of these should be treated as if the whooping-cough were not present, bearing in mind, of course, the risk which attends the use of sedatives in acute bronchial affections.

When there is much collapse of the lung, and the chest walls are unduly yielding, as in cases of rickets, I have succeeded in improving the thoracic breathing by applying a Martin's rubber bandage over the abdomen, so as to limit the abdominal and encourage the thoracic movements of respiration. The tightness of the bandage requires careful graduation, and it should be applied only intermittently at first; but after a time it will be found that the child tolerates it quite well. In such cases, rubbing the chest is a necessary adjunct to the use of the bandage.

Sublingual ulcers, which are surprisingly painless, are best painted with a solution of $\frac{1}{2}$ dr. of *salol* in 2 dr. of glycerin and 1 oz. of alcohol. Should they spread, they are best treated by touching with solid nitrate of silver. Sores about the nose and mouth are often very tiresome and painful. In treating them, preparations containing glycerin should be avoided, as should ordinary vaseline. Lanolin may be used, or white vaseline, which should form the basis of ointments used for the lips and nose.

The treatment of hæmorrhage, of subcutaneous emphysema, of hernia and prolapse, and of dilatation of the heart, calls for the addition of sedatives, but otherwise is conducted on the same lines as if no whooping-cough existed, except that operative procedures for the cure of hernia must be postponed. Empyemata should be opened and drained without delay. The liability to pulmonary tuberculosis, during and after an attack of whooping-cough, calls for the exercise of special attention to general hygienic measures, directed towards the prevention of infection with tuberculous material.

Isolation should be maintained for six weeks, and although for some months after an attack of whooping-cough a child on catching cold will have a paroxysmal cough and will occasionally whoop, yet such cases need not call for isolation.

Arthur Francis Voelcker

WORMS, INTESTINAL.

Tape-worms.—The treatment of tape-worm is very apt to be unsatisfactory unless it is taken in hand seriously, suitable preparation of the patient being of the first importance. The following plan will usually prove successful :—

For three days prior to the administration of the anthelmintic the patient should be kept in bed on a liquid diet, a pint and a half of milk and of beef-tea being sufficient. A mixture containing 20 gr. of sodium bicarbonate, 1 dr. of sodium sulphate, 20 min. of spirit of chloroform in 1 oz. of peppermint water should be given thrice daily. On the third night a draught should be given containing $\frac{1}{2}$ oz. of magnesium sulphate with 1 dr. of tincture of jalap (N.F.) and 20 min. of compound tincture of chloroform (B.P.C.) in 1 oz. of water. This should be repeated at 7 o'clock next morning if the bowels have not acted. At 8 a.m. 1 dr. of the liquid extract of male fern (B.P.) made up with 1 dr. of mucilage of tragacanth and 1 dr. of syrup of ginger in 1 oz. of chloroform-water should be given. At 9 a.m. this dose should be repeated. At 11 a.m. $\frac{1}{2}$ oz. of castor oil with 1 dr. of tincture of jalap (N.F.) should be given, and if the bowels do not act within an hour a soap and water enema should be administered.

The motions should be passed into warm water in a vessel lined with black crape to facilitate the recognition of the head.

An alternative method is as follows : Rest in bed on a diet of beef-tea and rusks for 3 days, 2 gr. of extract of cascara being given thrice daily. On the fourth day at 5 a.m., 1 oz. of compound infusion of senna should be given, followed at 9 a.m. by 15 min. of extract of male fern in capsule, this dose being repeated at intervals of a quarter of an hour for other three doses. At 11 a.m. the senna draught is again given.

The proprietary preparation, oil of filmaron,* which is the active principle of male fern dissolved in castor oil, may be given instead of the extract of male fern. The dose is 1 ounce for an adult, and there is no need for a purgative after it. It is specially suited to children.

Other anthelmintics are the following : (a) Pelletierin tannate (the active principle of pomegranate) 8 gr. ; (b) 1 to 2 min. of croton oil shaken up with 1 dr. of chloroform and taken in half a tumblerful of milk in the early morning fasting.

Round Worms are best treated with santonin, which should be given on an empty stomach, combined with an aperient such as scammony, calomel, or castor oil, e.g. :—

R. Santonini	gr iiss	Hydrargyri Subchloridi	gr ss
Pulv. Scammonii Compositi (B.P.)	gr ij		
(For a child of one year.)			
R. Santonini	gr v	Syrupi Simplicis	$\frac{3}{4}$ j
Olei Ricini	$\frac{3}{4}$ ss	Aque Menthæ Piperitæ	ad $\frac{3}{4}$ j
Mucilaginis Acaciæ	$\frac{3}{4}$ iv		

Fiat haustus. (For an adult or a child of twelve.)

Thread-Worms.—The presence of [thread-worms is usually an indication, in children at least, of an unhealthy state of the large bowel, and especially of an excessive secretion of mucus. This may be remedied by cutting down the starchy foods (see *DYSPEPSIA IN CHILDREN*) and by giving a mild aperient every night consisting of a grain of grey powder with 3 or 4 gr. of rhubarb powder. In many cases these measures are sufficient to effect a cure, but in

* There is an old belief that castor oil increases the probability of absorption and that it should not be given with, or near, a dose of male fern.—AMERICAN EDITOR.

more obstinate cases one can have recourse (1) to vermifuge drugs or (2) to local treatment.

1. Amongst the *drug treatments* which have been recommended are the following :—

a. A daily dose of an aperient sulphate water, e.g., Hunyadi.

b. A morning dose of 2 oz. of compound decoction of aloes (B.P.) before breakfast, with a pill of 2 gr. of extract of quassia (keratin-coated)* at night. Next day the pill should be repeated after each meal, and the aloetic purge given again on the third morning. The pills should be continued for a few days if worms are still present in the stools. This treatment is specially suited to adults, and throughout its course the diet should be rather spare.

c. Petroleum emulsion (B.P.C.) in drachm doses three or four times a day.

d. Santonin, 1 gr.; aloes and iron pill, $1\frac{1}{2}$ gr. (silvered), one every night for six nights, suitable for a child.

e. Oil of male fern, given in the same way as for tape-worm.

f. Sulphur, in doses of 9 gr. daily for an adult and $1\frac{1}{2}$ gr. three times daily for a young child.

2. *Local Treatment* :—

a. Enemata of salt and water (1 tablespoonful to a half pint) given warm after the bowel has been emptied. $1\frac{1}{2}$ pints may be given to an adult every other night. For a young child 6 oz. will be sufficient. The enema should be run in through a funnel and tube, the pelvis being raised.

b. Enemata of infusion of quassia (1 per cent) or garlic, with or without the addition of salt, used as above.

c. The following enema :—Oil of turpentine $\bar{3}$ ij, santonin gr. ij, starch mucilage $\bar{3}$ vj. Injected every other night for a week.

d. A small portion of unguentum hydrargyri inserted into the rectum every night.

e. Suppositories of strong mercurial nitrate ointment $7\frac{1}{2}$ gr. One to be inserted every other night at bedtime. For children below the age of four, a smaller suppository may be used.

f. Suppositories containing 3 gr of santonin, one to be inserted every second or third night for a week.

A little weak white precipitate or nitrate of mercury ointment may be applied locally for the relief of itching. As a prophylactic measure strict cleanliness should be practised, the hands and nails being washed to prevent re-infection. Salads, water-cress, and other raw vegetables should be avoided.

In very obstinate and old-standing cases in adults, the adoption of a strict diabetic diet for a few weeks sometimes gives good results. *Robert Hutchison.*

WOUNDS OF ARTERIES AND VEINS.—A wound in the blood-vessels may be complete or incomplete, subcutaneous or open, and involve arteries, veins, or capillaries.

If the division of an artery is complete and due to a sharp instrument, hæmorrhage is immediate and more or less serious, depending upon the size of the vessel injured and the freedom and rapidity with which blood escapes. The lesser vessels will spontaneously cease to bleed from contraction and retraction of their walls, clot formation, and weakening power of the heart; the larger cause such sudden and serious hæmorrhage that life can only be saved by the promptest help.

If complete division of an artery is produced by a blunt force, the outer elastic coat is likely to be drawn out beyond the intima and media, and the largest may be at least temporarily closed by torsion of this.

If the wound in an artery is incomplete, it may become blocked up by

* Keratin cannot be obtained in commerce.—AMERICAN EDITOR.

extravasated blood, and, if small, heal; if larger, a pulsating hæmatoma, traumatic aneurysm, arteriovenous aneurysm, or aneurysmal varix may form later. A traumatic aneurysm not infrequently follows subcutaneous injury.

The most frequent subcutaneous injuries occur in the visceral areas to the middle meningeal, mesenteric, splenic, and hepatic vessels. In the extremities they often occur as a complication of fracture and dislocation, and a diagnosis may be made by noting the presence or absence of pulsation in the vessels below the line of injury.

If a rapidly enlarging hæmatoma forms after such an injury, an operation must be done and the bleeding vessels found and secured. In the skull, signs of compression, commencing a short time after injury, are the chief indications for operation; and, in the abdomen, signs of free fluid, and the well-known indications of hæmorrhage everywhere—viz., increasing pallor, especially to be noted in the lips, increasing rapidity and weakening of the pulse, anxiety and restlessness, sighing respiration, cold forehead, a clammy sweat, and inability to see clearly. In any case the proper treatment is to expose without delay the bleeding vessel in order to stop the escape of blood from it.

In the treatment of urgent open surgical hæmorrhage, the most important thing to remember is that *any bleeding point which can be reached by the finger is under its control*. A slight degree of finger pressure well applied will temporarily arrest any bleeding.

The next, scarcely of less importance, is that wounds which have not been fingered or probed rarely fail to heal without infection, but those into which fingers or probes have been introduced rarely escape it. The only excuse, then, for the introduction of a finger is urgency, and when this has been met, the next indication is to disinfect the wound and its surroundings as soon as possible. For this purpose weak tincture of iodine painted around, and run into, the wound is a valuable aid. In the extremities, digital pressure on the main artery, or the use of a tourniquet, make interference with a wound before proper preparation unjustifiable.

An elevated posture, cold, heat, exposure to the air, the pressure of a pad, the actual cautery, and chemical agents, such as turpentine, perchloride of iron, suprarenal extract, and others, may suffice for the arrest of diffuse, but not profuse, hæmorrhagic oozing. Any serious hæmorrhage requires more direct and surgical measures.

The first rule should be to *see* the bleeding point. Free exposure and a good light are essential aids. The next is to ligature the divided vessels. These rules have few exceptions, which will be noted later.

Secondary Hæmorrhage.—A serious form of bleeding due to wound sepsis, and known as secondary hæmorrhage, less common than formerly, but still of too frequent occurrence, requires prompt and energetic treatment if the patient is not to be allowed to die as a result of it. Usually from the tenth to the twelfth day sudden arterial hæmorrhage occurs, without previous warning, from the septic wound. A suitably-placed pad and slight pressure easily arrests it for the time, but the tendency to recurrence is so great that reliance should not be placed upon this. The rule should be to open the wound freely without waiting for another hæmorrhage, to disinfect it as well as possible, to explore the bleeding points, and by one or other means secure the bleeding artery by ligatures in more healthy portions above and below, leaving the wound freely open and lightly packed with an antiseptic dressing. When all of this has been accomplished, it is still necessary to ensure constant skilled attendance for fourteen days afterwards, so that possible recurrence may be promptly dealt with.

Venous Hæmorrhage.—This is recognized by the darker colour of the blood

and the continuous discharge of it, as compared with the bright colour of arterial blood and its escape in jets. It is more readily arrested by a pad and pressure, but, if profuse, requires the same treatment as arterial hæmorrhage, viz., exposure and ligation of the bleeding points.

Venous hæmorrhage at the root of the neck or in the axilla may be accompanied by entrance of air into the veins, and the sudden hiss that follows is so alarming that, when it has been heard, no time should be lost in finding and closing the opening. My own experience of it must have been singularly fortunate, because I have never seen the entrance of air do any harm. To find the opening, the wound is filled with a moist gauze mop, and, keeping steady pressure upon it, this should be gradually slipped off the distal part of the vein until the opening is exposed. To close this opening, if ligation presents any difficulty, leave a pair of hæmostatic forceps on the hole in the vein and projecting from the wound for forty-eight hours, as this is a safe and successful measure.

Exceptions to the General Rules given.—When large and important vessels are wounded, occluding ligation of them is likely to be followed by serious consequences to the parts which they supply. It is now possible to close wounds in the blood-vessels and restore their lumen, to excise parts damaged beyond repair and remake the vessel by end-to-end anastomosis, or to fill up a gap by transplantation of portions of other vessels not so important. The principles of these operations are simple. They are asepsis, free exposure of the wounded vessels, complete control of the opening without damage to the vessel-walls, removal of all blood and clots from its lumen (irrigation with warm normal saline) without damage to the intima, and closure of the wound in the vessel-wall by a continuous fine silk suture through all the coats, everting the intima. Fine needles, gentle work, and sterile vaseline for the silk and needles are necessary for success, which in competent hands is now assured.

Bleeding from the scalp is arrested with difficulty by Nature's means, because the great aids to arrest, retraction and contraction of its blood-vessels, cannot occur owing to the density of, and their adhesion to, the tissues of the scalp. For the same reason a ligation is difficult to apply. If pad-pressure fails to stop the bleeding, it can always be effected by the skilful use of needles and thread, which will act at the same time as ligatures and sutures.

Bleeding from the palmar and plantar arches is usually an exception to the rule as to seeing the bleeding point. On account of the inelasticity of the parts, even a large incision may not permit of this, while an extensive incision is sure to inflict damage on the important structures underneath the palmar or plantar fascia. But the bleeding is likely to be serious, and is unlikely to stop until the bleeding point is effectually blocked. Taking the hand for example, the following steps should be taken :—

1. Apply a tourniquet to the upper arm.
2. Use every means to ensure the absence and prevention of sepsis by the use of cleansing, sterilization, and antiseptics.
3. Pack carefully, but thoroughly, into the bottom of the wound a small pad of sterile gauze, soaked in weak tincture of iodine. On this place a similar but somewhat larger pad, and on this a larger still, until a thick conical composite pad (graduated compress) projects upwards from the palm. Holding this in position, apply narrow rolls of lint along the course of the lower two-thirds of the radial and ulnar arteries, on the front of the forearm. (The course of the radial artery is indicated by a line drawn from the middle of the bend of the elbow to the base of the styloid process of the radius; and of the lower two-thirds of the ulnar artery by a line drawn from the tip of the internal condyle of the humerus to the radial side of the pisiform bone).
4. Apply a padded splint to the back of the forearm, reaching from the elbow

to the tips of the fingers, and bandage it on carefully but firmly from below upwards, leaving the finger tips exposed.

5. With the patient in bed, elevate the limb to a position at as nearly a right angle as convenient, and remove the tourniquet. A suitable method of securing elevation is by the application of a long strap of adhesive plaster, folded over the end to form a loop, and fixed over the splint and bandages to the back and front of the forearm. The loop can then be fastened to a hook in the ceiling, or to the horizontal pole of a French bedstead or other available apparatus.

The after-treatment consists in letting the arm down in twenty hours; and taking the splint and padding off the forearm in forty-eight hours, when the patient can be allowed to get up and use a sling. Unless there is pain, or rise in temperature, the dressing need not be disturbed for a week. It can then be soaked off in boracic lotion, and the wound dressed in an ordinary way.

Bleeding from the Tonsil.—This can be arrested by a finger pressed on the tonsil, assisted by outside counter-pressure applied just behind and below the angle of the jaw. The throat should then be examined in a good light, when some spouting vessel may be seen. If this can be secured by artery forceps, these may either be left on for some hours projecting from the mouth, or if it seems feasible, a ligature may be passed under them on a needle and tied.

These measures failing, a long pair of padded forceps, one blade over the tonsil and the other resting on the neck, with the handles tied sufficiently firmly to compress the part, may be left on for a few hours.

Where these measures fail, it is necessary to tie the external carotid artery between its lingual and superior thyroid branches.

Bleeding from an incised tonsillar abscess may be very serious, and is often difficult to stop. A small piece of disinfected sponge dipped in turpentine, packed into and left in the cavity, will occasionally arrest it when all ordinary means have failed.

Hæmatemesis and Melæna.—On one occasion I was asked to see a child two years of age, with hæmatemesis and melæna of one week's duration. It was nearly dead, had a waxy skin, was dropsical from anæmia, and fainted when its head was raised. There was no sign of anything wrong in its abdomen. On examination of the mouth, after depressing the tongue, I saw with the greatest ease and distinctness a little artery pumping at the bottom of a small crack far back on the dorsum of the tongue. With a thick knitting-needle and a cork a cautery was improvised which arrested the bleeding at once and permanently. The child slowly recovered.

Bleeding from the nose that has resisted the ordinary remedies, such as keeping the arms raised above the head, pinching the nose, and breathing through the mouth, etc., may be so serious as to demand active measures. At times, with a good illumination, retractors, and sponging, it is possible to see a bleeding vessel on the septum; when this has been blocked, the bleeding ceases. More commonly, it is not possible to find the source of the bleeding, and pressure, by some form of dressing, is necessary. For many years, plugging the posterior nares was regarded as the only resort in serious cases; but the discomforts of it were such as to be apt to make the most heroic rebellious; and it was not without danger, for septic inflammation of the middle ear was not infrequent. By careful plugging through the anterior nares it is possible to arrest any ordinary hæmorrhage from the nose. Gauze (preferably iodoform-formalin-glycerin), cut in the form of a square of sufficient size, is pushed by forceps pressing on its centre, along the floor of the nose to the back of it. The edges of the gauze, at the nostril, are then opened up to display the projecting mouth of the pocket, and the pocket is steadily filled by strips of gauze: first, directly backwards,

along the floor; next, upwards and backwards towards the floor of the orbit; and, finally, directly upwards. The hardness of this plug can be increased by pressure on the core and traction on the edges of the pocket. It is necessary, before leaving the patient, to be sure that blood is not escaping down the throat. Watch for the gulping efforts attending swallowing under such circumstances, and examine the back of the throat.

Bleeding after Tooth-extraction.—This is seldom serious except in hæmophilics. Styptics may first be tried, and the best of these is turpentine. To apply this, dry the socket as effectually as possible by pressing a sponge firmly over it, and continue the sponge pressure while a dossil of lint is being prepared and soaked in the styptic. Remove the sponge and quickly apply the lint, holding it in position till it becomes fixed by coagulated blood. If this fails, plug the socket from the bottom with a narrow strip of gauze, using a probe, and leave the projecting end to form a pad over the opening. Place a piece of cork over the pad, and fix the jaws together with a bandage sufficiently firmly to press on the cork. If the bleeding comes from an opening between two sound teeth, it can usually be arrested by fixing a piece of sponge firmly between them over the bleeding orifice.

Bleeding from the Preputial Artery.—Serious bleeding from this source has occasionally followed forcible or awkward coitus. It can usually be arrested at once by the application of a small dossil of absorbent wool pressed over the bleeding point and retained in position by drawing the prepuce forward over it. If this fails, the torn artery should be snipped across with scissors, and if the bleeding does not cease after the retraction and contraction of it which this allows, it must be secured in forceps and tied in the ordinary way.

Bleeding from the Urethra.—This is usually the result of injury, and ceases spontaneously on the assumption of a horizontal posture. If not, the source of the hæmorrhage, penile or deep urethral, must be ascertained by pressure tests. For the penile portion, a catheter should be introduced to the root of the penis, which should be firmly bandaged round it; for the deeper portion, after the catheter is in the bladder, a perineal pad and T-bandage supply the necessary pressure.

Bleeding from the Rectum.—If this is not arrested by rest in the horizontal posture and warmth to the surface, it is safest to administer an anæsthetic, to fix the patient in a good light in the lithotomy posture, and dilate the sphincter, when the bleeding point or surface can be seen and treated by ligature or cautery. If the arrest is not complete, a firm four-inch-long tube should be introduced and packed all round with iodoform gauze.

Bleeding from the Uterus.—Severe hæmorrhage is most frequently the result of a miscarriage, and demands emptying of the uterus for its arrest. The vagina should be packed with gauze wrung out of weak tincture of iodine. The patient should then be placed in the lithotomy position, and in a good light. The next step is to cleanse and shave the external genitals, and put on clean indiarubber gloves. The cervix is then exposed by a Sim's speculum and the source of bleeding discovered. (Bimanual pelvic examination will next be made when a cause for the hæmorrhage is likely to be discovered.) If the os is dilated or dilatable, a finger can then be swept round the interior of the uterus, and can remove its contents, if there are any, or be followed by packing with gauze wrung out of tincture of weak iodine if there is nothing to come away. By introducing an antiseptic sponge tent into the undilated cervix the most serious hæmorrhage can always be temporarily arrested.

Bleeding from an Intercostal Artery.—A stab or an operation for empyema may divide an intercostal artery. Bleeding from this can be arrested by a plug. A piece of gauze, four layers thick and one foot square, soaked in tincture of

iodine, should be laid over the wound so that its centre corresponds to the opening in the chest. The gauze is then pushed into the chest for about an inch, and the pouch so formed is packed with a strip till it forms a ball inside. By pushing on the packing and pulling on the gauze, sufficient pressure is produced on the intercostal artery against the rib to stop bleeding from it.

Bleeding from a Divided or Broken Bone is best treated by cutting off a small piece of muscle and pressing it over the bleeding surface.

Bleeding from an Extremity.—If any vessel is seen spouting, secure it at once in forceps. If the wound is large and deep and bleeding, arrest hæmorrhage by pressing upon the main artery above and get a tourniquet. None is better than the ambulance man's substitute, viz., a strong handkerchief folded narrow, tied loosely round the limb, and tightened up by twisting with a walking-stick or poker introduced between the limb and the handkerchief. Pack the wound gently with gauze wrung out of weak tincture of iodine, and cleanse the skin all round with a swab wrung out of the same. With the wound in a good light, sponge blood and clots away, if necessary enlarging the wound to see to the bottom of it. The open mouths of divided vessels may now be seen, caught, and ligatured. If the bleeding has been from a good-sized vessel, the distal as well as the proximal end should be sought for and tied. If no open mouth is seen, having sponged the wound dry and clean, make pressure circularly on the limb from above downwards, when a drop of blood squeezed out may point to the orifice of a divided vessel.

If no result follows, untwist the tourniquet gently. If there is then no bleeding, apply a pad to the wound and bandage the limb, leaving the slack tourniquet in position, with directions how to use it if bleeding should recur.

If a large vessel has been wounded, bleeding from it will be evident when the tourniquet is loosened, and it is probable that only a hole has been made in it, otherwise its mouth would have been exposed by the previous proceedings.

It is now necessary to expose the vessel fully by dissection, and to treat the opening in it by suture, or to tie it above and below the opening with ligatures passed by the help of an aneurysm needle. A good substitute for this may be found in a director and probe. The director is passed under the vessel and the probe guided under it by the groove.

Rutherford Morison.

WRITER'S CRAMP.—(See CRAFT PALSIES.)

WRY NECK, SPASMODIC.—In this condition there is a clonic spasm of some of the muscles of the neck. The sternomastoid is more often affected than the trapezius. But other muscles may be involved: the splenius, the complexus, and the muscles of the sub-occipital triangle.

Many of the patients are the subjects of nervous inheritance, and the condition in others supervenes on a severe shock. The cause is probably cortical, and the disease "functional."

Careful examination is necessary in order to discover the muscle at fault. Before the patient comes under the care of the surgeon, the usual antispasmodic remedies and nerve tonics will have been employed. Operation should not be considered until all other means have failed. Careful graduated exercises, aided by suggestion, will, if the medical man is able to gain his patient's confidence, succeed in many cases (see Tics). Operation, on the other hand, substitutes a paralysis for the clonic spasms of the affected muscles, and the spasmodic movements often reappear elsewhere.

If it is necessary finally to resort to operative measures, injection of alcohol deeply into the nerves supplying the affected muscles may be tried before employing more radical measures. Failing this, neurectomy must be performed.

If the sternomastoid or sternomastoid and trapezius are alone affected, it is usual to remove a portion of the spinal accessory nerve. This may afford immediate relief, but the result is as a rule quite transient, as a consideration of the nerve supply of these muscles would lead us to conclude.

The operation most generally necessary to paralyze the affected muscles is that devised by Gardner and by Keen independently—removal of a portion of the posterior primary divisions of the cervical nerves. This may be carried out by raising a triangular flap of skin, with its base in the mid-line extending from the occiput to the sixth cervical spine, and its apex at the mastoid process. The suboccipital triangle and semispinalis muscles are exposed by dividing the muscles covering them, and as much as possible of the nerves excised. (See also Tics, and for congenital wry-neck see TORTICOLLIS, CONGENITAL.)

James Sherren.

X RAYS.—(See RADIOTHERAPEUTICS.)

XEROSIS OF CONJUNCTIVA.—(See CONJUNCTIVA, DISEASES OF.)

XEROSTOMIA.—(See SALIVARY GLANDS, AFFECTIONS OF.)

YAWS (Frambæsia Tropica).—This disease is rarely met with in Europeans ; when it does occur it is usually in neglected children who have lived in close contact with natives. Cleanliness, good food, and careful attention to the evacuations greatly facilitate and expedite the cure.

The only specific treatment that appears to reduce the duration of the disease is salvarsan, but iodide of potassium, and mercury in full doses, have a decided effect in aborting the successive crops of the eruption, though they do not prevent their occurrence.

Beyond cleanliness, and protection from flies and irritation, no local treatment is required in most of the growths. When ulcerated, ordinary antiseptic dressing will suffice ; but touching with blue stone or nitrate of silver is useful if there be any tendency for the ulcers to become chronic.

The painful yaws, " crab yaws," on the soles of the feet are best treated by strong solution (20 per cent) of nitrate of silver dropped in, or the painful granulation at the base may be touched with nitric acid and so destroyed.

Salvarsan has a definite specific action, both in acute and chronic cases, and the results are permanent.

C. W. Daniels.

YELLOW FEVER.—The older plans of treatment were more active than those employed now, but venesection was abandoned long before the general reaction against it set in. Calomel and quinine, in large doses (20 gr. of the former and 22 gr. of the latter) were at one time largely employed. A brisk purgative (calomel or a saline) is now used at the commencement of the attack, but should not be repeated. Hot baths and sinapisms to the epigastrium check the vomiting and relieve cerebral congestion. The food should be fluid, well iced, and given in frequent small quantities, but the total amount of fluid given should be large. Some authorities give no food by the mouth during the first three days, and supply fluid to some extent by rectal injections of normal salines. Such injections should always be given when there is much vomiting, and particularly if the albumin rapidly increases or the amount of urine passed diminishes.

A number of drugs have been used, many of them of an antiseptic nature. Carbolic acid, in doses of 1 to 2 min. every hour, has been much employed. Alkaline carbonates relieve the thirst, check the vomiting, and correct the burning acidity of the mouth so often complained of.

Sternberg's treatment is to give an ounce and a half of a mixture composed of 150 gr. sodium bicarbonate and $\frac{1}{2}$ gr. perchloride of mercury dissolved in a quart of water, every hour. It certainly checks vomiting, both in this disease and in blackwater fever, and recoveries under it have been numerous. As the causal agent of yellow fever circulates in the blood, this treatment is not likely to be a specific one.

Alcoholic stimulants should not be resorted to at the commencement, but will usually be required on or after the third day. Like all other fluids, they must be well iced, and given in small quantities at a time. Many, and in some epidemics nearly all, of the cases are very mild, and recovery after the third day is rapid and without any dangerous symptoms.

Whether the case is mild or severe, the patient must be protected night and day from the bites of the yellow-fever carrier, *Stegomyia calopus*, otherwise the disease may spread to other occupants of the house, or more widely. Destruction of the breeding-places of these mosquitoes and by fumigation of any mosquitoes in the house, protection by suitable clothing, and proper use of mosquito nets, are the soundest methods of prophylaxis, whether the disease is endemic or epidemic.

C. W. Daniels.

APPENDIX.

Carbolic Oil	-	-	1 part		Olive Oil	-	-	19 parts
--------------	---	---	--------	--	-----------	---	---	----------

Chalk and Catechu Mixture

This is generally dispensed with the official Chalk Mixture B.P. with from 2 to 4 mls of Tincture of Catechu to every 20 mls of mixture.

Powdered Prepared Chalk	-	-	-	-	8 grammes
Tragacanth, in Powder	-	-	-	-	1 gramme
White Sugar, in Powder	-	-	-	-	16 grammes
Cinnamon Water	-	-	-	-	160 mls

Mix. Dose 28 mls or 1 oz.

Cimolite Powder = A proprietary preparation of Kaolin.

Confectio Sulphuris (B.P.)—

Precipitated Sulphur	-	-	-	-	450 grammes
Acid Potassium Tartrate, in Powder	-	-	-	-	110 grammes
Tragacanth, in Powder	-	-	-	-	5 grammes
Syrup	-	-	-	-	210 mls
Tincture of Orange	-	-	-	-	55 mls
Glycerin	-	-	-	-	170 mls

Dose 60–120 grains.

Corrosive Spirit = Mercuric Chloride, dissolved in sufficient Rectified Spirit (90 per cent) to make a $\frac{1}{2}$ per cent or 1 per cent solution.

Cyanide Gamgee Tissue — A double layer of gauze intersected with cotton wool, and generally sold in England in 1-lb. rolls. This is medicated with 3 per cent Double Cyanide of Mercury and Zinc.

Decoctum Hamatoxyli (B.P.)—

Logwood in Chips	-	-	-	-	50 grammes
Cinnamon Bark	-	-	-	-	10 grammes
Distilled Water	-	-	-	-	a sufficient quantity

Boil the Logwood with 1200 mls of Distilled Water for ten minutes, adding the Cinnamon Bark towards the end of the time; strain; pour enough Distilled Water over the contents of the strainer to make 1000 mls.

Dose $\frac{1}{2}$ –2 fluid ounces.

Enema Opii (B.P. 1885)—

Tincture of Opium	-	-	-	-	15 mls
Mucilage of Starch	-	-	-	-	60 mls

Extractum Belladonnæ Viride (B.P. 1898)—

A soft extract made by bruising the fresh leaves and young branches of *Atropa Belladonna*, pressing out the juice, and evaporating. Dose $\frac{1}{4}$ to 1 grain.

Extractum Filicis Liquidum (B.P.)—

Prepared by Ether extraction, and is similar to *Oleoresina Aspidii*, which is prepared by Acetone extraction. Dose 45–90 minims.

Fluid Magnesia = Liquor Magnesii Bicarbonatis (B.P.)—

Magnesium Sulphate	-	-	-	-	40 grammes
Sodium Carbonate	-	-	-	-	50 grammes
Distilled Water	-	-	-	-	a sufficient quantity

Dissolve separately; heat the solution of Magnesium Sulphate to boiling point, add the solution of Sodium Carbonate; boil until the reaction ceases; collect the precipitated Magnesium Carbonate; wash; mix the washed precipitate with 400 mls of Distilled Water; carbonate in a suitable apparatus. Dose 1–2 ounces.

Gelatinum Zinci—

Gelatin	-	-	-	-	3 parts
Water	-	-	-	-	9 parts

Soak twelve hours, then heat to dissolve, and add

Zinc Oxide	-	-	-	-	2 parts
Previously rubbed with Glycerin	-	-	-	-	4.5 parts

Glycerinum Acidi Borici (B.P.)—

Boric Acid	-	-	-	300 grammes
Glycerin	-	-	sufficient to make	1000 grammes

Add the Boric Acid to 450 grammes of Glycerin, boil until dissolved, stirring constantly; evaporate at a temperature rising to but not exceeding 150° C. until the weight of the mixture is 500 grammes, and add the remainder of the Glycerin.

Glycerinum Belladonnæ—

Green Extract of Belladonna	-	-	-	30 grammes
Boiling Distilled Water	-	-	-	4 mls
Rub to a smooth paste, and add				
Glycerin	-	-	-	to 60 mls

Glycerinum Boracis (B.P.)—

Borax	-	-	-	20 grammes
Glycerin	-	-	-	120 mls

Glycerinum Ferri Iodidi = Formulæ (non-official)—

(1) Fine Iron Wire (No. 36)	-	-	-	28.3 grammes
Iodine	-	-	-	56.7 grammes
Distilled Water	-	-	-	85 mls
Glycerin	-	-	-	767 mls

Dose 1 drachm in water

(2) Mix 56 mls of Glycerin with an equal quantity of water in a suitable flask; put in the Iron Wire and Iodine, and promote chemical union by gentle heat; when the froth becomes white, filter solution into 680 mls of Glycerin; wash the flask, and filter with 28 mls of water; and make up to 880 mls with Glycerin. Strength and dose same as Syr. Ferri Iodidi (B.P.).

Infusum Sennæ (B.P.)—

Senna	-	-	-	100 grammes
Ginger, sliced	-	-	-	5 grammes
Distilled Water, boiling	-	-	-	1000 mls

Dose $\frac{1}{2}$ –2 fluid ounces

Injectio Apomorphinæ Hypodermica (B.P.)—

Apomorphine Hydrochloride	-	-	-	1 gramme
Dilute Hydrochloric Acid	-	-	-	1 mil
Distilled Water	-	-	-	to 100 mls

Dose 5–10 minims

Iodized Phenol—

Iodine	-	-	1 part	Liquefied Phenol	4 parts
--------	---	---	--------	------------------	---------

Izal = Proprietary antiseptic.

Levuline = A preparation of yeast. Dose 60 grains.

Linimentum A. B. C. (B.P.C.)—

Liniment of Aconite	-	-	-	2 parts
Liniment of Belladonna	-	-	-	2 parts
Liniment of Chloroform	-	-	-	1 part

Linimentum Aconiti (B.P.)—

100 mls of the Liniment contain 3 grammes of Camphor and 0.2 gramme of the ether-soluble alkaloids of Aconite root in alcohol.

Linimentum Belladonnæ (B.P.)—

Liquid Extract of Belladonna	-	-	-	500 mls
Camphor	-	-	-	50 grammes
Distilled Water	-	-	-	100 mls
Alcohol (90 per cent)	-	-	-	to 1000 mls

Linimentum Crotonis (B.P.)—

Croton Oil	-	-	-	120 mls
Oil of Cajuput	-	-	-	440 mls
Alcohol (90 per cent)	-	-	-	440 mls

Linimentum Hydrargyri (B.P.)—

Ointment of Mercury (30 per cent)	-	-	-	50 grammes
Solution of Ammonia (10 per cent)	-	-	-	40 mls
Liniment of Camphor	-	-	-	80 mls

Linimentum Iodi = Liquor Iodi Fortis (B.P. 1898)—

Iodine	-	-	-	-	5 grammes
Potassium Iodide	-	-	-	-	3 grammes
Distilled Water	-	-	-	-	5 mls
Alcohol (90 per cent)	-	-	-	-	36 mls

Linimentum Opii (B.P.)—

Tincture of Opium, Soap Liniment	-	-	-	-	equal parts
----------------------------------	---	---	---	---	-------------

Linimentum Terebinthinæ Aceticum (B.P.)—

Glacial Acetic Acid	-	-	-	-	110 mls
Liniment of Camphor	-	-	-	-	445 mls
Rectified Oil of Turpentine	-	-	-	-	enough to make 1000 mls

Liquor Antimonii Chloridi

Antimonious Sulphide	-	-	-	-	453.5 grammes
Hydrochloric Acid (s.g. 1.160)	-	-	-	-	2.27 litres

Dissolve in a porcelain vessel by aid of a little heat, which must be augmented as the evolution of gas diminishes until the liquor boils. Maintain the liquid to boiling point for 15 minutes, then filter through calico until a clear solution is obtained, evaporate to 1.13 litres, and preserve in a stoppered bottle.

Liquor Bismuthi et Ammonii Citratis (B.P.)—

Bismuth Oxynitrate	-	-	-	-	70 grammes
Citric Acid	-	-	-	-	52 grammes
Solution of Ammonia	} of each enough to make the				
Distilled Water	} finished product measure				1000 mls

For details of making this solution reference should be made to the British Pharmacopœia. Dose 30–60 minims.

Liquor Calcis Saccharatus (B.P.)—

Calcium Hydroxide	-	-	-	-	50 grammes
Refined Sugar	-	-	-	-	100 grammes
Distilled Water	-	-	-	-	1000 mls

Dose 20–60 minims

Liquor Carbonis Detergens—Proprietary. Said to be similar to Liquor Picis Carbonis (B.P.).**Liquor Chloromorphiæ (Chlorodyne)—**

Chloroform	-	-	-	-	150 mls	Contains in a 10-min. dose
Glycerin	-	-	-	-	400 mls	℥ iss
Fluid Extract of Licorice	-	-	-	-	100 mls	℥ iv
Morphine Hydrochloride	-	-	-	-	10 grammes	℥ j
Solution of Atropine Sulphate	-	-	-	-	20 mls	gr. ʒo
Oil of Peppermint	-	-	-	-	2 mls	℥ ʒ
Alcohol (90 per cent)	-	-	-	-	to 1000 mls	℥ ʒo

Dose 5–15 minims

Liquor Epispasticus (B.P.)

Cantharidin	-	-	-	-	4 grammes
Castor Oil	-	-	-	-	25 mls
Resin	-	-	-	-	12 grammes
Acetone	-	-	-	-	q.s. to make 1000 mls

Liquor Ferri Pernitratæ (B.P. 1898)—

Iron	-	-	-	-	20 grammes
Nitric Acid	-	-	-	-	90 mls
Distilled Water	-	-	-	-	to 600 mls

Dose 5–15 minims

Liquor Opii Sedativus (Battley's)—Proprietary. A concentrated fluid preparation of Opium. Dose 5–20 minims.**Liquor Pepticum (Benger's)—Proprietary.****Liquor Picis Carbonis (B.P.)—**

Prepared Coal Tar	-	-	-	-	200 grammes
Quillaia Bark	-	-	-	-	100 grammes
Alcohol (90 per cent)	-	-	-	-	a sufficient quantity

Moisten the powdered Bark with 50 mls of the Alcohol; percolate with Alcohol until 1000 mls are produced; add the Prepared Tar and digest the mixture at 120° F. for two days. Filter.

Liquor Thyroidei (B.P. 1898)—

A liquid prepared from the fresh and healthy thyroid gland of the sheep; it contains Glycerin and 0.5 per cent of Phenol; 100 minims represent a thyroid gland. Dose 5–15 minims.

Lister's Green Protective—

Analogous to oiled silk, but thicker. It consists of oiled silk coated both sides with Copal Varnish, and when dry brushed over with Dextrin 1, Starch 2, Carbolic Solution (1-20) 16.

Lotio Acidi Borici = Four per cent Aqueous Solution.

Lotio Plumbi (B.P.C.)—

Stronger Solution of Lead Subacetate	-	-	1 part
Distilled Water	-	-	80 parts

Lotio Plumbi Spirituosus = Spirit Lotion—

Stronger Solution of Lead Subacetate	-	-	1 part
Glycerin	-	-	2 parts
Alcohol (90 per cent)	-	-	4 parts
Rose Water	-	-	to 32 parts

Lotio Plumbi et Opii—

Lead Acetate	-	-	3ij
Tincture of Opium	-	-	ss
Water	-	-	to 3xvj

Lotio Rubra—

Zinc Sulphate	-	-	gr. ij
Compound Tincture of Lavender	-	-	℥xij
Water	-	-	to 3j

Lysidine = A 50 per cent Solution of Ethylene Ethenyldiamine.

Mandl's Solution—

Potassium Iodide	-	-	gr. xxv
Iodine	-	-	gr. x
Oil of Peppermint	-	-	℥ij
Glycerin	-	-	to 3j

Mentholeate—

Menthol	-	-	20 parts
Oleic Acid	-	-	24 parts

Dissolve by gentle heat.

Menthol Ointment—

Menthol	0.3 gramme	White Vaseline	28 grammes
---------	------------	----------------	------------

Methylated Spirit = A mixture of 90 per cent Alcohol with 10 per cent Wood Naphtha.

Mistura Ætheris cum Ammonia—

Spirit of Ether	-	-	3 parts
Aromatic Spirits of Ammonia	-	-	3 parts
Water	-	-	to 48 parts

Dose $\frac{1}{2}$ –1 fluid ounce

Mistura Alba—

Magnesium Sulphate	-	-	2 grammes
Magnesium Carbonate	-	-	1 gramme
Peppermint Water	-	-	30 mls

Dose $\frac{1}{2}$ –2 fluid ounces

Mistura Ammoniaci (B.P.)—

Ammoniacum	-	-	30 grammes
Syrup of Tolu	-	-	60 mls
Distilled Water	-	-	sufficient to produce 1000 mls

Dose $\frac{1}{2}$ –1 fluid ounce

Mistura Amygdalæ (B.P.)—

Compound Powder of Almonds	-	-	20 grammes
Distilled Water	-	-	160 mls

Dose $\frac{1}{2}$ –1 fluid ounce

Mistura Sennæ Composita (B.P.)—Black Draught—

Magnesium Sulphate	-	-	250 grammes
Liquid Extract of Licorice	-	-	50 mls
Compound Tincture of Cardamoms	-	-	100 mls
Aromatic Spirit of Ammonia	-	-	50 mls
Infusion of Senna	-	-	to 1000 mls

Dose 1–2 fluid ounces

Nepenthe—A preparation having the same strength and dose as Tincture of Opium.

Neurosin—

Read "Neurodin." A trade-protected name for a proprietary preparation, Acetyl-phenyl-urethane.

Oleatum Hydrargyri cum Morphia—

Oleate of Mercury (10 per cent)	-	-	-	-	60 mils
Morphine	-	-	-	-	1 gramme

Oleum Amygdalæ Essentiale without Hydrocyanic Acid = Benzaldehyde.

Oxymel (B.P.)—

Purified Honey	-	-	-	-	500 mils
Acetic Acid	-	-	-	-	100 mils
Distilled Water	-	-	-	-	100 mils

Dose $\frac{1}{2}$ –2 fluid drachms

Oxymel Scillæ (B.P.)—

Vinegar of Squill	-	-	-	-	200 mils
Purified Honey	-	-	-	-	500 mils

Dose 30–60 minims.

Paraffin Oil = Liquid Petrolatum.

Paroleine = White Liquid Petrolatum.

Pasta Unna—

Zinc Oxide	-	-	-	-	2 parts
Glycerin	-	-	-	-	6 parts
Gelatin	-	-	-	-	3 parts
Water	-	-	-	-	8 parts

Melt, mix, and add

Ichthyol	-	-	-	-	2 per cent
----------	---	---	---	---	------------

Pasta Zinci Chloridi—

Zinc Chloride	-	-	-	-	1, 2 or 4 parts
Starch	-	-	-	-	6 parts
Lard	-	-	-	-	1 part

Mix and add Glycerite of Starch to form a paste

Petroleum Emulsion—

Liquid Petrolatum	-	-	-	-	℥ viij
Acacia	-	-	-	-	℥ iv
Oil of Cinnamon	-	-	-	-	℥ xxiv
Tragacanth	-	-	-	-	℥ ij
Distilled Water	-	-	-	-	q.s. ad ℥ xxiv

Dose 1–7 drachms

Pilula Aloes et Ferri (B.P.)—

Exsiccated Ferrous Sulphate	-	-	-	-	20 grammes
Aloes	-	-	-	-	40 grammes
Compound Powder of Cinnamon	-	-	-	-	70 grammes

Syrup of Glucose, to form a mass

Dose 4–8 grains

Pilula Ipecacuanhæ cum Scilla (B.P.)—

Compound Powder of Ipecacuanha	-	-	-	-	30 grammes
Squill	-	-	-	-	10 grammes
Ammoniacum	-	-	-	-	10 grammes

Syrup of Glucose, a sufficient quantity to form a mass

Dose 4–8 grains

This pill contains about 5 per cent of Opium.

Pilula Saponis Composita (B.P.)—

Opium	-	-	-	-	10 grammes
Hard Soap	-	-	-	-	30 grammes
Syrup of Glucose	-	-	-	-	10 grammes

Dose 2–4 grains

Poppy-head Stupes—

Boil 4 poppy-heads in 1000 mils of water for 5 minutes, and use as a fomentation or to inhale the steam.

Pulvis Amygdalæ Compositus (B.P.)—

Sweet Almonds	-	-	-	-	60 grammes
Sugar, Powdered	-	-	-	-	30 grammes
Acacia, in Powder	-	-	-	-	10 grammes

Pulvis Cretæ Aromaticus (B.P.)—

Cinnamon Bark in Powder	-	-	-	-	10 grammes
Nutmeg, in Powder	-	-	-	-	8 grammes
Cloves, in Powder	-	-	-	-	4 grammes
Cardamom Seeds, in Powder	-	-	-	-	3 grammes
Refined Sugar, in Powder	-	-	-	-	50 grammes
Prepared Chalk	-	-	-	-	25 grammes

Dose 10-60 grains

Pulvis Cretæ Aromaticus cum Opio (B.P.)—

Aromatic Powder of Chalk	-	-	-	-	39 grammes
Opium	-	-	-	-	1 gramme

Dose 10-60 grains

Pulvis Elaterini Compositus (B.P. 1898)—

Elaterin	-	-	-	-	1 gramme
Milk Sugar	-	-	-	-	39 grammes

Dose 1-4 grains

Pulvis Kino Compositus (B.P.)—

Kino	-	-	-	-	75 grammes
Opium	-	-	-	-	5 grammes
Cinnamon Bark	-	-	-	-	20 grammes

Dose 5-20 grains

Pulvis Olei Ricini—

A proprietary preparation termed Risiccol, or Demuth's Castor Oil Powder.

Pulvis Tragacanthæ Compositus (B.P.)—

Tragacanth, in Powder	-	-	-	-	15 grammes
Gum Acacia, in Powder	-	-	-	-	20 grammes
Starch, in Powder	-	-	-	-	20 grammes
Refined Sugar, in Powder	-	-	-	-	45 grammes

Dose 10-60 grains

Scott's Dressing = Unguentum Hydrargyri Compositum (B.P. 1898)**Soap Lotion—**

Soft Soap	-	-	-	-	1 part
Alcohol (90 per cent)	-	-	-	-	2 parts

Soap Spirit (Hebra)—

Soft Soap	-	-	-	-	4 parts
Rectified Spirit	-	-	-	-	2 parts

Sodii Citro-Tartras Effervescens (B.P.)—

Sodium Bicarbonate	-	-	-	-	510 grammes
Tartaric Acid	-	-	-	-	270 grammes
Citric Acid	-	-	-	-	180 grammes
Sugar	-	-	-	-	150 grammes

Mix, and place in a dish heated to 220° F. When the mixture has assumed a granular character, dry it at a temperature not exceeding 130° F. Dose 1-2 drachms.

Spirit = Spiritus Rectificatus (B.P.) = Alcohol (90 per cent).

Spiritus Armoracæ Compositus (B.P.)—

Horse-radish Root, scraped	-	-	-	-	125 grammes
Dried Bitter Orange Peel, bruised	-	-	-	-	125 grammes
Nutmeg, bruised	-	-	-	-	3 grammes
Alcohol (90 per cent)	-	-	-	-	625 mls
Distilled Water	-	-	-	-	750 mls

Mix, and distil 1000 mls

Dose 1-2 fluid drachms

Succus Conii (B.P. 1898)—

Bruise the fresh leaves and young branches of Conium Maculatum; press out the juice; to every 3 volumes of juice add 1 volume of Alcohol (90 per cent).

Dose 1-2 fluid drachms

Succus Taraxaci (B.P.)—

Expressed juice of fresh Taraxacum Root	-	-	-	3 volumes
Alcohol (90 per cent)	-	-	-	1 volume

Mix, set aside for seven days, and filter. Dose 1-2 fluid drachms.

Sulphur and Calamine Lotion—

Precipitated Sulphur	-	-	-	4 grammes
Prepared Calamine	-	-	-	8 grammes
Glycerin	-	-	-	8 grammes
Zinc Oxide	-	-	-	4 grammes
Rose Water	-	-	-	to 113.6 mils

Syrupus Chloral (B.P.)—

Chloral Hydrate	-	-	-	200 grammes
Distilled Water	-	-	-	200 mils
Syrup	-	-	-	sufficient to produce 1000 mils

Dose $\frac{1}{2}$ -2 fluid drachms

Syrupus Codeinæ Phosphatis (B.P.)—

Codeine Phosphate	-	-	-	5 grammes
Distilled Water	-	-	-	15 mils
Syrup	-	-	-	1000 mils

Dose $\frac{1}{2}$ -2 fluid drachms

Syrupus Ferri Phosphatis (B.P.)—

Iron Wine	-	-	-	8.6 grammes
Concentrated Phosphoric Acid	-	-	-	62.5 mils
Syrup	-	-	-	700 mils
Distilled Water	-	-	-	to 1000 mils

Dose $\frac{1}{2}$ -1 drachm

Syrup of Licorice—

Extract of Licorice	-	-	-	$\overline{3}ij$
Glycerin	-	-	-	$\overline{3}ij$
Sugar	-	-	-	$\overline{3}x$
Water	-	-	-	to $\overline{3}xvj$

The "Old Rhubarb Pill"—

Best Powdered Rhubarb	-	-	-	$\overline{3}iij$
Powdered Socotrine Aloes	-	-	-	$\overline{3}xviij$
Powdered Myrrh	-	-	-	$\overline{3}iss$
Hard Soap	-	-	-	$\overline{3}iss$
Oil of Peppermint	-	-	-	$\overline{3}iss$
Glycerin	-	-	-	$\overline{3}j$
Treacle (by weight)	-	-	-	$\overline{3}iij$

Mix the powders with the oil, then add the glycerin and sufficient treacle, and beat the whole into a uniform mass. Dose 5-10 grains.

Theriaca — Treacle.**Tinctura Cantharidis (B.P. 1898)—**

Cantharides in No. 40 Powder	-	-	-	12.5 grammes
Alcohol (90 per cent)	-	-	-	enough to make 1000 mils

Prepare by maceration. Dose 5-15 minims.

Tinctura Carminativa—

Cardamom Seeds, bruised	-	-	-	600 grains
Tincture of Ginger	-	-	-	600 minims
Oil of Cinnamon	-	-	-	100 minims
Oil of Caraway	-	-	-	100 minims
Oil of Cloves	-	-	-	100 minims

Macerate the Cardamom in 15 ounces of Alcohol (90 per cent) for one week; express and add the other ingredients and Alcohol (90 per cent) to make a pint. Dose 2-10 minims.

Tinctura Catechu (B.P.)—

Catechu	-	-	-	200 grammes
Cinnamon Bark, bruised	-	-	-	50 grammes
Alcohol (45 per cent)	-	-	-	1000 mils

Dose 30-60 minims

Tincture of Chloroform = Tinct. Chloroformi Co. (B.P.C. or B.P. 1885)—

Chloroform	-	-	-	2 mls
Rectified Spirit (90 per cent)	-	-	-	8 mls
Compound Tincture of Cardamoms	-	-	-	10 mls
Dose 5-60 minims				

Tinctura Chloroformi et Morphinæ Composita (B.P.)—

Chloroform	-	-	75 mls	$\mathfrak{M} \frac{3}{4}$
Morphine Hydrochloride	-	-	10 grammes	gr $\frac{1}{10}$
Dilute Hydrocyanic Acid	-	-	50 mls	$\mathfrak{M} \frac{1}{2}$
Tincture of Capsicum	-	-	25 mls	$\mathfrak{M} \frac{1}{4}$
Tincture of Indian Hemp	-	-	100 mls	$\mathfrak{M} \frac{1}{2}$
Oil of Peppermint	-	-	2 mls	
Glycerin	-	-	250 mls	
Alcohol (90 per cent)	-	-	to 1000 mls	
Dose 5-15 minims				

Tinctura Cinnamomi Composita—

Cinnamon Bark	-	-	-	16 grammes
Cardamom Seeds	-	-	-	8 grammes
Long Pepper	-	-	-	5 grammes
Ginger	-	-	-	5 grammes
Alcohol (60 per cent)	-	-	-	670 mls
Dose 30-60 minims				

Tinctura Convallariæ—

Convallaria Flowers	-	-	-	1 part
Alcohol (60 per cent)	-	-	-	8 parts
Dose 5-20 minims				

Tinctura Hamamelidis (B.P.)—

Hamamelis Bark in No. 20 powder	-	-	-	100 grammes
Alcohol (45 per cent)	-	-	-	to 1000 mls
Dose 30-60 minims				

Tinctura Iodi (Edin. Phar) = 1-16.**Tinctura Iodi Fortis (B.P.)**

Iodine	-	-	-	100 grammes
Potassium Iodide	-	-	-	60 grammes
Distilled Water	-	-	-	100 mls
Alcohol (90 per cent)	-	-	-	sufficient to make 1000 mls

The iodine and the potassium iodide are dissolved in the water and the alcohol is added to the solution.

Tinctura Iodi Mitis (B.P.)—

Iodine	-	-	-	25 grammes
Potassium Iodide	-	-	-	25 grammes
Distilled Water	-	-	-	25 mls
Alcohol (90 per cent)	-	-	-	sufficient to make 1000 mls
Dose 2-5 minims				

Tinctura Ipecacuanæ = 10 per cent in Alcohol (70 per cent)—Dose 5-10 minims**Tinctura Jaborandi (B.P. 1898)—**

Jaborandi Leaves, in No. 40 Powder	-	-	-	200 grammes
Alcohol (45 per cent)	-	-	-	enough to make 1000 mls
Prepared by percolation. Dose 30-60 minims.				

Tinctura Jalapæ (B.P.)—

Jalap, in No. 40 Powder	-	-	-	200 grammes
Alcohol (70 per cent)	-	-	-	a sufficient quantity

A tincture is prepared of such strength that it contains 1.5 per cent of resin. Dose 30-60 minims.

Tinctura Lobeliæ Ætherea (B.P.)—

Lobelia	-	-	-	200 grammes
Spirit of Ether	-	-	-	1000 mls
Dose 5-15 minims				

Tinctura Lupuli (B.P. 1898)—

Hops	-	-	-	200 grammes
Alcohol (60 per cent)	-	-	-	1000 mls

Dose 30-60 minims

Tinctura Opii Ammoniata (B.P. 1898)—

Tincture of Opium (1 per cent anhydrous morphine)	100 mls
Benzoic Acid - - - - -	20 grammes
Oil of Anise - - - - -	5 mls
Solution of Ammonia (10 per cent) - - - - -	200 mls
Alcohol (90 per cent) - - - - -	enough to make 1000 mls

The mixture is to be filtered before use. Dose 30–60 minims.

Tinctura Pruni Virginianæ (B.P.)—

Virginia Prune Bark - - - - -	200 grammes
Distilled Water - - - - -	375 mls
Macerate 24 hours, and add	
Alcohol (90 per cent) - - - - -	625 mls

Dose 30–60 minims

Tinctura Quininae Ammoniata (B.P.)—

Quinine Sulphate - - - - -	20 grammes
Solution of Ammonia - - - - -	100 mls
Alcohol (60 per cent) - - - - -	900 mls

Dose 30–60 minims

Tinctura Rhei Composita (B.P.)—

Rhubarb Root - - - - -	100 grammes
Cardamom Seeds - - - - -	12.5 grammes
Coriander Fruit - - - - -	12.5 grammes
Glycerin - - - - -	100 mls
Alcohol (60 per cent) - - - - -	1000 mls

Dose 2–4 fluid drachms

Tinctura Sennæ Composita (B.P. 1898)—

Senna - - - - -	200 grammes
Raisins, freed from seeds - - - - -	100 grammes
Caraway Fruit - - - - -	25 grammes
Coriander Fruit - - - - -	25 grammes
Alcohol (45 per cent) - - - - -	to 1000 mls

Dose 2–4 fluid drachms

Tinctura Sumbul (B.P. 1898)—

Sumbul Root, bruised - - - - -	100 grammes
Alcohol (70 per cent) - - - - -	1000 mls

Prepared by maceration. Dose 30–60 minims.

Tinctura Zingiberis Fortior = 50 per cent. Dose 5–20 minims

Trochisci Acidi Carbolici (B.P.)—Each contains 0.03 gramme, or about $\frac{1}{2}$ grain, of carbolic acid.

Trochisci Eucalypti Gummi (B.P. 1898) = 1 grain each.

Trochisci Ipecacuanhæ (B.P.) = $\frac{1}{2}$ grain each

Trochisci Sulphuris (B.P. 1898)—

Precipitated Sulphur - - - - -	2500 grains
Potassium Bitartrate - - - - -	500 grains
Sugar - - - - -	4000 grains
Acacia - - - - -	500 grains
Tincture of Orange - - - - -	500 minims
Mucilage of Acacia - - - - -	500 minims

Mix, and divide into 500 lozenges

Unguentum Belladonnæ (B.P.)—

Fluid Extract of Belladonna - - - - -	80 mls
Benzoated Lard - - - - -	60 grammes
Wool Fat - - - - -	20 grammes

Evaporate the Fluid Extract of Belladonna on a water-bath until it weighs 20 grammes, and incorporate the extract with the benzoated lard and wool fat.

Unguentum Calaminæ—

Prepared Calamine - - - - -	1 part
Benzoated Lard - - - - -	5 parts

Unguentum Creosoti (B.P.)—

Creosote	-	-	-	-	-	10 grammes
Hard Paraffin	-	-	-	-	-	40 grammes
Soft Paraffin, white	-	-	-	-	-	50 grammes

Unguentum Hydrargyri Compositum (B.P. 1898)—

Mercury Ointment (50 per cent)	-	-	-	-	-	150 grammes
Yellow Beeswax	-	-	-	-	-	90 grammes
Olive Oil	-	-	-	-	-	90 grammes
Camphor in fine Powder	-	-	-	-	-	45 grammes

Unguentum Hydrargyri Compositum (B.P.)—

The formula for this differs from the preceeding only in that the Mercury Ointment used is 30 per cent.

Unguentum Hydrargyri Nitratis Dilutum (B.P.)—

Mercuric Nitrate Ointment	-	-	-	-	-	20 grammes
Soft Yellow Petrolatum	-	-	-	-	-	80 grammes

Unguentum Hydrargyri Oleatis (B.P.)—

Mercuric Oleate	-	-	-	-	-	25 grammes
Benzoated Lard	-	-	-	-	-	75 grammes

Unguentum Hydrargyri Oxidi Flavi (B.P.)—

Yellow Mercuric Oxide	-	-	-	-	-	2 grammes
Petrolatum	-	-	-	-	-	98 grammes

Unguentum Sambuci Viride (Ph. D. 1826)—

Elder Leaves, fresh	-	-	-	-	-	3 parts
Lard	-	-	-	-	-	4 parts
Prepared Suet	-	-	-	-	-	2 parts

Heat together till the color is extracted, and strain through linen.

Unguentum Staphisagriae (B.P.)—

Stavesacre Seeds	-	-	-	-	-	40 grammes
Yellow Beeswax	-	-	-	-	-	20 grammes
Benzoated Lard	-	-	-	-	-	170 grammes

Crush the Seeds, and digest with the Lard for two hours on a water-bath; strain and express; add the Wax, and heat gently until melted; stir until cold.

Unna's Ointment—

Mercury Bichloride	-	-	-	-	-	gr ij
Phenol, Liquefied	-	-	-	-	-	℥xv
Zinc Ointment	-	-	-	-	-	3j

Vapor Coninae (B.P. 1885)—

Juice of Hemlock	-	-	-	-	-	4 parts
Solution of Potash	-	-	-	-	-	1 part
Distilled Water	-	-	-	-	-	8 parts

Dose, inhale about 20 drops

Vinum Colchici (B.P.)—

Colchicum Corm	-	-	-	-	-	200 grammes
Sherry Wine	-	-	-	-	-	1000 mils

Dose 10-30 minims

Zinc Ichthyol Salve Muslin—

Sq. metre contains Zinc Oxide 10 grammes, Ichthyol 2 grammes, made into a stiff ointment, and spread on muslin.

SUPPLEMENTARY INDEX.

	PAGE
A BBOTT'S jacket in scoliosis ..	920
Abdomen, gunshot wounds of ..	462
— method of massage of ..	621
Abdominal aneurysm ..	59
— compress, the ..	529
— cramp in children ..	190
ABDOMINAL INJURIES ..	1
— massage in chronic constipation ..	213
ABORTION ..	2
— in chorea gravidarum ..	181
— — induction of ..	182
Abrasions of cornea ..	349
ABSCCESS ..	3
— alveolar, necrosis of jaw from ..	566
— anal ..	5
— appendical, localized ..	87
— — residual ..	88
— axillary ..	4
— of Bartholin's glands, gonorrhœal ..	446
— cerebellar ..	170
— cerebral (see Cerebral Abscess) ..	171
— of Cowper's glands, gonorrhœal ..	444
— dental, toothache from ..	1020
— drainage of ..	3
— formation, specific therapy in ..	949
— hepatic ..	515
— irrigation of ..	4
— ischiorectal ..	4
— mammary ..	5, 617
— palmar and plantar ..	5
— peritonsillar (see Quinsy) ..	5
— peri-urethral gonorrhœal ..	444
— of septum nasi ..	927
— spinal, from caries ..	961
— submammary ..	618
— submaxillary ..	4
— subphrenic ..	992
— tonsillar, bleeding from incised ..	1096
— tuberculous, in bone disease ..	120
— — epididymitis ..	335
— — of hip ..	578
— — sacro-iliac joint ..	580
— vaccine therapy in sinuses follow- ing ..	952
Abscesses, Bier's hyperæmia in ..	105
— cupping-glasses in ..	107
Accessory sinuses, suppuration caus- ing septic anæmia ..	31
Acetanilide or antifebrin, poisoning by ..	779
Acetonæmia, vomiting with ..	1081
Acetonuria in diabetic mellitus ..	238
Achillis tendon, inflammation of ..	1024
— — rupture of ..	1024
ACHYLIA ..	6
— drug treatment ..	279
Acid dyspepsia ..	280
— intoxication ..	1081
ACIDOSIS ..	7
Acids, poisoning by ..	779

	PAGE
ACNE VULGARIS ..	7
— — deeper abscesses to be opened ..	7
— — vaccine therapy in ..	951
— — x rays in ..	849
Aconite poisoning ..	780
Acoria ..	7
Acromegaly ..	7
Acromioclavicular joints, disloca- tions of ..	257
Acromion process, fracture of ..	396
ACROPARÆSTHESIA ..	7
ACTINOMYCOSIS ..	8
— necrosis of jaw from ..	568
— of salivary glands ..	904
Adalin in insomnia ..	553
Adams's varus splint ..	1016
Addisonian anæmia ..	31
— — antiseptic treatment ..	33
— — general management and diet ..	32
